In memory of Lynn Margulis (1938–2011),
tireless champion of the microbial biosphere

Foreword

Be it for their importance in the planet's food web, for their originality in carrying out their cellular processes, or for their Haeckelian elegance, one writing about the protists soon finds oneself composing a paean. As is true for any of the large groupings of living organisms, protists are varied, complex, and beautiful – only more so. They are a grab bag of hugely distinct organisms, but what a grab they are! Their endless fascination beguiles students of all aspects of life, those with orderly, as well as those with unruly minds.

Protist variety is easily told by the vast range of their dimensions. Even leaving aside the giant algae, readily visible with the naked eye, many (e.g., *Ostreococcus tauri*) are minimalists hovering at the one micrometer lower limit of eukaryotic size. Some have very large genomes – the claim has been made that the appropriately named amoeba *Polychaos dubium* has 670 billion base pairs! Others, such as the parasitic microsporidian *Encephalitozoon cuniculi*, manage with a minute 2.9 million base pairs.

Cellular complexity is carried to extremes by the protists. The ciliates and flagellates (mastigotes), for example, possess – to shamelessly use anthropomorphic terms – a mouth (some with fancy lips), a stomach, an anus, a bladder, multiple propulsion devices, and an armamentarium of weapons that allow them to feed on other microbes. And some dinoflagellates sport that most amazing of cell structures, the eye-like ocelloid. In multicellular organisms, such structures and their functions are assigned to specialized cells; in the protists, one cell does it all by itself. One wonders about the trade-off involved, in doing everything yourself versus employing a differentiated consortium to do the work. The very existence of protist complex body plans brings up the distinction between unicellularity and multicellularity, a blurry one at best, but one especially relevant to this field. Multicellularity has originated on multiple occasions within the protists, hence they are most likely to provide relevant answers to our conjectures.

The protists also make eccentric uses of chemicals, including some elements that are seldom employed in the biological world. Diatoms use silica for their shells (tests), which is exciting enough, but other planktonic organisms (the acantharia or "ray animalcules") make skeletons out of strontium sulfate (celestite)! Yet others form intracellular crystals of barium sulfate (barite). And many there are that make structures of imposing beauty. Some, such as the radiolarians, coccolithophorids,

and diatoms, are pure eye candy. Moreover, their skeletons have accumulated in formations of such massive dimensions that they have changed the Earth's geology.

Photosynthetic protists (algae) account for perhaps half the world's total photosynthesis and are indispensable for life on Earth. The others, the heterotrophic protists, make their living largely by eating other microbes and also play a huge role in the movement of nutrients on the planet. They graze on prokaryotes, which by and large they regard as packets of nutrients, and in the process regulate prokaryotic population densities in many natural environments. They are themselves eaten, often by other protists. One wonders how many layers there are to this.

Letting my mind wander. . .about what would happen if Nobel Prizes were given to organisms for having evolved important and readily ascertainable phenomena, *as well as* to the researchers who discovered such evolutionary achievements. Surely, *Tetrahymena* warrant multiple prizes for contributing the first known example of splicing and ribozymes, plus telomeres and telomerases. And *Paramecium* also comes to mind for cortical inheritance and other genetic marvels. Also, doesn't the invention of the macronucleus – that talented device that permits rapid growth of intricate cells – deserve a special accolade? Someday, as researchers continue to delve into this rich treasure trove, many more organisms will qualify. Possibly *Oxytrichia*, *Cyanidioschyzon*, *Ostreococcus* or, closer to immediate human concerns, *Giardia*, trypanosomes, and *Toxoplasma*. Make your own list of protists deserving to become Nobelists.

Whatever phylogenetic diagram you prefer, most of the eukaryotic lineages by far will be of protists. Their evolution started at the very emergence of the eukaryotic cell and has repeatedly involved the lateral transfer of whole genomes. In some instances, endosymbiotic events have occurred not just once, but twice and even three times in the same lineage. It is evident that evolution here did not proceed by timid jumps, but rather by bold leaps.

For these reasons and many others I have not brought up, protists are the basis for the understanding of all eukaryotic life in both time and space. So, the study of protists is not an obscure topic to be left to a few specialists. It is the concern of all biologists as well as planetary scientists and who knows who else?

I was asked to write this piece by the late Lynn Margulis, a friend of old. I tried to wiggle out of it, but those of you who reacted in such manner to a request of hers should be smiling by now. In all ways, scientific, intellectual, and personal, she was utterly irresistible. It worked out – I am glad to contribute to this work, a fitting tribute to her unique contribution to the field in which she started in science and which she never forsook.

Moselio Schaechter

Preface to the Second Edition

This *Handbook of the Protists* is the 2nd edition of the *Handbook of Protoctista*, which was published in 1990 and edited by Lynn Margulis, John O. Corliss, Michael Melkonian, and David J. Chapman. The subject is the biology, diversity, and evolution of eukaryotic (nucleus-containing) microbes and their descendants, exclusive of animals, land plants, and typical fungi. The new edition largely follows the structure of the original Handbook, but its content has changed dramatically to reflect 27 years of progress in many areas of life science research, including microscopy, microbial ecology, biochemistry, molecular biology, and phylogenetics.

The new Handbook contains some 44 chapters, each focused on a different group of protists. Taxonomic rank varies somewhat from chapter to chapter; each includes a Summary Classification of the lineages discussed therein. Many of the chapters are thorough updates of those appearing in the original Handbook, although a few are not retained in the new edition; in most cases these omissions reflect shifts in knowledge stemming from a more complete understanding of the large-scale phylogenetic structure of eukaryotic diversity. For example, Ellobiopsida ("Incertae Sedis" in the 1st Ed.) are no longer covered as a stand-alone chapter, as the group is now within Dinoflagellata. The fate of Phylum Myxozoa (original chapter published by the late Jiří Lom) reveals a stunning twist in the history of knowledge. Myxozoan parasites were usually seen as an enigmatic group of spore-forming "protozoa"; however, molecular phylogenetics confirmed that they are in fact a highly derived lineage of animals. Still other chapters have no counterpart in the original – they explore groups of protists that have gained substantially in importance over the past quarter century. And a handful of chapters address traditional protist assemblages based on morphology that do not correspond to evolutionarily unified groups; in these cases the different subgroups are clearly distinguished.

The opening chapter, entitled "Protist Diversity and Eukaryote Phylogeny," serves as a guide to the Handbook's overarching structure and content. It summarizes the biology of the currently recognized high-level protist lineages and provides references to the literature for those wishing to learn more about specific groups that are not covered in detail in this Handbook.

In writing and updating their chapters, authors were given the freedom to adhere to terms used in the original Handbook (e.g., "protoctists" = protists,

"undulipodia" = flagella) or not and encouraged to bring all relevant research to the table, including advances coming from molecular biology and molecular phylogenetics.

Key Features at a Glance

- Explores the ecological, medical, and economic importance of major groups of protists
- Covers the morphology, molecular biology, biochemistry, ecology, and fossil record of protists
- Collates work on an unparalleled breadth of eukaryotic microorganisms
- Is organized by current protist systematics, as informed by molecular phylogenetics and genomics

List of First Edition Chapters and Contributors

I. Phyla in Which Members Lack Undulipodia at All Stages and Which Lack Complex Sexual Life Cycles

1. Rhizopoda, *F.L. Schuster*
2. Haplosporidia, *F.O. Perkins*
3. Paramyxea, *I. Desportes, F.O. Perkins*
4. Myxozoa, *J. Lom*
5. Microspora, *E.U. Canning*

II. Phyla in Which Members Lack Undulipodia at All Stages of Their Life Cycles and Which Display Complex Sexual Life Cycles

6. Acrasea, *R.L. Blanton*
7. Dictyostelida, *J.C. Cavender*
8. Rhodophyta, *P.W. Gabrielson, D.J. Garbary, M.R. Sommerfeld, R.A. Townsend, P.L. Tyler*
9. Conjugaphyta, *R.W. Hoshaw, R.M. McCourt, J.C. Wang*

III. Phyla in Which Members Display Reversible Formation of Undulipodia and Lack Complex Sexual Life Cycles

10. Xenophyophora, *Ø.S. Tendal*
11. Cryptophyta (Cryptomonads), *M. Gillott*
12. Glaucocystophyta, *L. Kies, B.P. Kremer*
13. Karyoblastea, *J.M. Whatley, C. Chapman-Andresen*
14. Zoomastigina

    Classes:

    a. Amebomastigota, *B.D. Dyer*
    b. Bicoecids, *B.D. Dyer*
    c. Choanomastigotes (Choanoflagellates), *K.R. Buck*
    d. Diplomonadida, *K. Vickerman*
    e. Pseudociliata, *J.O. Corliss*
    f. Kinetoplastida, *K. Vickerman*
    g. Opalinata, *J.O. Corliss*
    h. Proteromonadida, *G. Brugerolle, J.P. Mignot*
    i. Parabasalia, *B.D. Dyer*
    j. Retortamonadida, *G. Brugerolle, J.P. Mignot*
    k. Pyrsonymphida, *B.D. Dyer*

Acknowledgments

For us, this project began shortly after the unfortunate passing of Lynn Margulis. It has been a long and convoluted journey, and there are many people to thank for input along the way. First and foremost, we thank all the authors for their enthusiasm, patience, and hard work in producing authoritative chapters that reflect the tremendous advances that have taken place in so many different areas of protistology. And of course, for much of this work there is a huge debt owed to the authors of the original Handbook's chapters. These have served as the bedrock upon which the second edition is founded, even when the new chapters have been mostly or entirely rewritten to accommodate a quarter century of scientific advances. Michael Melkonian, David Chapman, and Yuemei Corliss are thanked for their help during the early stages of the project, and we greatly appreciate O. Roger Anderson for providing the initial link to Springer. We are grateful to Lars Koener, Associate Editor at Springer, for his interest and oversight in transitioning the Handbook into a Springer Reference Work. Susanne Friedrichsen, Neha Thapa, Flora Kenson, Monika Garg, Ankita Awasthi, Abhijit Baroi, and the rest of the team at Springer are thanked for their editorial expertise. We thank Marlena Dlutek for in-house assistance at Dalhousie University. Finally, we thank Jennifer Margulis for advice, assistance, and support. Jennifer felt strongly that Lynn would have wanted this book to serve as many students and professionals as possible, both within and beyond the protistological community. It is our sincere hope and belief that the *Handbook of the Protists* is up to the task.

About the Editors

John M. Archibald is a Professor of Biochemistry and Molecular Biology at Dalhousie University and a Senior Fellow of the Canadian Institute for Advanced Research, Program in Integrated Microbial Biodiversity. He is an Associate Editor for *Genome Biology and Evolution* and an Editorial Board Member of *Current Biology*, *Eukaryotic Cell*, *BMC Biology*, *Environmental Microbiology*, and *Protist Genomics*. He is the author of more than 100 research articles and two books, *One Plus One Equals One: Symbiosis and the Evolution of Complex Life* (Oxford University Press, 2014) and *Genomics: A Very Short Introduction* (Oxford University Press, 2018).

Alastair G. B. Simpson is a Professor of Biology at Dalhousie University and a Senior Fellow of the Canadian Institute for Advanced Research, Program in Integrated Microbial Biodiversity. He was an Associate Editor of the *Journal of Eukaryotic Microbiology* for more than a decade and is now a Monitoring Editor of *Protist*. He has served on the Systematics Committee of the International Society of Protistologists since 2004 (and is the current Chair) and received the Society's Seymour H. Hutner Young Investigator Prize in 2013. He has authored more than 100 scientific articles.

Claudio H. Slamovits is an Associate Professor in the Department of Biochemistry and Molecular Biology at Dalhousie University in Halifax, Nova Scotia. He is a Fellow of the Canadian Institute for Advanced Research, Program in Integrated Microbial Biodiversity. Dr. Slamovits is an active researcher with interests in the molecular biology and evolution of microbial eukaryotes. He holds board and committee memberships in the International Society for Evolutionary Protistology (ISEP) and the International Society of Protistologists (ISOP).

Protist Diversity and Eukaryote Phylogeny

1

Alastair G. B. Simpson, Claudio H. Slamovits, and John M. Archibald

Abstract

The last quarter century has seen dramatic changes in our understanding of the phylogenetic relationships among protist groups and their evolutionary history. This is due in large part to the maturation of molecular phylogenetics, to genomics and transcriptomics becoming widely used tools, and to ongoing and accelerating progress in characterizing the major lineages of protists in the biosphere. As an introduction to the Handbook of the Protists, Second Edition, we provide a brief account of the diversity of protistan eukaryotes, set within the context of eukaryote phylogeny as currently understood. Most protist lineages can be assigned to one of a handful of major groupings ("supergroups"). These include Archaeplastida (which also includes land plants), Sar (including Stramenopiles/Heterokonta, Alveolata, and Rhizaria), Discoba, Metamonada, Amoebozoa, and Obazoa. This last group in turn contains Opisthokonta, the clade that includes both animals and fungi. Many, but not all, of the deeper-level phylogenetic relationships within these groups are now resolved. Additional well-known groups that are related to Archaeplastida and/or Sar include Cryptista (cryptophyte algae and their relatives), Haptophyta, and Centrohelida, among others. Another set of protist lineages are probably most closely related

to Amoebozoa and Obazoa, including Ancyromonadida and perhaps Malawimonadidae (though the latter may well be more closely related to Metamonada). The bulk of the known diversity of protists is covered in the following 43 chapters of the Handbook of the Protists; here we also briefly introduce those lineages that are not covered in later chapters.

The Handbook is both a community resource and a guidebook for future research by scientists working in diverse areas, including protistology, phycology, microbial ecology, cell biology, and evolutionary genomics.

Introduction

It has been more than 25 years since the publication of the Handbook of Protoctista (Margulis et al. eds. 1990). Since then, there have been tremendous advances in our understanding of the diversity and phylogeny of protists/protoctists (i.e., all eukaryotes other than the animals, land plants, and true fungi; we will use the term "protist"). Central to this progress has been the maturation of molecular phylogenetics as a tool for inferring evolutionary relationships, initially using single markers, such as small subunit ribosomal RNA gene sequences, and culminating in "phylogenomic analyses" that incorporate data from dozens or hundreds of genes (van de Peer and De Wachter 1997; Baldauf et al. 2000; Rodríguez-Ezpeleta et al. 2007; Burki et al. 2007; Burki 2014). Genome sequencing (of organellar genomes as well as nuclear genomes), together with transcriptomic surveys, has also greatly enhanced our understanding of the distribution of important cellular and molecular characteristics across the breadth of eukaryotic diversity (e.g., Lang et al. 1997; Ramesh et al. 2005; Hodges et al. 2010; de Mendoza et al. 2014; Wideman and Muñoz-Gómez 2016). At the same time, the discovery of new major lineages of protists (and reinvestigations of known "mystery taxa") has continued apace and even accelerated in recent years. This has resulted in dramatic changes to the catalogue of organisms that are important to consider when inferring the broadscale tree of eukaryote life (e.g., O'Kelly and Nerad 1999; Shalchian-Tabrizi et al. 2006; Not et al. 2007; Yabuki et al. 2010; Glücksman et al. 2011), on top of many important discoveries of novel diversity within major lineages (e.g., Moore et al. 2008; Massana et al. 2014; see numerous other examples below). There have also

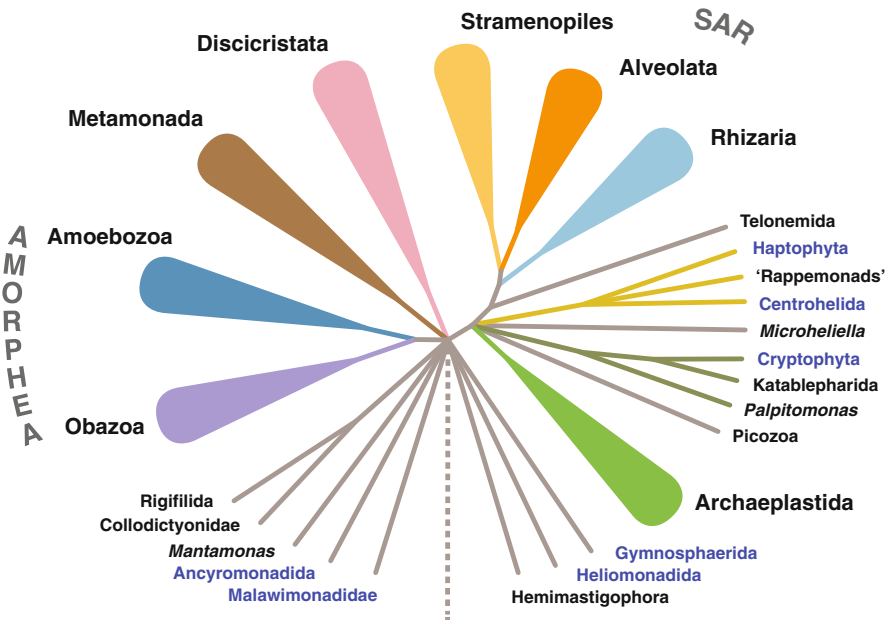

Fig. 1 Phylogeny of eukaryotes, based primarily on Brown et al. (2013), Cavalier-Smith et al. (2014), Kamikawa et al. (2014), Yabuki et al. (2014), Burki et al. (2016), and Leger et al. (2017). Groups with bulbous branches are examined in more detail in Figs. 2–5. Groups with narrow branches do not belong to well-established supergroups and are not illustrated separately; those covered in the Handbook are shown in *blue* and are as follows: ▶ Cryptophyta; ▶ Haptophyta; ▶ Centrohelida; ▶ Ancyromonadida; ▶ Malawimonadidae; ▶ Gymnosphaerida; ▶ Heliomonadida

been a number of important insights gained from electron microscopy studies, especially of the flagellar apparatus and cytoskeleton (e.g., Simpson 2003; Cavalier-Smith 2013; Heiss et al. 2013; Yubuki and Leander 2013).

The current picture of the tree of eukaryotic life can be characterized as largely resolved but with some major points of uncertainty. At present, it is common to divide the vast majority of known eukaryotic diversity into four to eight confirmed (or strongly suspected) monophyletic groups, usually referred to by the informal moniker "supergroups" (Fig. 1; Adl et al. 2012; Burki 2014; Worden et al. 2015; Simpson and Eglit 2016). The precise number and membership of the supergroups varies among accounts, reflecting not just personal taste but also the rapid pace with which important taxa are being added to broad molecular phylogenetic analyses. These supergroups are best thought of as standing well above the rank of "kingdom." For example, the animals and true fungi are generally each considered as a distinct kingdom but belong to the same supergroup (Obazoa, in our listing). The supergroups are often now amalgamated into as few as three or even two still more fundamental assemblages (Adl et al. 2012; Derelle et al. 2015), although this entails some bold assumptions about the position of the root of the tree (see below).

Our current understanding of eukaryote phylogeny confirms and extends a long-understood reality, namely, that most of the basic forms of protists identified by superficial morphology and physiology do not represent evolutionarily cohesive entities. Photosynthetic protists, or "algae," are found within most of the supergroups. In all of these groups (with the arguable exception of Archaeplastida – see below), the algae are intermingled with other kinds of protists, mainly "protozoa" (a term used to describe most heterotrophic protists, other than those that closely resemble fungi). Among the protozoa, "flagellates" (species which have eukaryotic flagella in the main feeding stage of their life history) are found across eukaryote diversity, reflecting the fact that all living eukaryotes descend from a heterotrophic, flagellum-bearing common ancestor. Amoebae, which lack flagella but produce one of the several distinct forms of pseudopodia, have evolved independently on multiple occasions, leading to a dozen or more major radiations of these lifeforms. Special forms of amoebae also have multiple origins. One example is the "heliozoa" – amoebae with many microtubule-supported pseudopodia radiating from a rounded cell body – which have at least three independent origins and likely more (Nikolaev et al. 2004; Bass et al. 2009). The "slime molds" are organisms that live mostly as amoebae (or as giant amoeboid plasmodia) but that also produce stalked structures bearing spores, either by differentiation of a single organism or by numerous amoebae aggregating together: collectively these strategies have evolved several times (Brown et al. 2012; Shadwick et al. 2009). Parasitic protozoa that are passed between hosts via infective spores have also evolved on numerous occasions. Other protists with more-or-less similarity to true fungi (e.g., they produce hyphae-like structures) are found in several different places within the eukaryote tree, mostly very distantly related to true fungi (Taylor and Berbee 2014).

As mentioned above, not all aspects of the deep-level phylogeny and evolutionary history of eukaryotes are well understood at present, which has consequences for any summary of protist diversity. Some important uncertainties and controversies revolve around particularly difficult problems in molecular phylogenetic inference. For example, it remains unclear what the relationships are among "excavate" lineages (Discoba, Metamonada, and Malawimonadidae), which include many groups with high overall rates of sequence evolution. The majority view at present is that they form two or more phylogenetically separate clades (Burki 2014). In a similar vein, phylogenomic analyses have yet to resolve whether the supergroup Archaeplastida truly represents a clade or whether other lineages (especially the Cryptista group) may belong inside it (Yabuki et al. 2014; Burki et al. 2016). The ongoing discovery of new lineages (discussed above) is itself a source of uncertainty, not least because it is unclear how many major lineages remain to be found and characterized. One of the most important open questions in eukaryote evolution concerns the precise history of plastids (chloroplasts). Most major lineages of photosynthetic eukaryotes actually have plastids that were obtained by symbiosis with eukaryotic algae, rather than by symbiosis with cyanobacteria; the number, sequence, and directions of these distinct eukaryote-eukaryote endosymbiotic events are all still unclear (Keeling 2013; Archibald 2015). Finally, one of the most difficult questions for eukaryote phylogeny is locating the "root" of the tree, that is,

identifying the very deepest division among the extant eukaryotes. Several mutually incompatible positions have been proposed in recent years, based mostly on sophisticated phylogenomic analyses or the distribution of particular genes across major groups of eukaryotes (e.g., Cavalier-Smith 2010; Derelle and Lang 2012, 2015; Katz et al. 2012; He et al. 2014).

An Overview of Protist Diversity

The remainder of this chapter gives a concise, up-to-date, and (in our view) appropriately cautious summary of the diversity and phylogeny of eukaryotes. The main aim is to provide a broad phylogenetic context for the various other chapters in the Handbook of the Protists, Second Edition (hereafter, "the Handbook"). The majority of these chapters cover a single phylogenetically coherent group and will then have a single placement within the account below. There are a few chapters that instead cover two or more unrelated groups that have historically been considered together (e.g., "heliozoa"); these chapters will be referenced more than once for this reason. Furthermore, we have sought to briefly introduce the important groups of protists that are not covered separately in the Handbook (for reasons of logistics alone; no perception of insignificance should be inferred in these cases). In some of these instances, we direct the reader to recent (2010–onward) publications that are reviews or are reasonably broad in scope. For the sake of brevity, single genera of uncertain phylogenetic position within eukaryotes are omitted (see Adl et al. 2012 for a partial listing), and most lineages known solely as environmental sequences are not discussed.

Archaeplastida (Fig. 2) The supergroup Archaeplastida (meaning "ancient plastids"; sometimes instead called Plantae) consists of the three principal photosynthetic groups with "primary" plastids, in other words eukaryotes whose plastids/chloroplasts were acquired directly through a symbiosis with a cyanobacterium. There is strong phylogenetic evidence, especially from the plastid genome and plastid-associated biochemical features (e.g., the protein import machinery), that true plastids stem from a single event of primary endosymbiosis and thus that all archaeplastids descend from a common primary plastid-containing ancestor (Reyes-Prieto et al. 2007; Price et al. 2012). ► Glaucophyta (also known as Glaucocystophyta) is the most obscure of the three archaeplastid lineages. Glaucophytes are rare freshwater algae that mostly associate with surfaces. ► Rhodophyta consists of several thousand described species of algae, most of which are marine. They range from a few unicellular species, to diverse filamentous forms, to complex red seaweeds. The third group, Chloroplastida (also known as Chlorobionta or Viridiplantae), includes both the green algae and the land plants. It is divided into two large clades, streptophytes and chlorophytes, with the former including land plants, as well as many green algae; streptophyte green algae are often referred to as "charophytes," and the best studied groups are the ► Zygnematophyta, which are unicellular or filamentous freshwater forms, and the ► Charophyceae (Charales), which are truly multicellular freshwater "plants." Despite

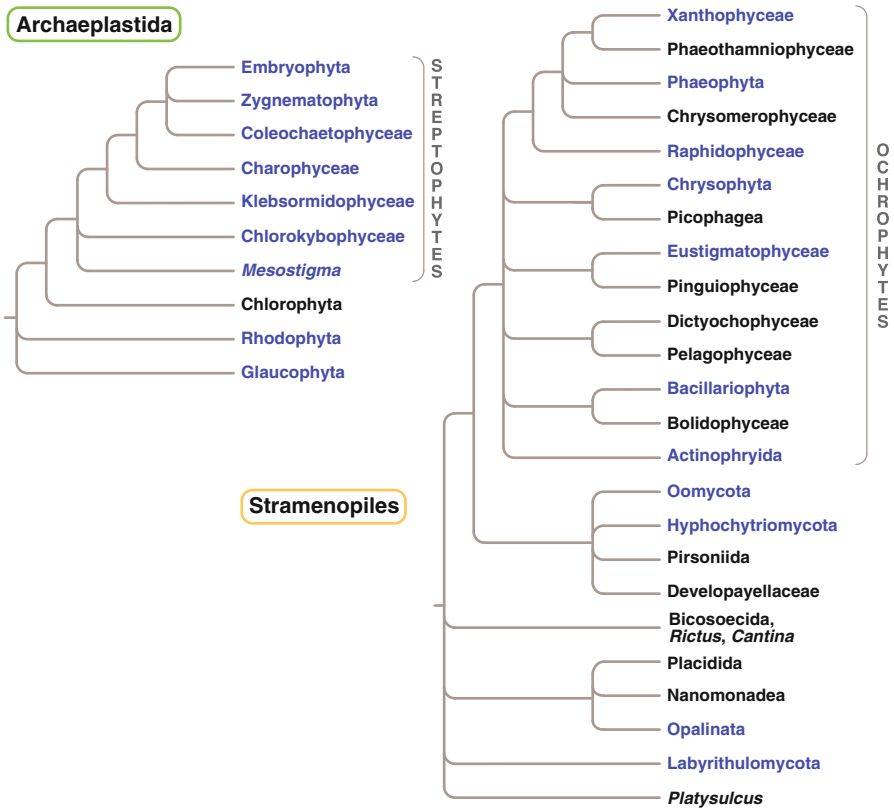

Fig. 2 Summary phylogenetic trees for Archaeplastida and Stramenopiles, based primarily on Leliaert et al. (2012) and Wickett et al. (2014) (Archaeplastida) and Riisberg et al. (2009), Cavalier-Smith and Scoble (2013), Yubuki et al. (2015), Shiratori et al. (2015), and Derelle et al. (2016) (Stramenopiles). Groups covered in Handbook chapters are shown in *blue* and are as follows: Archaeplastida: ▶ Glaucophyta; ▶ Rhodophyta; ▶ Zygnematophyta; ▶ Charophyceae; ▶ Chlorokybophyceae, Klebsormidiophyceae, Coleochaetophyceae, *Mesostigma*. Stramenopiles: ▶ Bacillariophyta; ▶ Phaeophyta; ▶ Raphidophyceae; ▶ Chrysophyta; ▶ Eustigmatophyceae; ▶ Xanthophyceae; ▶ Actinophryida; ▶ Hyphochytriomycota and Oomycota; ▶ Labyrinthulomycota; ▶ Opalinata. MAST clades without described representatives are not shown (see text)

the similarity in complexity between Charophyceae and land plants, recent phylogenetic evidence strongly indicates that land plants are more closely related to Zygnematophyta (Leliaert et al. 2012; Wickett et al. 2014). The remaining charophyte lineages, ▶ Chlorokybophyceae, Klebsormidiophyceae, Coleochaetophyceae, *Mesostigma*, are all discussed together. Chlorophytes include a wide diversity of unicellular flagellates (and some complex colonial forms), nonflagellated unicells and colonies, filamentous forms, and some more complex macroalgae, including green seaweeds. They are shown as a single branch in Fig. 2, but in reality, they are phylogenetically diverse. The best known subgroups include the Chlorophyceae (e.g., *Chlamydomonas*, *Volvox*), Ulvophyceae (marine macroalgae), and

Trebouxiophyceae. There are several additional distinct lineages, mostly of small flagellates, that collectively are referred to as "prasinophytes." The chlorophyte groups are not covered in the Handbook; the phylogeny and diversity of green algae, especially chlorophytes, is reviewed by Leliaert et al. (2012).

Sar; Stramenopiles (Fig. 2) The supergroup "Sar" (also known as SAR or Harosa) was identified through multigene/phylogenomic analyses (Burki et al. 2007; Hackett et al. 2007) and includes three lineages that are each hugely diverse and speciose in their own right: Stramenopiles, Alveolata, and Rhizaria (SAR is an acronym for these three groups). Stramenopiles, also known as Straminipila or Heterokonta, is distinguished by a characteristic form of rigid tubular flagellar hairs (the group name means "straw hairs"), although these have been lost in many species and several whole subgroups. Stramenopiles includes a wide range of photosynthetic forms as well as many heterotrophs (see Cavalier-Smith and Scoble 2013). Photosynthetic stramenopiles, also known as ochrophytes, have plastids derived ultimately from a red algal donor and form a monophyletic group (Cavalier-Smith and Scoble 2013; Derelle et al. 2016). The best known are the diatoms (► Bacillariophyta), which are unicellular/colonial forms with bipartite siliceous "cell walls" that are of huge ecological importance in the marine microplankton (for example), and the filamentous or genuinely multicellular ► Phaeophyta (Phaeophyceae), informally known as brown algae. As it happens, neither of these groups are flagellated in the vegetative state; the characteristic stramenopile flagellar hairs are seen only in (some) reproductive stages. Other ochrophyte groups include ► Raphidophyceae (Raphidophyta) and ► Chrysophyta, which are flagellates (though some famous chrysophytes are colonial and many are no longer photosynthetic), the mostly unicellular ► Eustigmatophyceae, and the ► Xanthophyceae, which are often filamentous and are among the closest relatives of the brown algae. Other, more obscure, groups of ochrophytes include Phaeothamniophyceae and Chrysomerophyceae (also related to brown algae) plus several groups of mostly unicellular marine forms: Bolidophyceae (the sister group to diatoms), Dictyochophyceae (including the well-known "silicoflagellates"), Pelagophyceae, Pinguiophyceae, and Picophagea (the latter being amoeboid and often non-photosynthetic): None of these are covered independently in the Handbook. Finally, ► Actinophryida, a small group of heterotrophic "heliozoan" organisms, belongs phylogenetically among ochrophytes (the exact placement is unresolved).

The heterotrophic stramenopiles are phylogenetically more diverse than the phototrophs and range from fungi-like organisms (most of which nonetheless produce flagellated dispersal stages) through to various kinds of "protozoa." ► Hyphochytriomycota and Oomycota are the most fungus-like stramenopiles: they produce (septate) hyphae with cell walls and generally parasitize plants or aquatic organisms. Oomycetes, in particular, cause several major diseases of agricultural crops (e.g., late blight in potatoes) and trees. ► Labyrinthulomycota produce non-walled extensions, with the best known, the labyrinthulids, existing as ectoplasmic networks containing numerous cell bodies. Pirsoniida (not covered) is a group of

parasitoids of algae that is related to oomycetes and hyphochytrids. Many groups of stramenopiles are heterotrophic flagellates with two flagella or sometimes one. The best known of these is Bicosoecida (sensu lato; also known as Bicosidia); others that are broadly similar but phylogenetically distinct include Placididea, *Cantina*, *Rictus*, *Platysulcus*, and Developayellaceae (the latter is also related to oomycetes and hyphochytrids; Cavalier-Smith and Scoble 2013; Yubuki et al. 2015; Shiratori et al. 2015). Furthermore, environmental sequencing studies have shown that the oceans contain a wide diversity of undescribed lineages of stramenopiles, collectively called "MASTs" (MArine STramenopiles; though some are also found in freshwater), which appear to be largely or entirely heterotrophic flagellates (Massana et al. 2014). In recent years, a couple of species that belong to one MAST lineage have been cultivated or reinvestigated (*Incisomonas* and *Solenicola*), and this group is now known as Nanomonadea (Cavalier-Smith and Scoble 2013). None of these various heterotrophic flagellate groups is covered in the Handbook; a summary of MAST diversity is given by Massana et al. (2014). Finally, the taxon ▶ Opalinata includes a range of inhabitants of animal intestinal tracts, including cells with two to four flagella, the multiflagellated opalinids, and the nonflagellated anaerobe *Blastocystis* (one of the most prevalent protists in the human gastrointestinal tract).

Sar; Alveolata (Fig. 3) Alveolata encompasses three of the most well-known groups of protists, Apicomplexa, Dinoflagellata, and Ciliophora, each represented by a chapter in the Handbook: ▶ Apicomplexa is quintessentially parasitic and includes species that are extremely harmful to humans and animals (e.g., *Plasmodium* spp., *Toxoplasma gondii*, *Cryptosporidium parvum*, etc.). The scope of the Handbook chapter has been extended to include the sister lineages to apicomplexan parasites, namely, colpodellids (which predate upon other protists or parasitize them) and the chromerid algae, which were only discovered this century (Moore et al. 2008). Colpodellids and chromerids are phylogenetically intermingled; recent analyses indicate they may be a clade, "chrompodellids" (Janouškovec et al. 2015). Research on these lineages has resulted in groundbreaking advances in our understanding of the evolution of apicomplexans and their relationships with dinoflagellates. Most notably, chromerids turned out to be the long-sought living descendants of the inferred photosynthetic ancestors of apicomplexans (most of which have non-photosynthetic plastids). ▶ Dinoflagellata includes numerous species that are conspicuous and important components of the marine microplankton, as autotrophs and/or grazers (many are mixotrophs and show both functions). Collectively, dinoflagellates are involved in several phenomena of great ecological importance, such as harmful algal blooms (e.g., *Karenia brevis*, *Alexandrium* spp.), symbioses with reef-forming corals (*Symbiodinium*), and important parasitic associations with animals or with other protists (e.g., *Hematodinium*, *Amoebophrya*). Dinoflagellates are closely related to Perkinsozoa, a small group of aquatic parasites with flagellated spores (not covered separately in the Handbook). While Apicomplexa-chrompodellids and Dinoflagellata-Perkinsozoa are closely related, there is still some uncertainty as to the position and evolutionary significance of several

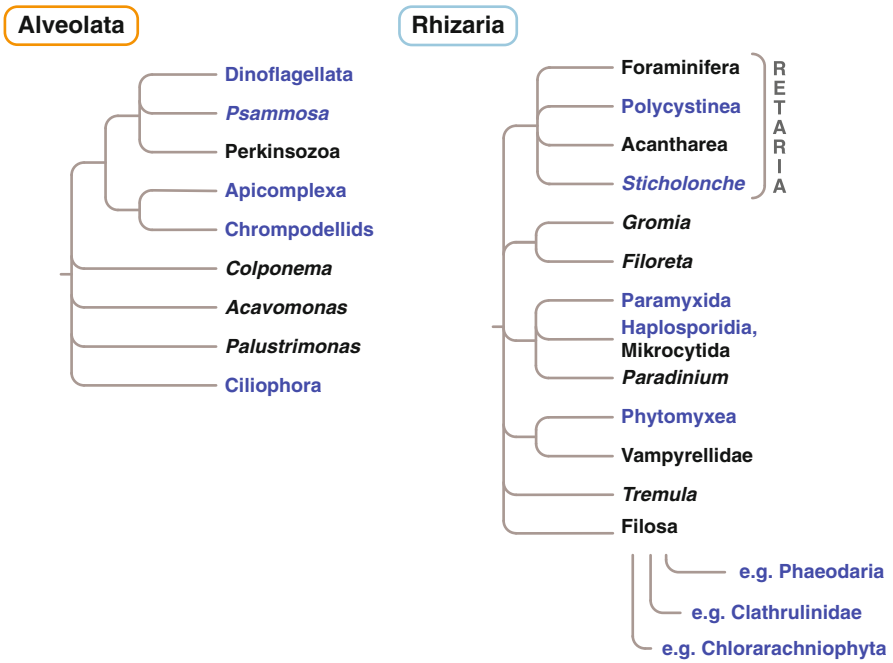

Fig. 3 Summary phylogenetic trees for Alveolata and Rhizaria, based primarily on Tikhonenkov et al. (2014), Janouškovec et al. (2015), Park and Simpson (2015), and Burki et al. (2016) (Alveolata) and Bass et al. (2009), Sierra et al. (2013, 2016), and Krabberod et al. (2017) (Rhizaria). Groups covered in Handbook chapters are shown in *blue* and are as follows: Alveolata: ▶ Apicomplexa (and "Chrompodellids"); ▶ Dinoflagellata (inc. *Psammosa*); ▶ Ciliophora. Rhizaria: ▶ Polycystinea; ▶ *Sticholonche*; ▶ Phaeodaria; ▶ Clathrulinidae; ▶ Chlorarachniophytes; ▶ Phytomyxea; ▶ Paramyxida; ▶ Haplosporidia. Note that Filosa contains many subgroups, and only those few subgroups covered in the Handbook are shown

heterotrophic flagellates lying at and near the split of these two groups (Fig. 3). Of these, *Psammosa* is often considered a basal dinoflagellate, while *Colponema*, *Acavomonas*, and *Palustrimonas* appear to represent one or more sister clades to the whole assemblage (none covered here; Tikhonenkov et al. 2014; Park and Simpson 2015). The third main group of alveolates, ▶ Ciliophora is extremely diverse and probably the most thoroughly studied group of (mostly) free-living heterotrophic protists. Most have large numbers of cilia (i.e., arrays of coordinated eukaryotic flagella), which in many species cover almost the entire cell, and they exhibit a characteristic form of nuclear dimorphism, with somatic macronuclei and germline micronuclei. In spite of the considerable wealth of knowledge on ciliates accumulated to date, the field of ciliate biodiversity is very active, and new environmental sequencing studies indicate that the full diversity of ciliates is far from uncovered.

Sar: Rhizaria (Fig. 3) One of the most morphologically diverse higher-order lineages, Rhizaria is comprised mostly of heterotrophic amoebae, flagellates, and amoeboflagellates, though it also includes some spore-forming parasites and unusual algae. No set of morphological features unites Rhizaria to the exclusion of other eukaryotes; they have emerged as a distinct taxon on the basis of molecular phylogenetic analyses (see Nikolaev et al. 2004). Reticulate or filose pseudopods are often present (thus the name "Rhizaria," referring to their often rootlike appearance), but these may be either actin- or microtubule-supported structures.

The most familiar rhizarians are foraminiferans (Foraminifera) and the radiolarians, most of which are large, often abundant, marine amoebae with microtubule-supported pseudopodia. Most foraminiferans inhabit multichambered tests that are constructed from calcium carbonate or assembled from agglutinated mineral particles; these have left an extensive fossil record extending back to the Cambrian. Foraminifera are not included in the Handbook (but see below). ▶ Radiolaria are subdivided into Polycystinea, usually with silica skeletons, and Acantharea, which have strontium sulfate skeletons (Acantharea are not covered in the Handbook). Foraminifera, Polycystinea, Acantharea, and the peculiar "rowing" radiolarian-like organism ▶ *Sticholonche* are related to one another (as Retaria), but their interrelationships are still unclear (see Sierra et al. 2013; Krabberød et al. 2017).

Much of rhizarian diversity falls within a clade called Filosa. This includes many free-living flagellates, which usually feed using some form of often-fine pseudopodia. The bulk of these flagellates associate with surfaces (e.g., most members of Cercomonadida, Glissomonadida, and Thaumatomonadida) but there are also some free-swimming forms (e.g., Ebriida). A few are parasites/parasitoids (e.g., *Pseudopirsonia*). Filosa also includes several groups of amoebae, the most famous being the filose testate amoebae (Euglyphida), although there is a greater diversity of naked forms (e.g., Bass et al. 2009). The Handbook has accounts of only a couple of groups of these organisms, namely, ▶ Phaeodaria, which are amoebae with siliceous skeletons that until relatively recently were considered to be radiolaria, and the "heliozoan" group ▶ Clathrulinidae. Filosa also includes two photosynthetic lineages, the mostly amoeboflagellate ▶ Chlorarachniophytes (e.g., *Bigelowiella* and *Lotharella*), which possess plastids of green algal secondary endosymbiotic origin, and *Paulinella chromatophora*, which is a euglyphid testate amoeba that harbors a cyanobacterium-derived photosynthetic "chromatophore" of separate origin than canonical plastids (Nowack 2014).

Most other rhizarian groups are various amoebae, including *Gromia*, *Filoreta*, and Vampyrellida (none covered in the Handbook), or are parasites. The latter include ▶ Phytomyxea, which are pathogens of plants and stramenopiles (e.g., *Plasmodiophora brassicae*, *Maullinia ectocarpi*), as well as ▶ Paramyxida and ▶ Haplosporidia, both of which parasitize marine invertebrates (though there are also freshwater haplosporidians). Other parasites infecting marine invertebrates (and not directly covered in the Handbook) include Mikrocytida, such as the oyster parasite *Mikrocytos* (which are very likely related to Haplosporidia or possibly descended from them), and *Paradinium*, which infects crustaceans. It is generally assumed that these parasites of invertebrates are all related, forming a taxon called

Ascetosporea, and this is incompletely supported by molecular phylogenies (e.g., Sierra et al. 2016). The flagellate *Tremula* (not covered) may represent the sister group to (other) Filosa (Howe et al. 2011).

Burki and Keeling (2014) provide a brief overview of the biology and evolution of rhizarian taxa, including some of the more important groups not covered in the Handbook. In addition, recent advances in the systematics of Foraminifera are treated by Pawlowski et al. (2013), and the current systematics of Euglyphida (and some other thecate amoebae within Filosa) was recently summarized by Kosakyan et al. (2016). The report by Howe et al. (2011) illustrates some of the range of free-living flagellates and small amoebae among Filosa. The diversity and phylogeny of Vampyrellida is examined and illustrated by Hess et al. (2012) and Berney et al. (2013). Hartikainen et al. (2014) give the first broad account of mikrocytids.

Other Archaeplastida- and Sar-Related Lineages (Fig. 1) A series of much smaller groups (in terms of the number of described species) are very likely related to Archaeplastida and/or Sar. The taxon Cryptista (sensu stricto) includes the well-known algal group ► Cryptophyta and two more obscure relatives, katablepharids and *Palpitomonas* (see Yabuki et al. 2014). Cryptophytes are mostly unicells with two flagella and with a plastid of red algal origin. Quite a few lack photosynthetic capabilities, including goniomonads, which are sister to other cryptophytes and may be ancestrally non-photosynthetic. Katablepharids and *Palpitomonas* are also biflagellated heterotrophs; neither is covered in the Handbook (Yabuki et al. 2010 and Nishimura et al. 2016 essentially summarize the published work on *Palpitomonas*). ► Haptophyta also known as Prymnesiophyta, is a major group of unicellular algae, especially in marine systems, where calcite-scale-producing coccolithophorid haptophytes are of regional and global significance in carbon cycling. They too have a plastid ultimately of red algal origin. Haptophyta are probably related to the recently discovered "rappemonads," which are uncultivated unicellular marine algae (not covered here; see Kim et al. 2011), and quite possibly to ► Centrohelida, a group of heterotrophic "heliozoan" amoebae with long, radiating microtubule-supported "axopodia" (another recently described heliozoan, *Microheliella*, is currently inferred to be a separate lineage from Centrohelida, but this has not been clearly resolved; Cavalier-Smith et al. 2015). Recent phylogenomic analyses suggest that cryptists are related to Archaeplastida, while haptophytes (and their relatives) are more closely related to Sar (Burki et al. 2016), but these relationships are not yet well resolved (e.g., Yabuki et al. 2014; Cavalier-Smith et al. 2015). Two further groups of obscure heterotrophic flagellates, Telonemida and Picozoa, are most likely related to Sar and Archaeplastida, respectively (Burki et al. 2016). Neither is covered in the Handbook; see Yabuki et al. (2013a), Seenivasan et al. (2013), and Moreira and Lopez-Garcia (2014) for recent publications on these groups.

Discoba (Fig. 4) This clade includes ► Jakobida, a group of heterotrophic flagellates best known for their particularly bacterial-like mitochondrial genomes, the recently discovered flagellate *Tsukubamonas*, and a clade called Discicristata which unites the well-known taxa Heterolobosea and Euglenozoa (Hampl et al.

2009; Yabuki et al. 2011; the name Discoba is a portmanteau of Discicristata and *Jakoba*). ▶ Heterolobosea are a collection of amoebae, flagellates, or "amoeboflagellates" with life cycles that include both cell types (the acrasids are also "slime molds" that produce sorocarps). Euglenozoa in turn includes three main subgroups: ▶ Euglenida encompasses many predatory species that glide over surfaces, as well as a large clade of algae with plastids of chlorophyte green algal origin (and very likely a group of specialist anaerobes – Symbiontida). ▶ Kinetoplastea includes a mix of free-living and parasitic flagellates, with the most famous being the trypanosomatids that cause sleeping sickness, Chagas' disease, and leishmaniases in humans. Diplonemids (Diplonemea) are the sister group to kinetoplastids. While previously obscure, diplonemids have recently been found to be extremely abundant and diverse in ocean waters (Flegontova et al. 2016). They also have remarkable mitochondrial gene expression systems, where genes are encoded as fragments on separate chromosomes and transcripts are trans-spliced together to produce functional mRNAs (and can be extensively edited too; Moreira et al. 2016). Diplonemids are not discussed further in the Handbook but are examined or reviewed in several recent publications (David and Archibald 2016; Flegontova et al. 2016; Gawryluk et al. 2016).

Metamonada (Fig. 4) The metamonads are a large group of anaerobic protozoa, almost all of which are flagellates. They are of contentious phylogenetic placement, with different molecular phylogenetic analyses favoring relationships with Discoba (see above) or Malawimonadidae (see below), this forming a part of the ongoing controversy about the phylogenetic coherence of the "excavates" (Hampl et al. 2009;

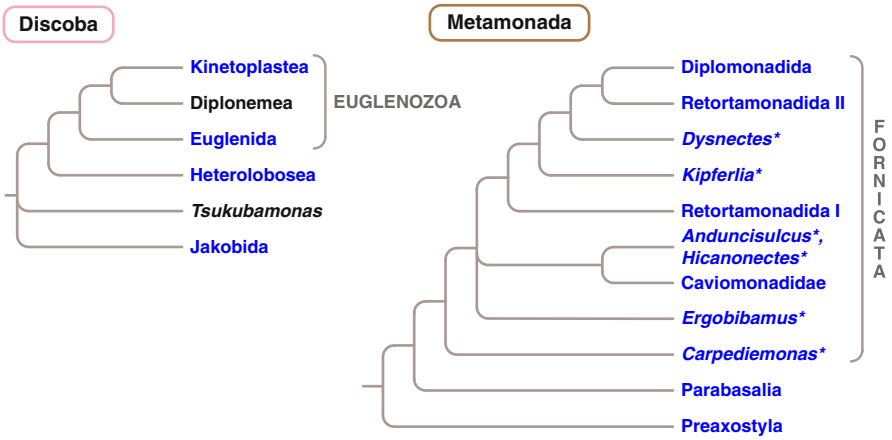

Fig. 4 Summary phylogenetic trees for Discoba and Metamonada, based primarily on Kamikawa et al. (2014) (Discoba) and Leger et al. (2017) and Yubuki et al. (2017) (Metamonada). Groups covered in Handbook chapters are shown in *blue* and are as follows: Discoba: ▶ Jakobida; ▶ Heterolobosea; ▶ Euglenida; ▶ Kinetoplastea. Metamonada: ▶ Preaxostyla; ▶ Parabasalia; ▶ Diplomonadida; ▶ Retortamonadida, Caviomonadidae, and *Carpediemonas*-like organisms (CLOs). CLOs are indicated by *asterisks*

Cavalier-Smith et al. 2014; Derelle et al. 2015). There are three main subgroups within Metamonada. ▶ Preaxostyla includes the oxymonads, which are gut commensals/symbionts, plus the free-living trimastigids. ▶ Parabasalia is a very diverse group (almost entirely) of endobiotic organisms. They range from small parasites (e.g., *Trichomonas vaginalis*, in humans) to giant multiflagellated cells of diverse kinds that are symbiotic in certain wood-eating termites and cockroaches. The third group, Fornicata, includes ▶ Diplomonadida, which are mostly "doubled" cells with two nuclei and flagellar apparatuses (e.g., *Giardia lamblia/intestinalis* in humans). The other members of Fornicata are the commensal/parasitic retortamonads and Caviomonadidae, as well as the various free-living "*Carpediemonas*-like organisms" (e.g., *Carpediemonas*, *Dysnectes*, *Kipferlia*); these are collectively a paraphyletic assemblage of relatives of diplomonads, but covered in a single chapter of the Handbook, ▶ Retortamonadida (with notes on *Carpediemonas*-Like Organisms and Caviomonadidae).

Amorphea; Amoebozoa (Fig. 5) The Amorphea assemblage unites two huge clades that are inferred to be related in most recent global analyses of eukaryotic phylogeny: (i) the animals, fungi, and their immediate protist relatives ("Obazoa"; see below) and (ii) the large grouping of heterotrophic protists called "Amoebozoa" (Adl et al. 2012; Burki 2014). As the name suggests, Amoebozoa mostly (though not entirely) consists of organisms that are amoebae for much or all of their life cycle. Many lineages are various kinds of "slime molds," which also produce a spore-releasing fruiting body. Due to this "fungus-like trait," these have often been studied separately from non-fruiting amoebae and are covered separately in the Handbook. Since "protosteloid" slime molds are phylogenetically intermingled with non-fruiting Amoebozoa, there is an imperfect fit between some chapters of the Handbook and the known phylogeny of the group (which is crystallizing rapidly as insights from phylogenomic analysis are integrated with those from taxon-rich ribosomal RNA gene phylogenies; e.g., Shadwick et al. 2009; Berney et al. 2015; Cavalier-Smith et al. 2016; Tice et al. 2016).

At present there are three reasonably well-accepted groupings that are largely or entirely composed of "lobose" amoebae with no other stages in the lifecycle – Tubulinea, Discosea, and the recently distinguished Cutosea (Cavalier-Smith et al. 2016). Tubulinea includes *Amoeba* itself and many other naked amoebae with thick pseudopodia, as well as the Arcellinida or lobose testate amoebae. Discosea tend to be flatter cells; examples include *Acanthamoeba*, *Vanella*, and *Thecamoeba*. Cutosea is a small group including particular scaled amoebae. The non-fruiting amoebae in these groups are covered in a single chapter, ▶ Amoebozoan Lobose Amoebae (Tubulinea, Flabellinea, and Others). A fourth group, Variosea, includes a few non-fruiting amoebae that often have filose or reticulate pseudopodia but also most of the "protosteloid" slime molds, some of which have flagellated stages as well as amoebae (Variosea also includes a couple of "flagellate-only" taxa, *Phalansterium* and *Multicilia*, that are not covered in the Handbook). A few of the amoebae are explicitly discussed in the lobose amoebae chapter (see above); the protosteloids are treated authoritatively in a separate chapter (▶ Protosteloid Amoebae). This latter

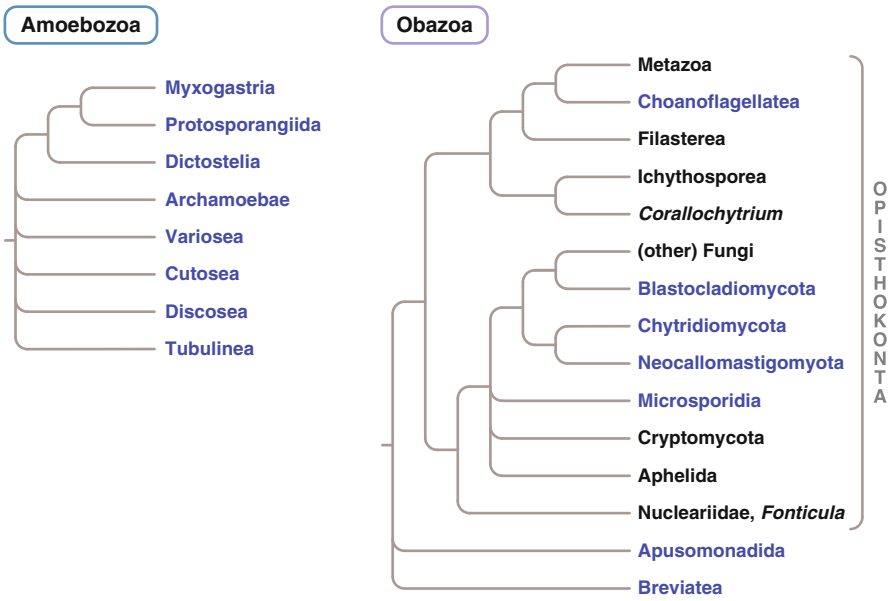

Fig. 5 Summary phylogenetic trees for Amoebozoa and Obazoa, based primarily on Berney et al. (2015), Cavalier-Smith et al. (2016), Tice et al. (2016), and M.W. Brown, pers. comm. (Amoebozoa) and Brown et al. (2013), Cavalier-Smith et al. (2014), Karpov et al. (2014), and Torruella et al. (2015) (Obazoa). Groups covered in Handbook chapters are shown in *blue* and are as follows: Amoebozoa: Many non-fruiting amoebae from Tubulinea, Discosea, Cutosea and Variosea are covered in ▶ Amoebozoan Lobose Amoebae (Tubulinea, Flabellinea, and Others); Protosteloid members of Variosea and Discosea, plus Protosporangiida, are covered in ▶ Protosteloid amoebae; ▶ Archamoebae; ▶ Myxomycetes; ▶ Dictyostelia. Obazoa: ▶ Choanoflagellatea; ▶ Blastocladiomycota; ▶ Chytridiomycota (and Neocallomastigota); ▶ Microsporidia; ▶ Apusomonadida (and Breviatea)

chapter also covers four small groups of fruiting amoebae that belong phylogenetically within Discosea (see above), as well as Protosporangiida, which are actually most closely related to Myxogastria (see below), and the couple of "protosteloid" members of Myxogastria.

The three remaining groups of Amoebozoa are each characterized by distinctive biological traits. Members of ▶ Archamoebae are amoeboid flagellates or amoebae (or cycle between these forms) that are anaerobic and have highly modified mitochondrial organelles (e.g., *Mastigamoeba*, *Pelomyxa*, *Entamoeba*). ▶ Myxomycetes or Myxogastria, is a well-known group of slime molds with complex life cycles that include small amoebae (and flagellates) but also multinucleate plasmodia that are macroscopic in size. It is the plasmodium stage that differentiates into the spore-bearing fruiting body. ▶ Dictyostelia are also slime molds, but unlike protosteloids or myxomycetes, they produce the fruiting body through aggregation of numerous unicellular amoebae. Myxogastria, Protosporangiida, and Dictyostelia are closely related, and they have sometimes been referred to collectively as Macromycetozoa.

Amorphea; Obazoa (Fig. 5) It is now well understood that animals (Metazoa) and Fungi are closely related to one another but also that they are specifically related to a heterogeneous assemblage of protist lineages, collectively forming a group called Opisthokonta (Cavalier-Smith 1987; Brown et al. 2009; Torruella et al. 2015). The protists most closely related to animals are the choanoflagellates (► Choanoflagellatea), which are unicellular or colonial flagellates that capture food using a characteristic "collar" of microvilli. Other close animal relatives include the Ichthyosporea (Mesomycetozoea), which are diverse parasites, mostly of aquatic animals and anurans, the isolated genus *Corallochytrium*, and Filasterea, the latter being a small group of free-living or parasitic forms mostly with fine pseudopodia. These groups are not discussed in detail in the Handbook; Ichthyosporea are reviewed by Glockling et al. (2013). Fungi are closely related to the nucleariid amoebae (Nucleariidae), with fine filose pseudopodia, and the slime mold-like organism *Fonticula* (not covered further). The phylogenetic and systematic distinction between Fungi and protists has perpetually been a gray area, and the Handbook contains accounts of groups that are usually considered the deepest branches among the fungi. These include ► Blastocladiomycota and ► Chytridiomycota with the latter chapter also including a brief account of Neocallimastigomycota; these organisms function as saprotrophs as well as parasites (or symbionts) and typically reproduce via uniflagellate zoospores. The other major taxa at the base of fungi include ► Microsporidia, an extensively studied and speciose group of spore-forming intracellular parasites, and the much more poorly known Cryptomycota (Rozellida) and Aphelida (not covered; see reviews by James and Berbee 2012; Karpov et al. 2014). Finally, two obscure groups of free-living heterotrophic flagellates, ► Apusomonadida and Breviatea, are now known to be sister taxa to the opisthokonts. It is this clade of all three taxa that is now known as Obazoa (Brown et al. 2013; OBA is an acronym for the three lineages).

Other Lineages (Fig. 1) There are a number of protist lineages that do not belong to any of the taxa listed above. Many are very poorly known groups for which there are very little data (e.g., limited or no electron microscopy data and no molecular sequence information). However, several lineages of free-living heterotrophs appear to be related to Obazoa and Amoebozoa (i.e., Amorphea) in phylogenetic/phylogenomic analyses (Zhao et al. 2012; Cavalier-Smith et al. 2014): Collodictyonidae (also known as diphylleids) are swimming flagellates, while their likely close relatives, Rigidifilida, are partly amoeboid cells without flagella. Ancyromonadida (Planomonadida) and *Mantamonas* are small gliding flagellates. Malawimonadidae is a small group of "excavate" flagellates that closely resemble Jakobida (in Discoba) and *Carpediemonas*-like organisms (in Metamonada) but do not branch with either Metamonada or Discoba in many phylogenomic analyses (though this is a topic of considerable contention; see above). Ancyromonadida is covered in a coda of the chapter on ► Apusomonadida and Malawimonadidae in the chapter on ► Jakobida Collodictyonidae, Rigidifilida, and *Mantamonas* are not covered in the Handbook, but recent publications on these protists include Zhao et al. (2012), Yabuki et al. (2013b), and Glücksman et al. (2011), respectively.

A different category of unplaced taxa consists of the few well-known groups of several species and genera for which there are substantial morphological data (albeit phylogenetically ambiguous) but no molecular data yet. One conspicuous example is Hemimastigophora, a taxon of multiflagellated cells that consume other smaller protists (Foissner and Foissner, 1993: not covered in the Handbook). We also highlight two groups of "heliozoa," Gymnosphaerida and Heliomonadida (formerly Dimorphida), each of which include several genera. One or both are sometimes placed tentatively within Rhizaria (Bass et al. 2009; Adl et al. 2012), but this awaits testing using molecular phylogenetics. Both are discussed briefly in the chapter on ► Centrohelida and Other Heliozoan-Like Protists.

Closing Remarks

Three decades ago, it would have been impossible to provide an accurate phylogenetic framework linking the many groups of protists covered in this edition of the Handbook. We are now able to present a reasonably comprehensive account of that framework, with confidence that most of it is essentially correct. Getting to this position has been a major achievement by the scientific community; this fact should not be lost amid concerns over the parts of the eukaryote tree that remain unresolved, contentious, or unknown. In a similar vein, while it has been necessary in this chapter to emphasize lineages that are not covered by the rest of the book, the Handbook is nonetheless an authoritative account of a substantial majority of known protist diversity. It represents an important collective effort by a large part of the protistology community and a major resource documenting the current state of knowledge on these organisms. We hope that this Handbook has a positive influence on the future direction of protistology, leading to greater depth and breadth in the understanding of our fascinating organisms.

Glaucophyta

2

Dana C. Price, Jürgen M. Steiner, Hwan Su Yoon,
Debashish Bhattacharya, and Wolfgang Löffelhardt

Abstract

The Glaucophyta is by far the least species-rich phylum of the Archaeplastida comprising only four described genera, *Glaucocystis*, *Cyanophora*, *Gloeochaete*, and *Cyanoptyche*, and 15 species. However, recent molecular and morphological analyses reveal that glaucophytes are not as species poor as hitherto assumed with many novel lineages existing in natural environments. Glaucophytes are freshwater phototrophs of moderate to low abundance and retain many ancestral plastid traits derived from the cyanobacterial donor of this organelle, including the remnant peptidoglycan wall in their envelope. These plastids were originally named "cyanelles," which was later changed to "muroplasts" when their shared

ancestry with other Archaeplastida was recognized. The model glaucophyte, *Cyanophora paradoxa*, is well studied with respect to biochemistry, proteomics, and the gene content of the nuclear and organelle genomes. Investigation of the biosynthesis of cytosolic starch led to a model for the transition from glycogen to starch storage during plastid endosymbiosis. The photosynthetic apparatus, including phycobilisome antennae, resembles that of cyanobacteria. However, the carbon-concentrating mechanism is algal in nature and based on pyrenoids. Studies on protein import into muroplasts revealed a primordial Toc/Tic translocon. The peptidoglycan wall was elucidated with respect to composition, biosynthesis, and involvement of nuclear genes. The muroplast genome is distinct, not due to the number of encoded genes but, rather, because of the presence of unique genes not present on other plastid genomes. The mosaic nature of the gene-rich (27,000) nuclear genome came as a surprise, considering the relatively small genomes of unicellular red algae.

Introduction

General Characteristics

The phylum Glaucophyta Kies and Kremer 1986 (synonym: Glaucophyta Skuja 1954) contains a single class, the Glaucocystophyceae Schaffner 1922. It comprises a small group of unicellular mastigotes (monadoid members), unicellular and colonial organisms devoid of flagella with persistent contractile vacuoles (capsalean members), and unicellular and colonial organisms lacking any characters of mastigotes in the vegetative stage (coccoid members). Currently, four genera are known with at least 15 species. Glaucophytes live photoautotrophically with the aid of their unique plastids that are surrounded by a remnant peptidoglycan wall. These organelles were named cyanelles by Pascher (1929), a denomination which was later proven to be incorrect and thus was replaced by the more appropriate term "muroplast" coined by Schenk (1994) (Fig. 1). Muroplasts owe their origin to cyanobacteria, providing direct proof for the endosymbiotic theory of plastid evolution. The glaucophytes are thought to be the most ancient phylum of phototrophic eukaryotes although molecular data provide inconclusive data regarding this hypothesis (Martin et al. 1998; Reyes-Prieto and Bhattacharya 2007a; Price et al. 2012). Together with rhodophytes and chlorophytes/streptophytes, they constitute the Archaeplastida (Adl et al. 2005) that contain "primary" plastids surrounded by two envelope membranes. The major reason that we understand the evolutionary importance of glaucophytes is the excellent and meticulous ultrastructural studies conducted by Ludwig Kies as summarized in Kies (1992). The unifying characters of this phylum are the presence of muroplasts with peptidoglycan layers in their envelopes (Fig. 1) and a number of shared morphological features (see below). This grouping was later corroborated by phylogenetic analyses based on 16S (Helmchen et al. 1995) and 18S rRNA (Bhattacharya et al. 1995a; Marin et al. 1998) and concatenated protein sequences (Rodríguez-Ezpeleta et al. 2005).

Occurrence

Glaucophytes are relatively rare in nature, occupying niches. All members inhabit freshwater environments in the plankton or benthos of lakes, ponds, or ditches. Only

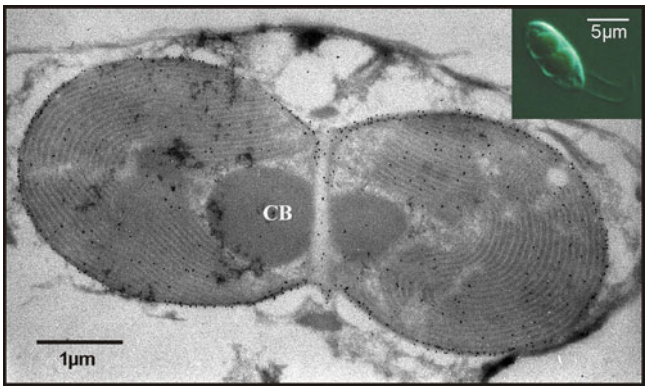

Fig. 1 *Cyanophora paradoxa* SAG 29.80. Immuno-EM of a dividing muroplast. Primary antibodies directed against peptidoglycan from *E. coli*. Gold particles mainly decorate the envelope and the newly formed septum. The division furrow neatly cleaves the RuBisCo-containing central body (CB), the genetic material surrounding it, and the concentric thylakoids into two halves destined for the daughter muroplasts. *Insert*: Interference contrast micrograph showing the ovoid cell, the flagella, and two muroplasts

four genera are maintained in culture collections, i.e., *Cyanophora*, *Gloeochaete*, *Cyanoptyche*, and *Glaucocystis* (Table 1), and thus are available for research. Almost all biochemical and molecular data acquired during the past 25 years (after the review by Kies and Kremer 1990) were obtained from *Cyanophora paradoxa*, which is the model organism for this phylum. A relatively fast growth rate, ease of cell lysis, and stable muroplasts account for its wide usage in research. Species that once were grouped together with the glaucophytes but were not deposited in an algal culture collection are not further dealt with here.

Literature and History of Knowledge

Kies and Kremer (1990) review the early literature, until the end of the 1980s, and explore the morphological criteria characteristic of glaucophytes. The excellent EM work of Ludwig Kies is presented in this chapter whenever possible. Bhattacharya and Schmidt (1997) review the phylogenetic analyses supporting the phylum Glaucophyta. Löffelhardt et al. (1997a) and Löffelhardt and Bohnert (2001) include the forthcoming molecular (muroplast genome sequence) and biochemical (fine structure of muroplast peptidoglycan) data until the end of the 1990s. The important issue of protein targeting to the muroplasts of *C. paradoxa* is dealt with in two reviews (Steiner and Löffelhardt 2002, 2005). Genomic data from *C. paradoxa* and *G. nostochinearum* and microarray data revealing CO_2-responsive genes and their involvement in the inorganic carbon-concentrating mechanism (CCM) are presented in Rodríguez-Ezpeleta et al. (2005) and Burey et al. (2007), respectively. The landmark paper describing the nuclear genome sequence of *C. paradoxa* (Price

et al. 2012) provided distinct support for a single plastid primary endosymbiotic event and gave rise to a number of related reviews (Bhattacharya et al. 2014; Löffelhardt 2014; Facchinelli and Weber 2015; Jackson et al. 2015).

The recognition of Glaucophyta is intimately connected to the concept of endosymbiosis between protists and cyanobacteria and the theory of the evolution of eukaryotic cells (Mereschkowsky 1905; Margulis 1981; Margulis and Sagan 2003). After thorough investigations, both Geitler (1959a) and Pascher (1929) concluded that *Cyanophora* species (Fig. 1), *Gloeochaete wittrockiana* (Figs. 2, 3, and 5) and *Glaucocystis nostochinearum* (Figs. 4a, b, 6, and 7), were cases of symbioses between heterotrophic host cells and modified autotrophic cyanobacterial endosymbionts functioning like plastids. Such endosymbionts were named "cyanelles" by Pascher (1929) who created the terms "endocyanome" for the whole consortium and "endocyanosis" for this particular type of endosymbiosis. Nowadays, the kingdom "Archaeplastida," also known as "Plantae," is thought to have resulted from a single successful primary endosymbiotic event between a cyanobacterium and a heterotrophic protist. Once this immensely complicated and lengthy process was successfully completed, the "protoplastid" became the ancestor of all plastids known to date, regardless of differences in traits such as pigmentation and morphology. This does not rule out much more recent instances of endosymbiotic organellogenesis as in *Paulinella* (Nowack et al. 2008) or *Rhopalodia* (Kneip et al. 2008).

In contrast to all other plastids, with the potential exception of the moss *Physcomitrella patens* (Hirano et al. 2016), the muroplasts of *Cyanophora paradoxa* (Fig. 1), *Gloeochaete wittrockiana* (Fig. 5), *Glaucocystis nostochinearum* (Fig. 6), and *Cyanoptyche gloeocystis* (Fig. 4c, d) have thin lysozyme-sensitive cell walls clearly recognizable with electron microscopy (EM) between the two envelope membranes (Kies 1992), which in *C. paradoxa* (Schenk 1970; Aitken and Stanier

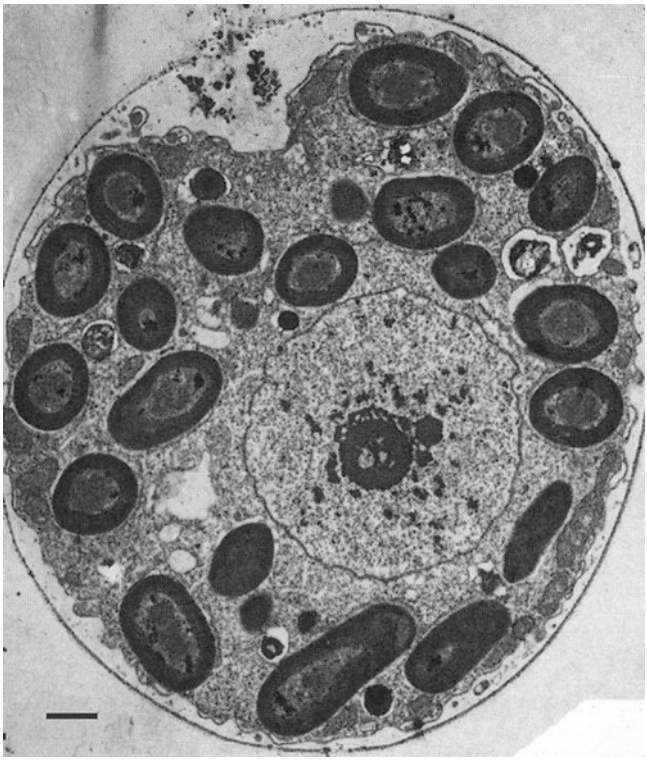

Fig. 3 *Gloeochaete wittrockiana*, strain SAG 46.84 (Kies strain IABH 2323), in longitudinal section, with apical depression, numerous muroplasts, and in the center of the cell a conspicuous nucleus with a nucleolus. Transmission electron micrograph. *Scale line* = 1 μm (Taken from Kies and Kremer (1990))

1979; Pfanzagl et al. 1996a), *G. nostochinearum* (Scott et al. 1984; Pfanzagl et al. 1996b), and *C. gloeocystis* (Pfanzagl et al. 1996b) have been identified as peptidoglycan layers. Skuja's taxonomic treatment of the phylum (Skuja 1954) was adopted: Skuja included in his phylum Glaucophyta *Gloeochaete*, *Glaucocystis*, and all endocyanomes described by Korshikov, Pascher, Geitler, and Skuja. Motile endocyanomes such as *Cyanophora* were not included in this framework. Kies (1979) suggested reviving the class Glaucocystophyceae (Skuja 1954) to accommodate the genera *Cyanophora*, *Gloeochaete*, *Glaucocystis*, and *Glaucosphaera*, which share ultrastructural characters not encountered together in any other algae (see Table 2). An emendation including a typification of several taxa of the Glaucophyta is given by Kies and Kremer (1986). *Cyanoptyche* was confirmed as a new member in 1989 (Kies 1989), whereas *Glaucosphaera* was removed in 1995 (Bhattacharya et al. 1995a).

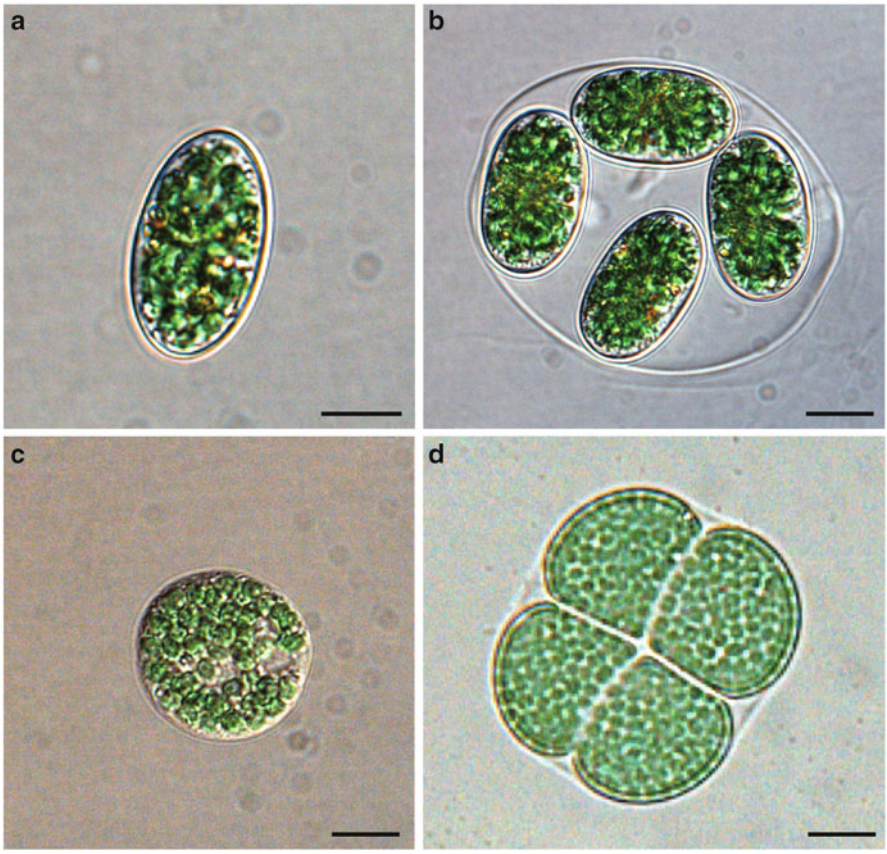

Fig. 4 **a**, **b** *Glaucocystis nostochinearum* SAG 45.88; C-D: *Cyanoptyche gloeocystis* SAG 4.97. A vegetative cell and autospores are shown for each species. *Scale bar* = 10 μm

Practical Importance

The Glaucophyta have not been exploited for economic or medical applications. A potential use of the eukaryotic peptidoglycan is as a model for the impact of beta-lactam antibiotics on eukaryotes, because the doses effective on *C. paradoxa* are similar to those for *E. coli* (Berenguer et al. 1987). In addition, a pigment extract of *C. paradoxa* containing pheophorbide *a*, beta-cryptoxanthin, and zeaxanthin as the main components has been shown to have strong antiproliferative activity against three cancer cell lines (Baudelet et al. 2013).

Habitats and Ecology

In terms of being reported in the literature, the cosmopolitan *G. nostochinearum* is most frequent, followed by *C. paradoxa* and *G. wittrockiana* (see also Table 1). Because the knowledge of their distribution pattern and ecological niches is incomplete, and there is only a limited and dispersed literature on their ecology, glaucophytes are not easy to collect.

Cyanophora paradoxa, originally found in small eutrophic ditches near Kharkov, Ukraine (Korshikov 1924), was isolated by Pringsheim in England from alkaline water and from a soil sample taken from a fishpond near Erlangen, Germany, by Kies (Kies 1979; Pringsheim 1958). *Cyanophora tetracyanea* has been collected from river plankton in the Gorki district of Belarus and from the littoral zone of Lake Fibysjon, Sweden (Skuja 1956). *Cyanoptyche gloeocystis* and its subspecific taxa have been found in *Sphagnum* bogs (Pascher 1929) and in ponds rich in submerged cormophytes and diatoms (Geitler 1959b). It has been found on the underside of floating leaves of *Potamogeton natans*, a monocotyledonous angiosperm (Pascher 1929). In some instances it occurred together with other glaucophytes such as *Gloeochaete* and *Glaucocystis. Gloeochaete wittrockiana* is epibiotic on filamentous chlorophytes such as *Oedogonium*, *Rhizoclonium*, *Chara*, and *Nitella*, the xanthophyte *Vaucheria*, and the leaves of aquatic mosses and submerged angiosperms. It has been found both in acidic *Sphagnum* bogs, soft water lakes poor in plant nutrients (Skuja 1956), and ditches with medium levels of inorganic nutrients (Kies 1979). Skuja frequently found its zoospores in the plankton of some Swedish lakes. It often occurred together with *Glaucocystis nostochinearum. Glaucocystis nostochinearum* has been found in acid and alkaline waters (Geitler 1959a); it was reported from the plankton of Swedish lakes and ponds where it occurred together with *Gloeochaete wittrockiana* (Skuja 1956) and from swamps and bogs. It was collected from a drainage ditch near Hamburg, Germany, rich in submerged land plants and also containing *Gloeochaete wittrockiana* (Kies 1979). The pH was 6.5–8.2.

Characterization and Recognition

Glaucophytes are distinguished by ultrastructural and biochemical characters. The phylum Glaucophyta can be defined as follows (for references see Tables 1 and 2): Glaucophyta (glaucophytes) are mastigote (Fig. 1) or coccoid algae (Fig. 4a), single or in colonies (Fig. 2). Typical carotenoids of cyanobacteria such as echinenone and myxoxanthophyll are absent. They display characters of oxygenic prokaryotic photosynthesizers (photosystems I and II). The thylakoids are concentrically arranged (Figs. 1, 5, and 6), and the muroplast pigments are chlorophyll *a*, β-carotene, zeaxanthin, β-cryptoxanthin, allophycocyanin, and C-phycocyanin.

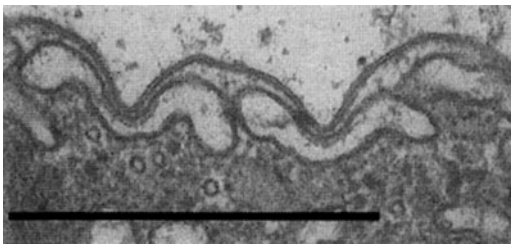

Fig. 7 Pellicle of *Glaucocystis nostochinearum*, strain IABH 2344 (Kies strain). Flat vesicles (lacunae) associated with microtubules form a layer beneath the plasma membrane. Transmission electron micrograph. *Scale line* = 0.5 μm (Taken from Kies and Kremer (1990))

Flagellated vegetative cells and asexual reproductive cells (mastigotes), if present, have a dorsoventral construction. In motile forms, two flagella (Heimann et al. 1989; Fig. 1) both with mastigonemes arise in an apical groove. One is directed toward the direction of swimming, the other laterally. In vegetative cells of *Gloeochaete*, stiff, hairlike extensions called pseudocilia arise (Fig. 2) in an apical depression (Fig. 3). In *Glaucocystis*, reduced flagella are present. The cruciate kinetid contains four multilayered structures (MLS) (Table 2) in *Gloeochaete* and *Glaucocystis* and two in *Cyanophora.*

Glaucophytes contain mitochondria with flattened cristae. An open spindle appears during mitosis, but centrioles and phycoplasts are absent. Cytokinesis occurs by infurrowing of the plasma membrane. Reproduction is by longitudinal binary fission in the mastigotes, by multiple mastigotes or immotile reproductive cells ("autospores," Fig. 4b, d) in capsalean and coccoid members. Sexuality has not yet been reported; a lacuna pellicular system is present (Heimann et al. 1997; Fig. 7). The polysaccharide reserve product (starch) accumulates in the cytoplasm of the host cell in the form of minute granules.

Classification

A classification scheme was first proposed by Skuja (1954). A more recent treatment of the Glaucophyta (Kies and Kremer 1986; Kies 1992) differs from Skuja's scheme in that:

1. The diagnosis of the phylum and class is emended to include ultrastructural and biochemical characters. Typified names instead of descriptive names are used for all taxa.
2. Mastigotes, which comply with the emended diagnosis, are included.
3. Separate orders are established for monadoid (Fig. 1), capsalean (Fig. 3), and coccoid (Fig. 4a) genera.
4. Taxa of uncertain affiliation with the Glaucophyta due to incomplete description and/or lacking ultrastructural and biochemical evidence are treated here as genera and species inquirendae.

Maintenance and Cultivation

Gloeochaete and *Glaucocystis*, the only common glaucophytes, are isolated by use of a capillary pipette (Hoshaw and Rosowski 1973). From fresh natural collections, single cells or colonies are removed and transferred with a sterile capillary pipette in a Petri dish through at least ten drops of sterile culture medium to dilute out undesired organisms. Between each step the capillary pipette is newly pulled through a flame. *Gloeochaete* living epibiotically on filamentous freshwater algae should be isolated together with parts of the filaments. In fresh culture medium multiple mastigotes are formed readily and may be isolated as described.

Axenic cultures have been established from *Cyanophora* and *Glaucocystis* species (see Table 1). Fluorescence-activated cell sorting (FACS) proved to be the method of choice. The criteria adopted were maximum chlorophyll autofluorescence and maximum forward scatter. A total of 20–30% of the sorted single cell cultures grew successfully, and among these more than 20% were axenic (Sensen et al. 1993). Isolates from four genera were deposited in culture collections (Table 1), among them at least five species of *Cyanophora*, whereas the other genera appeared to be monospecific: *Cyanoptyche gloeocystis*, *Glaucocystis nostochinearum*, and *Gloeochaete wittrockiana*. However, recently a more thorough investigation of the genus *Glaucocystis* (Chong et al. 2014; Takahashi et al. 2016) led to a splitting into several species as has also happened for *Cyanophora* (Takahashi et al. 2014). A compilation including the latest results is presented in Fig. 8. The best sources are the SAG (Göttingen, Germany), the NIES (Tsukuba, Japan), and the CCAC (Cologne, Germany) that keep several Kies strains (Table 1).

Culture media recipes can be found in the SAG catalogue and web site (http://www.uni-goettingen.de/). *Cyanophora paradoxa* cultures show a requirement for vitamin B_{12} as an essential cofactor for methionine biosynthesis, which in natural habitats likely is provided by environmental bacteria (Croft et al. 2005).

Biochemistry, Molecular Biology, and Cell Biology

Here, research done during the past 25 years will be reviewed. Almost all data were obtained with *C. paradoxa*, and most of them deal with various aspects of muroplast biology. The clear outcome is that muroplasts are primary plastids sensu stricto.

The Muroplasts of *Cyanophora paradoxa*: Protein Import, Biochemical Pathways, and Plastome Organization

Emphasis is given to processes and structures for which biochemical and cell biological experiments corroborate and extend the information obtained from plastome and genome sequencing.

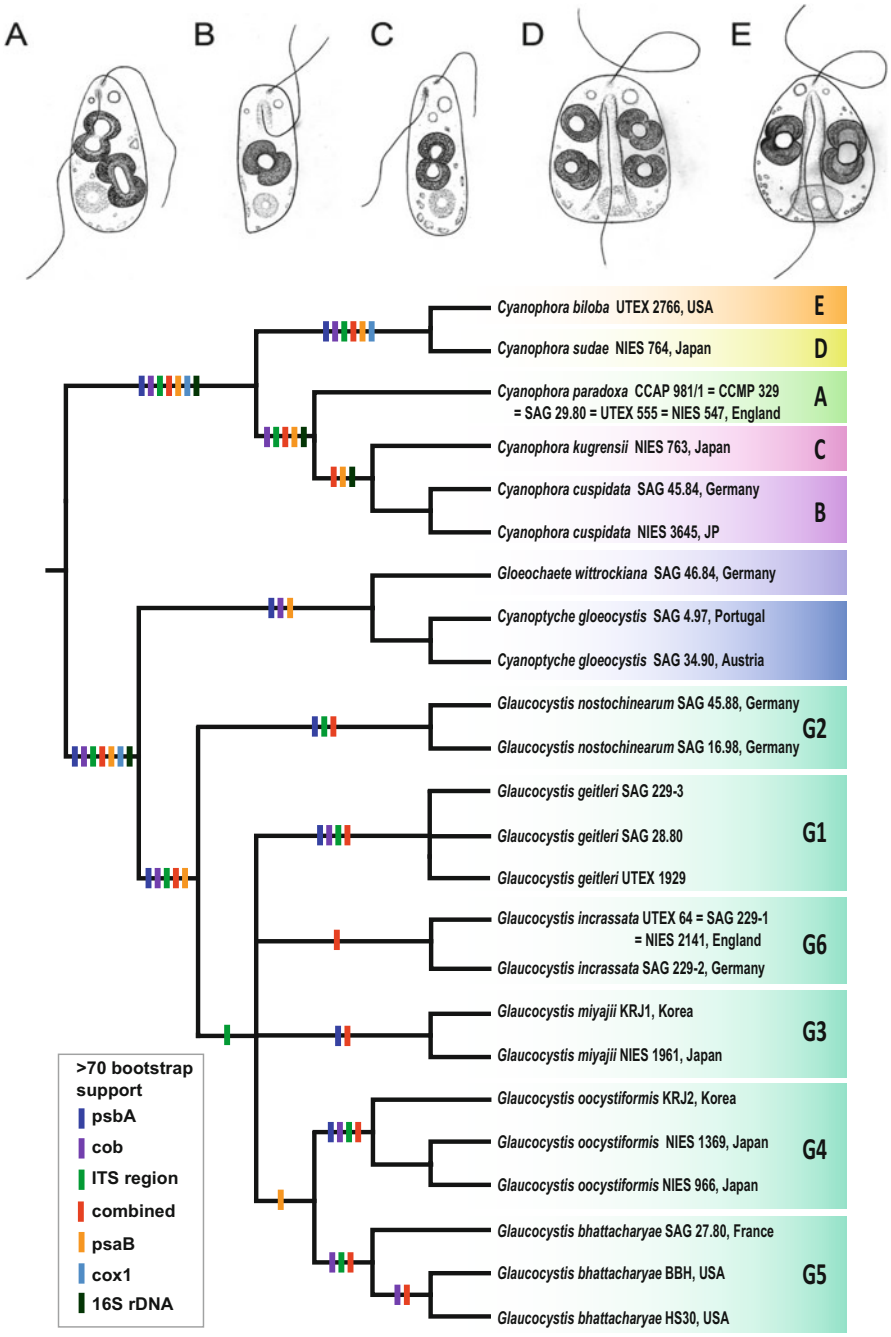

Fig. 8 Phylogenetic relationship of the Glaucophyta based on plastidal psbA, psaB, 16S rRNA, mitochondrial cox1, cob, and nuclear ITS region including ITS 1 and 2, 5.8S, partial SSU, and LSU

Protein Import into Muroplasts

Considerable progress has been made during the past 20 years with respect to components and mechanism of the import apparatus of land plant chloroplasts. It consists of two independent but cooperating translocons, Toc and Tic (Paila et al. 2015), at the outer envelope membrane (OEM) and the inner envelope membrane (IEM), respectively. Important translocon components are Toc75 (channel), Toc34 and Toc159 (receptors), Tic110 (putative channel), Tic20 (putative channel), Tic21, Tic22, and Tic40. GTP is the energy source for OEM translocation, and ATP energizes further translocation across the IEM via chaperone action. There is agreement that the import apparatus constitutes a eukaryotic "invention" which does not preclude the recruitment of suitable cyanobacterial membrane proteins (Reumann et al. 2005; Kalanon and McFadden 2008).

Nucleus-encoded muroplast polypeptides are synthesized in the cytosol as precursors containing cleavable N-terminal transit sequences that are 35–90 aa in length (Steiner and Löffelhardt 2002). These resemble chloroplast stroma-targeting peptides (Bruce 2000) in domain structure, amino acid composition (especially at the processing site; Köhler et al. 2015), and positive net charge. However, the N-terminal motif MA(A)FVxxVP is found with slight variation in nearly all muroplast transit sequences (Steiner and Löffelhardt 2002, 2005) but not in those for land plant or green algal chloroplasts. Pre-FNR and pre-transketolase from *C. paradoxa* were efficiently imported into isolated muroplasts (Ma et al. 2009; Jakowisch et al. 1996). Other precursors as pre-cytochrome c_6 and pre-RuBisCO activase performed even better during in vitro import and were completely internalized after 3–7 min incubation (Burey et al. 2005; Steiner et al. 2000). The energy requirements (ATP, temperature) corresponded to those for chloroplast import. The observed stability of muroplasts due to their peptidoglycan armor is misleading: even a slight osmotic shock causes damage of the OEM and loss of import competence (Steiner and Löffelhardt 2002), CO_2 fixation (Trench 1982), and in organello protein synthesis (Löffelhardt and Bohnert 2001).

In addition to pre-FNR (Jakowitsch et al. 1996), all other *Cyanophora* precursors tested are readily imported into isolated chloroplasts from spinach or pea (Ma et al. 2009; Steiner and Löffelhardt 2002, 2005). However, the inverse heterologous import, i.e., of precursors from land plants into isolated muroplasts, did not occur. Therefore, the N-terminal consensus sequences appear to be the sole recognizable difference between muroplast and chloroplast stroma- targeting peptides. The phenylalanine residue, usually at position three or four, is conserved and might be

Fig. 8 (continued) rDNA (Modified from Chong et al. 2014; Takahashi et al. 2014). Strain number and its origin were indicated beside the species name. Six clades of *Glaucocystis* species complex were marked as G1–G6 (Chong et al. 2014), while three new *Cyanophora* species from Takahashi et al. (2014) have been adopted in this phylogeny. Color bars indicate >70% bootstrap support values for each node from each individual gene. Ink drawings for A–E (*Cyanophora* species) were taken from Takahashi et al. 2014

crucial for successful translocation across the muroplast envelope. Its prevalence was recently confirmed through proteomic studies on isolated muroplasts (Köhler et al. 2015). Indeed, deletion or exchange of this amino acid from *C. paradoxa* pre-FNR led to impeded or even completely abolished import into muroplasts (Steiner et al. 2005a). The obvious next step was to engineer a chloroplast precursor, pre-FNR from *Mesembryanthemum crystallinum*, with the missing phenylalanine in the N-terminal region of the transit sequence. This enabled heterologous import with an efficiency comparable to homologous import (Steiner et al. 2005a).

The high gene content of their plastomes, the PBS light-harvesting antennae, and results of phylogenetic analyses make it possible to categorize muroplasts and rhodoplasts as "plastids with ancestral characteristics." An inspection of putative transit sequences of nucleus-encoded rhodoplast proteins from various red algae revealed N-terminal consensus sequences very similar to those for muroplast stroma-targeting peptides. The crucial phenylalanine residue is always present, even in precursors targeted to secondary plastids derived from endosymbiotic red algae where a phenylalanine residue is created as the first amino acid of the transit sequence after cleavage of the preceding signal sequence (Patron and Waller 2007; Gould et al. 2006; Kilian and Kroth 2005). On the other hand, this is not found in precursors to chloroplasts or secondary plastids from the "green lineage." When this feature is considered as typical for primordial plastids, it might as well have been taken over or adapted from the prokaryotic ancestor: phenylalanine has been reported to occupy a prominent position in the sequence of bacterial proteins targeted to the outer membrane (Struyvé et al. 1991) as porins (C-terminus) or type IV pilins (N-terminus, created by prepilin peptidase cleavage). An outer membrane protein, Omp85, acting as receptor/chaperone for such proteins recognizes their exposed phenylalanine residue and assists in their correct membrane assembly (Voulhoux and Tommassen 2004). When such a preexisting cyanobacterial protein was recruited (after transfer of its gene to the nucleus) for the development of a protein import apparatus in the endosymbiont envelope, it could have been oriented inversely so that precursors with a phenylalanine signature coming from outside, i.e., from the eukaryotic cytosol, would be recognized. Indeed, this reorientation could recently be demonstrated (Sommer and Schleiff 2014). Thus, an Omp85-like protein (due to its sequence similarity, chloroplast Toc75 is included in the Omp85 family) could have been adapted to fulfil dual functions, that of the "Phe-receptor" and that of the protein import channel (Steiner and Löffelhardt 2005; Steiner et al. 2005a). Blue-native gels of isolated muroplasts yielded a distinct signal (αToc75) for the Toc complex at about 550 kDa. (Yusa et al. 2008). The muroplast import apparatus is considered as a prototype that has not undergone many changes relative to that of the ancestral protoplastid which might also apply to rhodoplasts and, likely, to secondary plastids derived from red algal endosymbionts (with respect to the two innermost membranes). Omp85 proteins are suitable for the proposed dual role because: (i) these are the only members of the Omp85 family that can form pores of sufficient diameter to allow protein translocation and (ii) they display a presequence (Phe)-binding domain. Phe in the transit sequence of pre-FNR from *C. paradoxa* was shown to reduce unspecific binding to liposomes but to enhance binding to

proteoliposomes containing Omp85 from *Anabaena variabilis* (Wunder et al. 2007). There is now evidence for the minimal set of components of the Toc/Tic complexes (see section on Genome Analysis of Glaucophytes; Bhattacharya et al. 2014; Löffelhardt 2014). The interaction of both complexes might be more pronounced than in chloroplasts, resulting in fixed positions of import sites coinciding with localized lesions in the organelle wall. The latter are necessary to allow translocation of large proteins that would have problems with the narrow mesh size of the peptidoglycan network and could be generated through the action of lytic transglycosylases bound to the import complex (Steiner and Löffelhardt 2005).

Conservative Sorting

The "conservative sorting" hypothesis posits that organelles (mitochondria, plastids) that are derived from prokaryotic endosymbionts not only had to develop a selective protein import apparatus at their envelope but also retained prokaryotic preprotein translocases at their inner envelope (mitochondria) and thylakoid membranes (chloroplasts). Conservative sorting in land plant chloroplasts is widely accepted (Smeekens et al. 1990). Bipartite presequences, i.e., a transit sequence followed by a signal sequence, are indicative of intraplastidic sorting to the thylakoid lumen or thylakoid integration. According to the translocons involved and the respective energy requirements, the Sec pathway transporting unfolded passenger proteins and the ΔpH-dependent or Tat pathway for folded proteins are defined (Cline and Dabney-Smith 2008), both being paradigms for conservative sorting of (largely) lumenal proteins. Cyanobacteria, the ancestors of plastids, are capable of "exporting" cytosolically synthesized preproteins either to the periplasmic space or into the thylakoid lumen (Mackle and Zilinskas 1994). Muroplasts also possess a periplasmic space between IEM and OEM containing the peptidoglycan wall, seven penicillin-binding proteins, enzymes of peptidoglycan degradation and modification, cytochrome c_6, etc. (Steiner et al. 2000; Löffelhardt and Bohnert 2001). Therefore it is justified to postulate conservative sorting for both the thylakoid and inner envelope membranes (Fig. 9) as was first shown for cyanobacteria with respect to the Sec translocase (Nakai et al. 1993).

Sec pathway: Here, muroplasts have played a leading role for some time because *secY* is a muroplast gene and was shown to complement the thermosensitive *secY24* mutation in *E. coli* (Flachmann et al. 1993). In subsequent work, an expressed sequence tag (EST) for nuclear-encoded SecA was found in *C. paradoxa*. Muroplast SecA appeared to be quite susceptible to inhibition by sodium azide during import experiments with homologous precursors: the amount of mature cytochrome c_6 was reduced and intermediate accumulated in the stroma, whereas thylakoid translocation of the larger intermediate form of PsbO was completely abolished (Steiner et al. 2005b). Cyanobacterial thylakoids do not form tight vesicles upon isolation and thus are not suitable to demonstrate protease protection of internalized, processed lumenal proteins. With improved muroplast fractionation methods, it was possible, at least for PsbO, to show Sec-dependent translocation in organello and, after

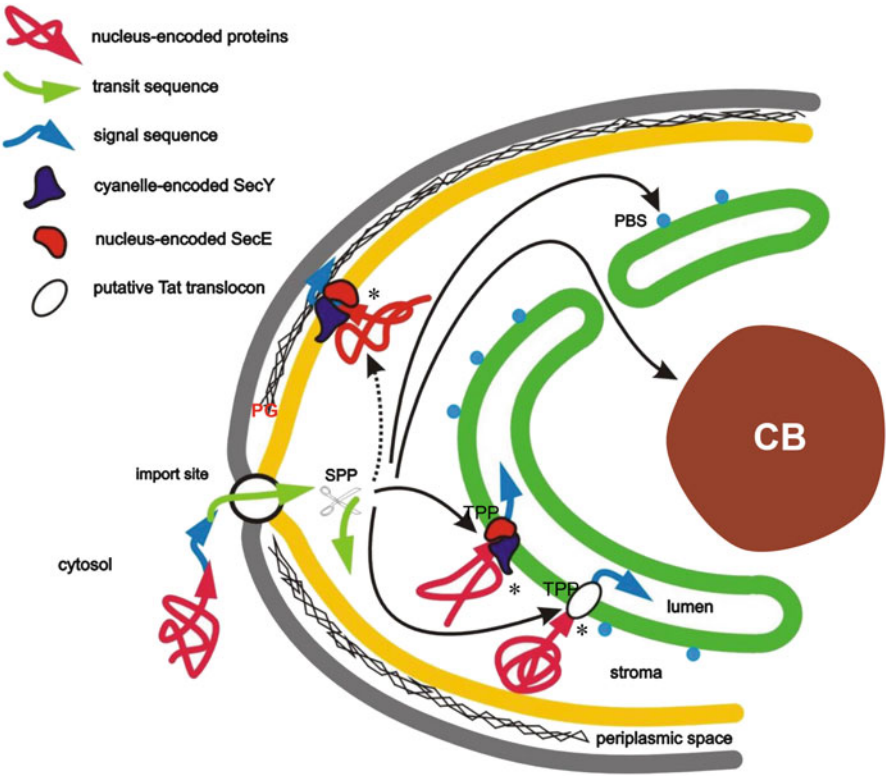

Fig. 9 Conservative sorting within the muroplasts of *Cyanophora paradoxa*. Proteins directed by a specific transit sequence (muroplast stroma-targeting peptide) across the muroplast envelope into the stroma can either stay there, or can be integrated into a microcompartment, or can be sorted by a signal sequence (in case of a bipartite presequence) to the thylakoid lumen or the periplasmic space, respectively. *CB* central body, *PBS* phycobilisome, *PG* peptidoglycan, *Spp* stroma processing peptidase, *TPP* thylakoid processing peptidase, * conservative sorting

muroplast lysis and thylakoid isolation, for the first time protease protection of the mature protein inside of phycobilisome-bearing thylakoids. Nigericin did not interfere; addition of azide to the import assay abolished protease protection of PsbO by inhibiting thylakoid translocation (Steiner et al. 2005b). However, import experiments into isolated thylakoids are only possible in land plant systems. The *Cyanophora* Genome Project revealed contigs for secA and thylakoid processing proteases (TPP) but no additional, nucleus-encoded SecY (Table 3; Steiner et al. 2012): there is but one *secY* gene and one *secA* gene, as in cyanobacteria. The generation of specific antisera directed against muroplast SecY allowed the demonstration of dual localization (Fig. 9) of the Sec translocon in muroplasts (Yusa et al. 2008). SecY-containing bands of distinct size were immuno-decorated on blue-native gels of thylakoid membranes and IEM, respectively (Koike et al. 2007). In land plant chloroplasts, a second Sec translocase was recently shown at the IEM, but

Table 3 Genes for components of protein sorting pathways within the muroplasts of *Cyanophora paradoxa* and for candidate passengers undergoing spontaneous membrane insertion (Steiner et al. 2012)

Protein	Function	Comments
SecY	Sec translocase	One copy on the muroplast genome
SecE (n.d.)	Sec translocase	Should be present. Low sequence conservation
SecA	Sec translocase	N-terminal fragment with STP[a]
TatC	Tat translocase	5 TM domains, negatively charged N-terminus[a]
TatA	Tat translocase	STP, 1 TM domain, highly polar C-terminus[b]
TPP	Signal peptide cleavage	LepB1 homolog[a], 1 TM domain
TPP	Signal peptide cleavage	Fragment, putative LepB2 homolog[a]
mpSRP54	Signal recognition particle	STP, GTP-binding domain[a]
mpFtsY	SRP receptor	GTP-binding domain[b]
Albino3	D1 insertase	STP, 5 TM domains[b]
Vipp1	Thylakoid stabilization	STP, amphipathic α-helix at C-terminus[a]
PsbW	Spontaneous insertion?	STP, SP, 1 TM domain[b]
PsaK	Spontaneous insertion?	2 TM domains[a]

n.d. not detectable, *mp* muroplast, *STP* stroma-targeting peptide, *SP* signal peptide, *TM* transmembrane

[a]Best hits among cyanobacteria

[b]Best hits among green algae and plants

SecY and SecA are derived from nuclear genes different from those giving rise to the thylakoid Sec translocon (Skalitzky et al. 2011).

Tat pathway: In *C. paradoxa* EST databases, nucleus-encoded candidate passengers were found, as pre-PsbU and pre-PsbQ', with bipartite presequences containing the typical "twin-arginine" motif in the signal sequence (Cline and Dabney-Smith 2008) that did not respond to azide. The problem is that the effect of nigericin on muroplasts obviously is weaker than on land plant chloroplasts. In the non-cleavable signal-anchor sequence immediately after the transit sequence, a KR motif is found in both cases (RR only in cyanobacterial pre-PetC). In the presence of azide, but not of nigericin, it was possible to detect low amounts of protease-protected (i.e., internalized) mature protein trimmed by removal of five N-terminal amino acids (preceding the single transmembrane domain) protruding into the stroma. This was interpreted as evidence for operation of the Tat pathway in the muroplast thylakoid membrane (Steiner et al. 2005b). With the availability of the genomic sequence, genes for TatA and TatC could be identified (Table 3; Steiner et al. 2012). There is now also evidence for dual localization of the Tat translocase in cyanobacteria (Aldridge et al. 2008). In the absence of any experimental data, this is also a likely scenario for muroplasts resulting in fully conservative sorting, whereas for chloroplasts an IEM-resident Tat translocase is rather not envisaged (Skalitzky et al. 2011). The muroplast signal recognition particle (SRP) protein and the corresponding receptor (distinct from the cytosolic counterparts) were also identified and included in the compilation of Table 3. Since LHCP is missing from glaucophytes and rhodophytes, a posttranslational SRP pathway should not be operative in the plastids

from both phyla. However, the cotranslational SRP pathway with the important function of thylakoid integration of PSII and PSI reaction centers (Ossenbühl et al. 2006) can be considered as another example of conservative sorting and is expected to be active in muroplasts and rhodoplasts. Consequently, the genes for Albino3/Oxa1/YidC and Vipp1 were identified, whereas the SRP-RNA which is encoded on all rhodoplast genomes could not be found on muroplast DNA (M. Rosenblad, personal communication). Obviously, mpSRP54 alone can fulfill its function without an RNA component. Table 3 is completed by two candidates for spontaneous (i.e., unassisted) thylakoid insertion (Tissier et al. 2002) which seems to be a special feature of galactolipid-rich plastid membranes.

Structure and Biosynthesis of the Unique Eukaryotic Peptidoglycan

In contrast to chloroplasts, isolated muroplasts of *C. paradoxa* are stable in hypotonic medium. This is due to the presence of a lysozyme-sensitive murein sacculus in the muroplast envelope (Schenk 1970). This "organelle wall" with an estimated thickness of 7 nm has hitherto only been found in the eubacterial kingdom. Such a peculiar prokaryotic wall around a eukaryotic organelle, perhaps the most striking biochemical evidence for the cyanobacterial origin of plastids, was assumed to mimic early stages of primary endosymbiosis and justified (for some time) consideration of *C. paradoxa* and glaucophytes in general as "living fossils." The basic components of muroplast peptidoglycan were identified as those known for the $A_1\gamma$-type found in Gram-negative bacteria: *N*-acetylmuramic acid, *N*-acetylglucosamine, L-alanine, D-glutamic acid, *m*-diaminopimelic acid, and D-alanine (Aitken and Stanier 1979). Analogous results were reported for the muroplast wall from *G. nostochinearum* (Scott et al. 1984). Cleavage of purified muroplast peptidoglycan from *C. paradoxa* with *Chalaropsis* muramidase and separation by HPLC yielded a muropeptide pattern different from that of *E. coli*: Only 7 of the 29 major muropeptides investigated by a combination of amino acid analysis and mass spectrometry were identical to bacterial counterparts. The remaining 22 appeared to be derived from known muropeptides of *E. coli* by a substitution leading to an increment in MW of 112 or multiples thereof (Pfanzagl et al. 1996a). The modification was localized to the C-1 carboxylic group of the D-isoglutamoyl moiety, and *N*-acetylputrescine was identified as the substituent (Pittenauer et al. 1993). The structures of all 29 major muropeptides (4 monomers, 8 dimers, 11 trimers, and 6 tetramers) have been elucidated (Pfanzagl et al. 1996a). In fact, the muroplast wall is thicker and more cross-linked than the cell wall of *E. coli*. The substitution (not detected in cyanobacteria) and the reduced thickness (as compared to the cyanobacterial wall) could thus both serve the purpose of increasing the permeability of the peptidoglycan network. This might be especially important for a cell organelle which requires extensive protein import from the cytoplasm. Indeed, *N*-acetylputrescine was also found in the muroplast walls from two other glaucophytes, *G. nostochinearum* and *C. gloeocystis* (Pfanzagl et al. 1996b), indicating that it really constitutes a signature for muroplasts in general, i.e., for the "eukaryotic"

peptidoglycan of an armored organelle. An alternative, less likely function might be in connecting the PG layer to the OM in the absence of murein lipoprotein (Pfanzagl et al. 1996a) as was reported for some rare cases of anaerobic Gram-negative bacteria that show cadaverine or putrescine linked to C-1 of the isoglutamoyl moiety (Kojima et al. 2010).

The biosynthetic pathway of *C. paradoxa* murein appears to be analogous to that of *E. coli* with respect to intermediates, the participating enzymes, and their compartmentation. Penicillin-binding proteins (PBPs) possess transglycosylase and/or transpeptidase activity and perform the last steps of bacterial peptidoglycan biosynthesis by introducing new monomeric building blocks into the growing carbohydrate chain and cross-linking the peptide side chains (Sauvage et al. 2008). Seven PBPs in the size range from 110 to 35 kDa were identified in the muroplast envelope by labelling with a radioactive derivative of ampicillin (Berenguer et al. 1987). Accordingly, β-lactam antibiotics are lethal for *C. paradoxa* in much the same concentrations as for eubacteria. Also, differential sensitivity of individual PBPs toward different penicillin derivatives was demonstrated (Berenguer et al. 1987). Muroplast division is arrested whereas cell division continues, finally leading to colorless, nonviable cells. Dumbbell-shaped muroplasts were also observed upon benzyl penicillin and vancomycin treatment of *C. paradoxa* (Iino and Hashimoto 2003). Indirect evidence was obtained for a periplasmic localization in the muroplasts of *C. paradoxa* of DD- and LD-carboxypeptidases and DD-endopeptidase, enzymes hydrolyzing defined bonds in peptidoglycan (Plaimauer et al. 1991). As in the cytosol of *E. coli* (Barreteau et al. 2008), the biosynthesis of the soluble precursor of peptidoglycan, UDP-*N*-acetylmuramoyl pentapeptide, was shown to occur in the muroplast stroma (Plaimauer et al. 1991). The membrane-bound steps, i.e., the transfer of UDP-*N*-acetylmuramoyl pentapeptide to undecaprenylphosphate (yielding Lipid I) and disaccharide formation with *N*-acetyl glucosamine (yielding lipid II), occur in analogy to *E. coli* (Bouhss et al. 2008) at the inner envelope membrane of muroplasts followed by putrescinylation at C-1 of the D-isoglutamyl moiety and then *N*-acetylation (Pfanzagl and Löffelhardt 1999). Amidation of *Staphylococcus aureus* PG at the same position was recently reported to also occur at the stage of lipid II (Münch et al. 2012). Surprisingly, the muroplast genome encodes only a single protein potentially involved in peptidoglycan biosynthesis during septum formation, FtsW (Löffelhardt et al. 1997). One proven function of *E. coli* FtsW is the recruitment of PBP3 (FtsI) to the divisome. More than 30 eukaryotic genes specifying enzymes responsible for building up the prokaryotic organelle wall must therefore reside in the nuclear genome of *C. paradoxa*. Recently, a homolog to the cyanobacterial division protein SepE, which has a role in assembly and stability of the FtsZ ring (Hamoen et al. 2006), was also identified on the muroplast genome. The expression of *ftsW* and *sepE* appear to be cell cycle independent (Miyagishima et al. 2012).

Muroplast division in *C. paradoxa* shows intermediate features between cyanobacterial and plastid division (Iino and Hashimoto 2003; Sato et al. 2009). This was to be expected since it is strictly dependent upon the formation of a peptidoglycan septum in contrast to all other plastid types which nevertheless rely

on a number of cell division genes of bacterial origin as *ftsZ*, *ftn2* (*arc6*), *minD*, *minE*, etc. (Yang et al. 2008). Interestingly, there is but one gene for (muroplast-targeted) FtsZ on the *C. paradoxa* genome (as in cyanobacteria) and no mitochondrial counterpart, whereas algae and plants possess at least two genes for the chloroplast proteins and, more recently (e.g., in case of stramenopiles), additional genes for the mitochondrial FtsZ were described (Leger et al. 2015). Muroplasts and chloroplasts show in the stroma a distinct inner plastid division (PD) ring, corresponding to the FtsZ ring superimposed by a thicker, electron-dense ring. However, muroplasts lack the outer chloroplast division ring and the adjacent ring formed by the dynamin-related protein ARC5 (DRP5B). These components of the chloroplast division machinery are considered as host cell contributions after the endosymbiotic event. Nuclear genes for MinD and MinE, proteins determining the site of the division septum, and for ARC6 (assumed to tether the FtsZ ring to the IEM) were identified in *C. paradoxa*, and their expression was shown to be regulated by the cell cycle (Miyagishima et al. 2012). In contrast, FtsZ was found to be constitutively expressed. In (cyano)bacteria, various hydrolases function in PG splitting during septum formation. Recently, a homolog of the gene for DipM was detected on the nuclear genome of *C. paradoxa*, and the protein was shown to localize to the intermembrane space of dividing muroplasts at the site of septum formation (Miyagishima et al. 2014a). Again, the expression of DipM followed the cell cycle with a peak in the S phase.

In the *Cyanophora* Genome Project, three different approaches were used for PBP gene identification: (1) domain searches, (2) BLAST searches against the eight PBP genes of *Synechocystis* sp. PCC6803 (Marbouty et al. 2009) and the *Anabaena* sp. PCC7120 homologs, and (3) BLAST searches against *Physcomitrella patens* PBP-like genes. In most cases, the results converged leading to the identification of at least 11 genes or gene fragments (Bhattacharya et al. 2014); examples of which are shown in Table 4. In general, sequence similarity was higher to homologs in cyanobacteria than to those in *P. patens*. In some cases of periplasmic proteins, bipartite presequences consisting of a transit peptide and a signal peptide could be found. This suggests import to the muroplast stroma, followed by export to the periplasmic space. This special variant of "conservative sorting" would necessitate a dual location of Sec (already documented) and Tat (seems possible as another parallel to cyanobacteria) translocases on thylakoid and inner envelope membranes of muroplasts. In a Gram-negative background, the low molecular weight (MW) peptidases VanX and VanY are not linked to vancomycin resistance but rather to D-alanine recycling and to an additional endolysin, respectively. Peptidoglycan biosynthesis requires cleavage of existing glycan chains to allow for insertion of new material. This is performed by soluble and membrane-bound lytic transglycosylases: one gene of this kind could also be identified in *C. paradoxa*. A lysozyme family protein with significant similarity to protist lysozymes displays a signal peptide indicating a vacuolar (lysosomal) location that is likely involved in the autophagosomal digestion of damaged muroplasts. Genes for stromal proteins that are involved in the synthesis of the soluble precursor are also listed in Table 4. The N-terminal transit peptide identifies one such gene in *C. paradoxa* (*glmS*, specifying

D-glucosamine-1-phosphate synthase) as a member of the muroplast-resident PG biosynthesis pathway, whereas the cytosolic counterpart would be expected to participate in protein glycosylation. The complete set of enzymes that are involved in UDP-*N*-acetylmuramate biosynthesis as well as the peptide side-chain adding enzymes and the alanine (Alr) and glutamate (MurI) racemases are encoded on the nuclear genome of the alga. The IEM-bound or associated MraY and MurG proteins complete this compilation.

Genes for enzymes of PG biosynthesis were transferred twice into Archaeplastida during the course of evolution – from the more ancient donor of the mitochondrion and from the subsequent cyanobacterial ancestor of plastids. These genes retain a high sequence similarity in *Arabidopsis thaliana* (few genes) and the moss

Physcomitrella patens (almost complete set), but their functions are likely to have changed. As long as chemical and structural proof is lacking, (pleiotropic) effects of antibiotics or gene knockouts on plastid division do not provide sufficient evidence to claim the presence and biosynthesis of PG in the plastids of bryophytes (Takano and Takechi 2010). FtsZ in (cyano)bacteria and muroplasts (derived from a single gene) is assumed to recruit the divisome proteins forming the peptidoglycan septum. In rhodoplasts and chloroplasts, the FtsZ ring is thought to instead recruit the outer PD ring and the dynamin ring to perform the constriction of the OEM. The *C. paradoxa* genome does not encode any of the host cell-derived plastid division proteins, whereas *P. patens* encodes three DRP5B dynamins (Miyagishima et al. 2014b).

With the present state of knowledge, glaucophyte PG – in the sense of a contiguous, stress-bearing layer between the envelope membranes – appears unique among Archaeplastida. In the rhizarian testate amoeba *Paulinella chromatophora*, the situation is different: there is also PG in this eukaryote, but all genes necessary for its biosynthesis are encoded on the endosymbiont (i.e., "chromatophore," photosynthetic organelle) genome which exceeds the size of plastid genomes by a factor of five to ten (Nowack et al. 2008). Unlike their counterparts in *C. paradoxa*, these genes retain their prokaryotic character; i.e., they were not transferred to the nuclear genome, and thus no import of precursor proteins is required for biosynthesis of the sacculus in photosynthetic *Paulinella* species.

The finding of more than one gene to a given function is not uncommon among cyanobacteria. For example, one of two genes with high sequence similarity to *murG* is more closely related to MGDG synthases, the likely function of "MurG" in plants. In an analogous fashion, *murD*-like genes might instead play a role in folate biosynthesis. Thus, one should expect modified functions for "mur-like" genes, e.g., "MurE" of *Arabidopsis* is involved in chloroplast development but not in chloroplast division (Garcia et al. 2008). However, should it become possible to demonstrate PG in bryophyte chloroplasts through novel, highly sensitive detection methods, as in the case of the cell wall-less bacterium *Chlamydia trachomatis* (Liechti et al. 2014), the chloroplast division apparatus of *P. patens* will have to be reevaluated. A first step in that direction was reported very recently (Hirano et al. 2016).

The Photosynthetic Apparatus of *Cyanophora paradoxa* Muroplasts

The first comprehensive investigation of the components of photosynthesis in *C. paradoxa* was performed by Burnap and Trench (1989). These authors purified ferredoxin, cytochrome b_6, and cytochrome c_6 and verified the absence of plastocyanin from muroplasts. They also isolated photochemically active PSI complexes and could resolve five subunits ranging from 66 kDa to 11 kDa. Further data included the preparation of PSII core particles and of phycobilisomes. More than 10 years later another round of research papers on this topic emerged after the muroplast genome sequence was published. This certainly was very helpful since more than 50% of the thylakoid proteins are contained therein. Shibata et al. (2001) prepared

oxygen-evolving thylakoid membranes and solubilized PSII particles. These contained PsbO and PsbV (cytochrome c_{550}; muroplast encoded), but PsbU was lost from the preparation. Enami et al. (2005) described PsbO, PsbV, and PsbU as the extrinsic proteins of the oxygen-evolving complex (OEC) of cyanobacteria and *C. paradoxa* muroplasts. PsbO, PsbV (rhodoplast encoded), PsbU, and PsbQ' were assigned to *C. merolae* rhodoplasts (Enami et al. 2005), whereas the chloroplasts of green algae and land plants were long known to harbor the OEC components PsbO, PsbP, and PsbQ, all of them as the products of nuclear genes. PSI preparations now allowed the identification of ten subunits, whereby N-terminal protein sequencing was adopted. Sequence alignments in some cases yielded higher similarity to cyanobacterial homologs, in other cases to the counterparts from plants and green algae (Koike et al. 2000). In a comparison of supercomplex organization (where unicellular cyanobacteria possess a PSI trimer), the filamentous N_2-fixing *Anabaena* sp. PCC 7120 and *C. paradoxa* had a PSI tetramer and dimer instead, and the lack of LHCI, likely in all glaucophytes (in contrast to all other phototrophic eukaryotes), was corroborated. On the other hand, PSI monomers only were reported for the extremophilic rhodophyte *C. merolae*. Thus, with respect to PSI, glaucophytes are closer to cyanobacteria than to rhodophytes which also are distinct from the former through their LHCI antennae (Watanabe et al. 2011).

The next quantum leap to come was the *Cyanophora* Genome Project that stimulated a number of related investigations, e.g., on the muroplast proteome of *C. paradoxa* (Facchinelli et al. 2013). A total of 510 polypeptides were identified, among them the proteins of the photosynthesis apparatus with few exceptions, e.g., AtpA. Meanwhile, the state of the art with respect to cyanobacterial OEC components has changed to PsbO, PsbV, PsbU, PsbQ', and PsbP' (the latter two with sequence similarity to chloroplast PsbQ and PsbP), PsbP' being present in substoichiometric amounts with a presumed function in assembly/stability of PSII (Bricker et al. 2012). Muroplast proteomics confirmed PsbO and PsbV and identified PsbP' as an additional component (Facchinelli et al. 2013). PsbU is known to be encoded on the *Cyanophora* genome. The precursor contains the twin-arginine motif in the signal sequence and is one of the candidate passengers for the Tat translocase (Steiner et al. 2005a). Muroplast prePsbP' (also equipped with the RR signature) was proven to be imported into the thylakoid lumen via the Tat pathway in heterologous and homologous import experiments (Kleiner 2014), in analogy to PsbP from land plants. Very recently, a contig representing a PsbQ' homolog (J.M. Steiner, unpublished) completed the list for *C. paradoxa* resulting in a very similar OEC subunit structure for cyanobacteria, glaucophytes, and red algae. Thus, the "primitive" muroplasts and rhodoplasts differ from chloroplasts not only with respect to their extrinsic PBS antennae on the stromal side but also with respect to the extrinsic OEC proteins on the lumenal side of the thylakoid membranes. Chloroplasts have lost PsbV and PsbU in the course of evolution, whereas the gene for PsbP expanded to a small multigene family in land plants (Bricker et al. 2012).

Cyanophora RuBisCO belongs to form IB (as in cyanobacteria and chloroplasts) whereas rhodoplasts contain form ID. Common to muroplasts and rhodoplasts is the *rbcL-rbcS* transcription unit on the respective plastomes and the concentration and

compaction of RuBisCO into a microcompartment, the pyrenoid (see below). Calvin cycle enzymes corresponded to major transcripts (frequent in EST collections) and grouped among abundant stromal proteins with respect to spectral counts (Facchinelli et al. 2013). Again, canonical STPs were found throughout. Ferredoxin-NADP+ oxidoreductase (FNR) of *Cyanophora paradoxa* was characterized at the protein and cDNA level (Gebhart et al. 1992; Jakowitsch et al. 1993). The 34 kDa protein showed high amino acid sequence similarity to land plant counterparts and lacked the C-terminal extension of the cyanobacterial homologs responsible for binding to phycobilisomes. The availability of the ^{35}S-labeled precursor was important for the establishment of an efficient muroplast in vitro import system (see section on Protein Import into Muroplasts). A NAD(P)-dependent glyceraldehyde-3-phosphate dehydrogenase (GAPDH) was purified from a muroplast extract of *C. paradoxa* as a 142 kDa homotetramer with features similar to the cyanobacterial counterpart (Serrano and Löffelhardt 1994). This is in agreement with the postulated duplication of the *GapA* gene early in streptophyte evolution (Petersen et al. 2006).

The gene for the CP12 protein involved in the formation of inactive complexes of Calvin cycle enzymes during night was also characterized (Petersen et al. 2006). A muroplast-localized fructose-1,6-bisphosphate aldolase of class II was fractionated from *C. paradoxa* extracts as a 85 kDa protein and was shown to be bifunctional for fructose-1,6-bisphosphate and sedoheptulose-1,7-bisphosphate cleavage (Flechner et al. 1999). The cDNA of pre-transketolase was sequenced. In a neighbor-net graph, the *Cyanophora* enzyme occupied a position intermediate to the plastid and cyanobacterial homologs (Ma et al. 2009). The single copy gene was downregulated upon shift to low CO_2 conditions, typical for Calvin cycle enzymes (Burey et al. 2007).

Photorespiration: The oxygenase activity of RuBisCO inevitably leads to photorespiration (in different variations) in cyanobacteria and in all oxygenic phototrophs (where peroxisomes and mitochondria are involved in addition to plastids). The *Cyanophora* Genome Project inspired a study about evolution and phylogeny of this pathway in the earliest branching phototrophic eukaryote (Kern et al. 2013). The outcome was that some cyanobacterial genes (originally obtained through endosymbiotic gene transfer [EGT]) were lost, as for glycerate-3-kinase, or later replaced by α-proteobacterial homologs, as for glycine decarboxylase. Only phosphoglycolate phosphatase appears to be derived from Archaea. Glycolate oxidase was described to be of cyanobacterial origin in *Cyanophora* and all other algae/plants. A cyanobacterial origin was also postulated for serine:glyoxylate aminotransferase of *C. paradoxa*, whereas the counterparts from red algae and green algae/plants were found to be derived from proteobacteria through HGT. A similar situation is assumed for hydroxypyruvate reductase. Taken together, *Cyanophora* seems to have retained more cyanobacterial genes of the C_2 pathway than other algae and land plants in accordance with the predicted basal position of glaucophytes among Archaeplastida (Kern et al. 2013). Certainly, more biochemical research in this field is needed, as the lack of glycerate-3-kinase points toward some changes in the C_2 pathway of glaucophytes. Proteomics confirmed the muroplast localization of phosphoglycolate

phosphatase that showed the canonical transit sequence at the gene level (Facchinelli et al. 2013). There is but one experimental paper investigating glycolate metabolism in *C. paradoxa* that revealed glycolate oxidase and glycolate dehydrogenase activity. Furthermore, multiple forms of hydroxypyruvate reductase were shown, whereas serine:glyoxylate aminotransferase could not be detected. This was also taken at that time to indicate some deviations from the glycolate metabolism observed in leaves of land plants (Betsche et al. 1992).

The potential C_4 pathway of CO_2 fixation in algae including *C. paradoxa* was assessed in the light of emerging genome data: most of the respective enzymes, if present at all, appear to be derived from archaea/proteobacteria rather than from cyanobacteria, which are assumed to lack a complete C_4 pathway. Nevertheless, some algae, e.g., diatoms, seem to contain the enzymes necessary for the C_4 pathway, whereas *C. paradoxa*, lacking pyruvate:phosphate dikinase, malic enzyme, and alanine amino transferase, is not likely to perform C_4 photosynthesis (Chi et al. 2014). After all, a pyrenoidal CCM is operative in glaucophytes to cope with low CO_2 conditions (see below).

The Phycobilisomes of *Cyanophora paradoxa*

Phycobilisomes (PBS) are the primary light-harvesting pigment complexes of cyanobacteria, red algae, and glaucophytes and are attached to the stromal surface of the thylakoids (for review see, e.g., Adir 2008). These high molecular weight protein complexes with multiple functions consist of 400–700 subunits originating from more than 20 individual polypeptides with 600–2,000 covalently linked chromophores. Sequential assembly, conformational flexibility, and interaction between the chromophore and protein components are the main features of this complex network. Linker polypeptides play a central role in all of these processes, modulate the spectral characteristics of the phycobiliprotein chromophores, and mediate the attachment of the PBS to the photosynthetic membrane. Two structural domains, the central core complex and the peripheral rods, form this superstructure. For PBS without phycoerythrin, the core is composed of three cylinders, each formed by four allophycocyanin (APC) trimers $(\alpha\beta AP)_3$ with additional minor phycobiliprotein components and core-specific linker proteins. The rods radiate from the core and consist of three to four hexameric phycocyanin (PC)-rod linker (L_R) complexes $(\alpha\beta PC)_6L_R$. The rods are connected to specific domains of the core via rod-core linker polypeptides. In rhodophytes and the model glaucophyte *Cyanophora paradoxa*, the phycobiliprotein genes reside on the plastid genome, while the colorless linker proteins are encoded by the nucleus (Egelhoff and Grossman 1983). In cyanobacteria, the PBS most likely undergo a self-assembly process mediated by the amount of PBS assembly interaction partners and assisted by chaperones and processing enzymes (Anderson and Toole 1998). In muroplasts, where the PBS components are genetically separated, transcription events in the nucleus followed by translation in the cytosol and subsequent protein import must be coordinated with transcription events of muroplast-encoded subunits and in organello biosynthesis. In

Table 5 Components of purified, intact muroplast phycobilisomes

Apparent MW (kDa)	Abundance	Phycobiliprotein	Correlated cyanobacterial gene	Function
98	Medium	Yes	*apcE*	Core-membrane linker
55	Medium	No	n. m. (*cpcK1*)	Rod linker
53	Medium	No	n. m. (*cpcK2*)	Rod linker
38	Low	No	*cpcG2*	Rod-core linker
31	Low	No	*cpcG1*	Rod-core linker
18–20	High	Yes	$cpcA^{a},B^{a}$	Phycocyanin subunits
17–18	High	Yes	$apcA^{a},B^{a},D^{a},F^{a}$	Allophycocyanin subunits
10	Low	No	*apcC2*	Core linker (ApcD associated)
9	Low	No	*cpcD*	Terminal rod linker
8	Low	No	*apcC1*	Core linker

n. m. No orthologous match to rod linkers from phycocyanin-PBS, size comparable to red algal linkers and to an unusual chromophorylated phycoerythrin linker from *Synechococcus* sp. WH 8102, see Six et al. (2005)
[a]Muroplast encoded

vitro PBS assembly could be shown after import of the radiolabeled small core linker precursor protein preApcC1 from *Cyanophora paradoxa* into isolated muroplasts and subsequent isolation of the PBS (Steiner et al. 2003).

Phycobilisome components: *Cyanophora* PBS are of dual genetic origin, as are plastid microcompartments in general. The gene distribution is clear-cut: The seven phycobiliproteins including the "core-membrane linker" ApcE are muroplast encoded, whereas the non-chromophorylated linker polypeptides are nuclear encoded (Table 5; Steiner and Löffelhardt 2011; Watanabe et al. 2012). All these precursors show the canonical transit sequence containing a phenylalanine residue in the N-terminal domain. The functional assignments are based on MS measurements, on 2D gel electrophoresis of purified intact PBS, and on PBS dissociation studies followed by sucrose density gradient fractionation and SDS-PAGE (Steiner et al., manuscript in preparation). The genes encoding all non-chromophorylated PBS subunits in *C. paradoxa* could be identified from abundant ESTs (and later in the Genome Project; Price et al. 2012) and by research conducted in parallel by others (Watanabe et al. 2012).

The two large rod linkers, CpcK1 and CpcK2 (Watanabe et al. 2012), were shown to result from tandem duplications of the *cpcG* (rod-core linker) gene and are – in that respect – not related to the large linker polypeptides from red algae. There is but one similar special case among cyanobacterial PBS: a 59 kDa chromophorylated phycoerythrin linker originating from a fusion of two smaller linkers (Six et al. 2005). Further, two additional truncated *cpcG* genes were found adding up to a third version (*cpcG3*) – up to four genes were reported for filamentous cyanobacteria. CpcG3 might be part of a rudimentary PSI antenna (consisting of a rod only) as was

reported for cyanobacteria (Kondo et al. 2007) and red algae (Busch et al. 2010). The three small linkers are interpreted as follows: The two core linkers, ApcC1 and ApcC2, form complexes with ApcA,B and ApcA,B,D, respectively. In cyanobacteria, just one core linker is common, whereas in red algae also two core linkers are reported. The third small linker is the terminal rod linker CpcD that determines rod length.

A typical cyanobacterial rod linker protein CpcC consists of two domains, an N-terminal pfam00427 (PBS linker domain) and a C-terminal pfam01383 (CpcD/APC linker domain). The two CpcK linker proteins from *Cyanophora* consist of two pfam00427 domains in tandem, while the pfam01383 domain is missing. Two competing models exist for the location of linker proteins in the PBS rod. Novel "skeleton-like" structures have been described in the phycobilisomes of *C. paradoxa* (Watanabe et al. 2012). The authors showed, via native polyacrylamide gel electrophoresis (PAGE), two subcomplexes (ApcE/CpcK1/CpcG2/ApcA/ApcB/CpcD and ApcE/CpcK2/CpcG1/ApcA/ApcB) that may serve as a scaffold for the whole PBS assembly. CpcK1 and CpcK2 correspond to the large pfam00427 (PBS linker domain) tandem-duplicated rod linkers. However, data obtained by different types of native PAGE combined with limited proteolysis (Steiner et al., manuscript in preparation) suggest that these "skeleton-like" structures are most likely protein aggregates originating from phycobilisome degradation. When appropriate protease inhibitors are used, isolated subcomplexes showed a more "classical" pattern in native PAGE where the main APC core particle was complexed to ApcC1, the smaller of the two tandem-duplicated rod linkers (CpcK2) migrated in a complex together with phycocyanin and the terminal rod linker (CpcD), whereas the larger tandem-duplicated rod linker (CpcK1) migrated in a complex with phycocyanin only (Fig. 10; Weisser 2012). Since both complexes show a molecular weight of about 460 kDa, an association of cpcK1 and cpcK2 with three PC trimers (one trimer about 120 kDa without linkers) seems reasonable. Moreover, CpcG2 could be shown to form a separate complex with PC, APC, and ApcC2 (Maluck 2012). Limited proteolysis followed by native and SDS-PAGE allowed to estimate the amount of protected linker protein fragments and therefore the size of the different phycobilisome subparticles. Altogether a model is favored where the two tandem-duplicated rod linkers are part of the same rod with CpcK1 being the core-proximal hexamer rod linker and CpcK2 being the core-distal hexamer rod linker (Fig. 11, right; Steiner et al., manuscript in preparation) as opposed to the model with only one of the large linkers per rod, in more stretched conformation (Fig. 11, left; Watanabe et al. 2012). A schematic view of the *Cyanophora* PBS as a whole is given in Fig. 12.

The Nature of the RuBisCO-Containing Microcompartment of Muroplasts

The conspicuous, electron-dense central body of *C. paradoxa* muroplasts was shown to contain the bulk of RuBisCO (Mangeney and Gibbs 1987) and has been denoted the "carboxysome" in most publications. Despite the fact that eukaryotes contain

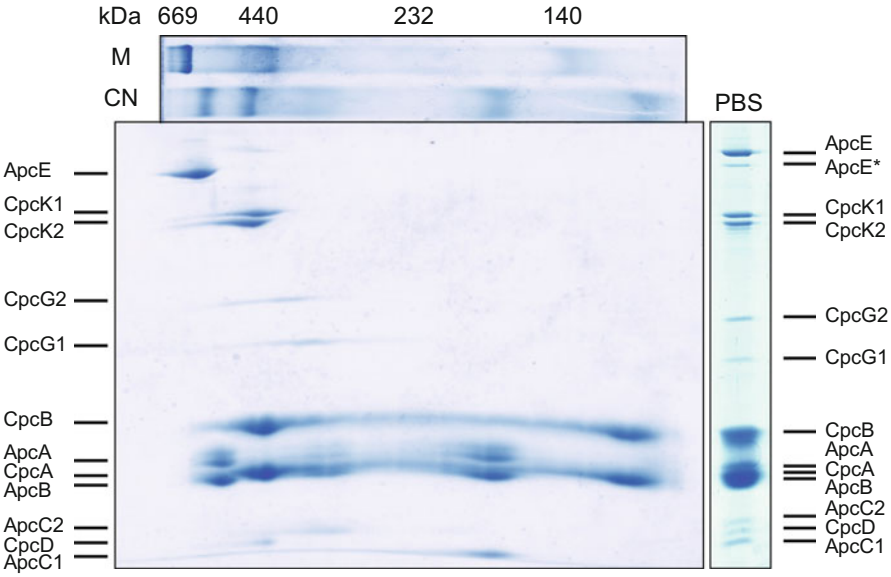

Fig. 10 Colorless native (CN)-PAGE of isolated *Cyanophora* phycobilisomes followed by SDS-PAGE: *upper* horizontal panel (M), high molecular weight marker; *upper* horizontal panel (CN), first dimension (CN-PAGE). *Lower* panel, second dimension (SDS-PAGE). pyrenoids (Meyer and Griffiths 2013) functioning in the carbon-concentrating mechanism (CCM), this coinage emphasized the often-postulated transitional position of glaucophytes between plastids and cyanobacteria. Further, the hypothesis of

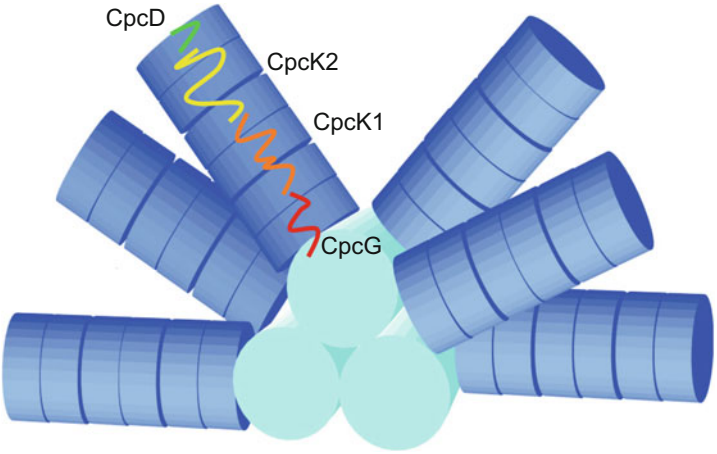

Fig. 12 Complete model of the *Cyanophora* phycobilisome according to Steiner et al. *Blue*, phycocyanin rods; *cyan*, allophycocyanin core; *green*, *yellow*, *orange*, and *red*, linker proteins

Raven (2003) that muroplasts had retained the peptidoglycan wall for osmotic protection since these were the only plastids that had also retained carboxysomes was quite appealing: A carboxysomal CCM (Badger and Price 2003) would lead to a much higher accumulation of bicarbonate in the stroma than a pyrenoidal CCM. However, all attempts to identify genes for carboxysomal shell proteins corresponding to cyanobacterial ccmKLMNO in the *C. paradoxa* genome have failed (Price et al. 2012) as did proteomic studies on isolated muroplast central bodies (Fathinejad et al. 2008). Indeed, it might be problematic to harbor shell protein genes in the nucleus, because they have high affinities to each other and likely self-assemble as carboxysomal prestructures (Kinney et al. 2011), thereby interfering with protein import into muroplasts. On the other hand, evidence was obtained (Table 6; Bhattacharya et al. 2014) for a number of genes (e.g., *LCIB* and *LCIC*) with functions in the pyrenoidal CCM of *Chlamydomonas reinhardtii* (Yamano et al. 2010). LCIB and LCIC were shown to form a hexameric complex (ca. 360 kDa) close to the pyrenoid under light and low [CO_2]. A role for this complex is assumed in trapping of CO_2 that has escaped from the pyrenoid via interaction with the carbonic anhydrase CAH6. Alternatively, Yamano et al. (2010) envisage physical blockage of CO_2 from escaping the pyrenoid (somehow analogous to the function of the carboxysomal shell). Some putative cyanobacterial plastid ancestors – given their filamentous nature (*Lyngbya*) or capability of producing a starch-like reserve carbohydrate (*Cyanothece*) – contain *LCIB* and *LCIC*. These cyanobacteria might use mechanisms of the type discussed above that are superimposed on their carboxysomal CCM. At present, the more recent *Paulinella chromatophora* "plastid" origin (ca. 100 Ma) constitutes the only proven example of "eukaryotic carboxysomes." Here, the necessary genes remain on the genome of the cyanelle (photosynthetic organelle; Nowack et al. 2008), interestingly originating from HGT (Marin et al. 2007). If carboxysomes were transferred to early plastids

[b]CO2-responsive gene; *TP* muroplast transit peptide, containing phenylalanine in the N-terminal region

via endosymbiosis, the separation between carboxysomal and pyrenoidal CCM could have occurred within the phylum Glaucophyta, i.e., *C. paradoxa* and *Glaucocystis nostochinearum* already progressed toward a pyrenoidal CCM, whereas *Gloeochaete wittrockiana* (Fig. 5; Kies 1976) and *Cyanoptyche gloeocystis* (Kies 1989), with their polyhedral microcompartments confined by an electron-dense, shell-like layer (both features missing in the two former species), might have retained the carboxysomal CCM (Fathinejad et al. 2008). Under such a scenario, the *ccmKLMNO* genes would be expected to reside on the muroplast genomes of *G. wittrockiana* and *C. gloeocystis*. The PG wall, though no longer necessary, was retained for unknown reasons in the plastids of *C. paradoxa* and *G. nostochinearum*. Table 6 includes two genes encoding the putative bicarbonate transporter LCIA (Yamano et al. 2015) and several genes with strong sequence similarity to genes for LCIB, LCIC, and LCID from *C. reinhardtii*. Because these are closely related, an exact assignment is difficult. However, whenever the N-termini are intact, unequivocal muroplast presequences were found for these proteins.

A key enzyme of the CCM is carbonic anhydrase (CA), either co-packaged with RuBisCO in cyanobacterial carboxysomes or located in the lumen of thylakoids traversing the pyrenoid of *C. reinhardtii* (Karlsson et al. 1998). The number of CAs can vary among algae, e.g., from 9 in *C. reinhardtii* to 13 in some diatoms (Tachibana et al. 2011). Five CAs from *C. paradoxa* are shown in Table 6. Two of these belong to the gamma-CA family with high sequence similarity to homologs in plants. The other three contain the conserved Zn-binding site (VCGHSHCGAMKG) of (cyano)bacterial beta-CAs. In the case of the putative mitochondrial CAs, high sequence similarities to *C. reinhardtii* CAH4 and CAH5 are observed. The third beta-CA resembles the periplasmic CAH8. A bona fide muroplast CA (e.g., the stromal CAH6 or the lumenal CAH3 of *C. reinhardtii*) is missing from this compilation. In a recent data mining effort among 15 microalgae, Meyer and Griffiths

(2013) revealed two additional bicarbonate transporters in the *Cyanophora* database via sequence similarity to *Chlamydomonas* homologs: the plasma-membrane-localized ABC transporter HLA3 (Yamano et al. 2015) and CCP1 in the plastid envelope. As a consequence, if we assume a pyrenoidal CCM in *C. paradoxa*, the organism must utilize a mechanism different from that in *C. reinhardtii* (Meyer and Griffiths 2013). There is no evidence in *C. paradoxa* of a muroplast microcompartment traversed by thylakoid membranes. A recent high-resolution ultrastructural study of the *C. reinhardtii* cell (Engel et al. 2015) posits that the thylakoid-derived pyrenoid tubules contain several minitubules thought to transport ATP, RubP, etc. across the starch sheath to the RuBisCO in the pyrenoid interior. Because starch is stored in the cytosol of glaucophytes, such a function may not be necessary here. In the diatom *Phaeodactylum tricornutum*, the carbonic anhydrase CA-1 (CO_2 responsive) is co-packaged with pyrenoidal RuBisCO and does not reside in the lumen of the traversing thylakoid (Tachibana et al. 2011). Mass spectrometric analysis of central body proteins from *C. paradoxa* did not reveal a CA-like protein either. The only outcome of these studies (in addition to RuBisCO LSU and SSU) was RuBisCO activase that was also corroborated by Western blotting and assembly studies after in vitro import into isolated muroplasts (Fathinejad et al. 2008). *C. paradoxa* activase, whereas showing high sequence similarity to both cyanobacterial and plant homologs, lacks the C-terminal extension typical for filamentous cyanobacteria but shows the N-terminal extension present in plant homologs only. Taken together, the domain structure of RuBisCO activase from *C. paradoxa* does not support the carboxysome concept either. Several genes listed in Table 6 were shown to be CO_2 responsive in the closely related *C. cuspitata* SAG 45.84 (Kies strain) underlining their postulated role in the CCM (Burey et al. 2007).

Other Metabolic Pathways in Muroplasts

The *C. paradoxa* genome project, in combination with the muroplast proteome (Facchinelli et al. 2013) and some biochemical investigations, allows interesting insights into the metabolism of a primitive plastid in comparison to the abundant data on chloroplast metabolism.

Glycolysis: With respect to glycolysis, significant deviations from the known chloroplast pathways were found: Phosphoglyceromutase and enolase are present in the muroplast stroma in contrast to the situation in chloroplasts, allowing direct production of PEP from photosynthetically generated 3-phosphoglycerate. On the other hand, hexokinase and phosphofructokinase are missing from muroplasts. Fructose-1,6-bisphosphatase and phosphoglucomutase are sufficient to generate glucose-6-phosphate, the metabolite to be exported to the cytosol (see below).

Glucose-6-phosphate dehydrogenase was purified from a *C. paradoxa* muroplast extract (Fester et al. 1996). The 59 kDa protein forms enzymatically active dimers and tetramers. 6-Phosphogluconate dehydrogenase was identified in the stroma

through proteomics. The corresponding gene showed a canonical muroplast STP (Facchinelli et al. 2013). This points toward a muroplast-localized oxidative pentose phosphate pathway.

Isoprenoid lipid biosynthesis: Proteomics yielded very conclusive results concerning isoprenoid metabolism. With one exception, all enzymes of the 1-deoxy-xylulose-5-phosphate/2-C-methylerythritol-4-phosphate (MEP) pathway of isopentenyl diphosphate synthesis were demonstrated in the muroplast stroma (Facchinelli et al. 2013) but none of the mevalonate pathway. Proteomics also corroborated the muroplast localization of other enzymes of the prenyl lipid pathway (Facchinelli et al. 2013) as geranyl-geranyl diphosphate reductase (phytol biosynthesis), geranyl-geranyl diphosphate synthase (CrtE, muroplast encoded), solanesyl diphosphate synthase (PreA, muroplast encoded), and homogentisate solanesyl transferase (plastoquinone biosynthesis). In most of these cases, nucleus-encoded muroplast proteins possess canonical transit sequences (with F replaced by Y or W in a few instances).

Amino acid biosynthesis: As plastids, muroplasts are the main contributors to amino acid biosynthesis. This became apparent from the genome data where muroplast STPs preceded the respective genes and also from the analysis of the muroplast proteome (Facchinelli et al. 2013).

Photooxidative stress management: *Cyanophora paradoxa* is known to prefer low light intensities for growth (Löffelhardt and Bohnert 2001). A recent survey showed that *C. paradoxa* does not use the ascorbate/ascorbate peroxidase system that plays an important role in coping with reactive oxygen species (ROS), which is unparalleled among phototrophs (Wheeler et al. 2015). Furthermore, *C. paradoxa* is devoid of glutathione reductase (Serrano and Löffelhardt 1994). However, *C. paradoxa* contains catalase, glutathione peroxidase, and peroxiredoxins, and its muroplasts harbor the unusual peroxidase symerythrin (Cooley et al. 2011). In glaucophytes, the low levels of ascorbate synthesized by the unusual enzyme gulonolactone oxidase (land plants and green algae use a gulonolactone dehydrogenase) might have a role as enzyme cofactor but neither in the ascorbate/glutathione antioxidative pathway nor in the xanthophyll cycle (Wheeler et al. 2015).

Miscellaneous: The NADP-dependent malate dehydrogenase of *C. paradoxa* was shown not to be responsive to reductive activation (Ocheretina et al. 2000) as red algal enzymes, in contrast to enzymes of the "green" lineage. Accordingly, attempts to demonstrate thioredoxin *m* in *C. paradoxa* were unsuccessful (Dai et al. 1992). A muroplast pyrophosphatase (sPPase I) was isolated from *C. paradoxa* and characterized by N-terminal sequencing and MW determination via MALDI-TOF mass spectrometry (Gómez-García et al. 2006). The monomeric 30 kDa protein is more related to PPases from heterotrophic eukaryotes than to the smaller cyanobacterial enzymes. This also applies to the plastid enzymes from other algae, e.g., *C. reinhardtii*, and from plants. Taken together, this means that early in plastid evolution, the endosymbiont gene was lost and the product of a host cell gene was relocalized to the organelle.

Genome Analysis of Glaucophytes

Glaucophyte genome-wide analyses are relatively scarce when compared to plants and green algae. This is explained by the limited expressed sequence tag (EST) and complete genome data available from these taxa. For many years, the only sources of EST data were from the Pringsheim (Reyes-Prieto et al. 2006) and Kies strains of *Cyanophora paradoxa* and from *Glaucocystis nostochinearum* (http://tbestdb.bcm.umontreal.ca/searches/login.php). The complete plastid genome sequence of *C. paradoxa* (Pringsheim strain; Stirewalt et al. 1995; Loeffelhardt et al. 1997) was also available (see section on the Muroplast Genome; Table 7). Uses of the EST data from *C. paradoxa* included assessment of the divergence position of glaucophytes within Plantae/Archaeplastida (Reyes-Prieto and Bhattacharya 2007a; Deschamps and Moreira 2009) and estimation of the contribution of cyanobacterial genes to the nuclear genome of glaucophytes via EGT (e.g., Timmis et al. 2004; Reyes-Prieto et al. 2006). Bioinformatic analyses suggested that 6–11% of *C. paradoxa* nuclear genes owed their origin to EGT from the endosymbiont (Reyes-Prieto et al. 2006; Qiu et al. 2013a). The *C. paradoxa* plastid genome has been invaluable to many researchers who have used it to infer the phylogenetic history of this organelle, its gene content, and gene order (e.g., Stirewalt et al. 1995; Rodriguez-Ezpeleta et al. 2005; Sato et al. 2005; Janouškovec et al. 2010; Qiu et al. 2013a). A recent biochemical characterization of the *C. paradoxa* plastid proteome that identified a partial list of 586 non-redundant proteins (Facchinelli et al. 2013) demonstrated their complex evolutionary histories. Maximum likelihood analysis of these proteins by Qiu et al. (2013a) showed that 25% were plastid encoded, 12% were derived from EGT candidates encoded in the nucleus, 7% were of non-cyanobacterial (HGT) origin, and the remaining (56%) were derived from the host or were of ambiguous provenance based on analysis of current data. The phylogenetic origins of non-redundant plastid proteins in *C. paradoxa*, *Chlamydomonas reinhardtii* (1,057 proteins), and *Arabidopsis thaliana* (1,660 proteins) are shown in Fig. 13 (Qiu et al. 2013a). More recently, mitochondrial genomic data have been analyzed from seven different glaucophytes and used to test (and validate) Archaeplastida monophyly (Jackson and Reyes-Prieto 2014). These organelle genomes have a highly conserved gene content but show significant variation in gene order across taxa (Jackson and Reyes-Prieto 2014).

Genome data: A significant step forward for the field of glaucophyte genomics came in 2012 with the publication of the draft genome assembly from the *C. paradoxa* Pringsheim strain CCMP329 (SAG 29.80; Price et al. 2012). This work was supported by the United States National Science Foundation and resulted in the generation of 8.3 billion base pairs (Gbp) of Roche 454 and Illumina GAIIx sequence data that were co-assembled with 279 Mbp of random-shear Sanger sequence from this taxon. The resulting assembly comprised 60,119 contigs, totaling 70.2 Mbp. More recent sequencing of this strain using the long-read PacBio platform suggests that the genome size is closer to 120 Mbp based on the initial assembly output. Pulsed-field gel electrophoresis suggests the existence of at least seven chromosomes in *C. paradoxa* with the smallest being less than 3 Mbp in size

Table 7 Muroplast genes from *Cyanophora paradoxa*. Gene nomenclature follows the guidelines for chloroplast genes (Stoebe et al. 1998). Genes marked with an asterisk are not found on any other plastid genome. Genes underlined are absent from the chloroplast genomes of land plants

(Price et al. 2012). Given the initial Sanger/Roche/Illumina and the later PacBio genome data, we posit that the Price et al. (2012) assembly likely captured most of the gene inventory in the gene-rich regions (see below), whereas assembly of the complex (e.g., repeated or with strong nucleotide bias, such as homopolymers) DNA regions was only possible with the PacBio long-read technology. Generation and analysis of a hybrid Illumina/PacBio genome assembly are underway in the Bhattacharya and Andreas P.M. Weber labs. Interestingly, the PacBio results are

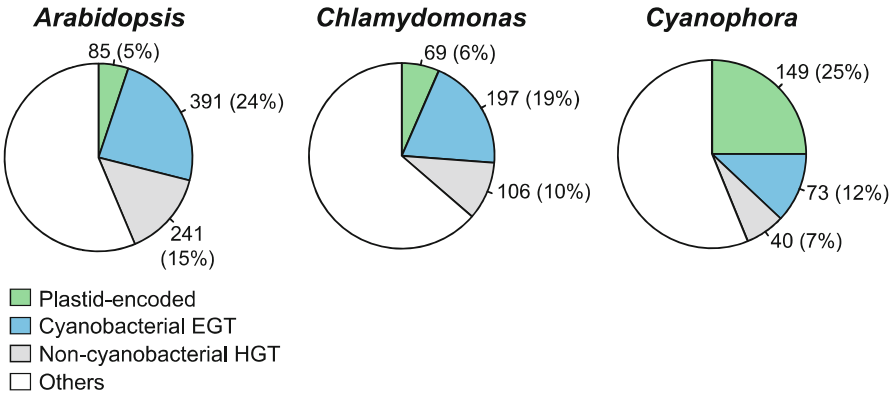

Fig. 13 Results of phylogenetic analysis of single proteins represented as pie charts that show the relative contribution of cyanobacterial and non-cyanobacterial sources to Archaeplastida plastid proteomes (for details, see Qiu et al. 2013a)

more in line with previous fluorescence-activated cell sorting (FACS) work that suggested the haploid genome size in *C. paradoxa* to be ca. 140 Mbp (Löffelhardt et al. 1997).

Consistent with these observations, genome analysis done by Price et al. (2012) demonstrated an unusually high G + C content in *C. paradoxa* (83.8% at third codon positions) that likely explains the highly fragmented, initial assembly. Nonetheless, BLASTN analysis using 3,900 Sanger-derived EST unigenes from the glaucophyte against the draft assembly showed that 99% of the ESTs had hits (at *e*-value ≤1E-10), suggesting that the vast majority of expressed genes were present in these genome data. Given this promising result, 15 Gbp of Illumina mRNA-seq data were used to train ab initio gene predictors to generate 27,921 gene models for downstream analysis (Price et al. 2012). Below we will discuss some of the insights that were gained through analysis of the *C. paradoxa* genome data generated by Price et al. (2012), recognizing that the PacBio results will likely lead to additional novel insights.

Phylogenomic analysis test Archaeplastida monophyly: Given that many multi-gene (i.e., concatenated protein dataset) phylogenies have provided conflicting topologies regarding the monophyly of Archaeplastida in the eukaryote tree of life (e.g., Burki et al. 2007; Baurain et al. 2010; Parfrey et al. 2010; Yabuki et al. 2014; Jackson et al. 2015) and have failed to reach any consensus on this important question, Price et al. (2012) took another approach. Rather than joining proteins, often with uncertain histories into a single dataset, they analyzed each protein separately using maximum likelihood (ML) phylogeny reconstruction and tabulated the overall signal for Archaeplastida monophyly. In their analysis, a total of 4,628 proteins had significant BLASTP hits (*e*-value ≤1E-10) to sequences in a comprehensive local database that were used for comparative analysis (e.g., Moustafa et al. 2009; Chan et al. 2011). Using an automated approach (Chan et al. 2011), they generated 4445 ML trees for *C. paradoxa* proteins that had significant database hits.

Only trees containing ≥3 phyla were considered and a minimum number of terminal taxa (*N*) that ranged progressively from 4 to 40 (Fig. 14a). Using this approach they found that >60% of all trees supported (at bootstrap value ≥90%) a sister-group relationship between glaucophytes and red and/or green algae. The glaucophytes were most often positioned as sister to Viridiplantae in trees that excluded non-Archaeplastida algae, a result that was found even though a large number of trees favored glaucophyte-red-green (Archaeplastida) monophyly (44, 40, 32, 18, and 16 trees at $N = 4$, 10, 20, 30, and 40, respectively), and they had substantial red algal genome data in the database. Most of the trees showed *C. paradoxa* to be monophyletic with other Archaeplastida in a clade ("shared") that also included non-Archaeplastida phyla (GlR/GlVi/GlRVi in Fig. 14). When they sorted the phylogenomic output using the red or green algae as the query to test Archaeplastida monophyly, these results also identified Archaeplastida as the most frequently recovered clade. Expectedly, red and green algae showed far more gene sharing than glaucophytes because they, unlike glaucophytes, are involved in secondary endosymbioses (Harper and Keeling 2003; Moustafa et al. 2009; Baurain et al. 2010; Chan et al. 2011; Bhattacharya et al. 2013). These results demonstrate a highly complex phylogenetic history for glaucophyte and algal genome data in general, showing that EGT and HGT have moved genes between disparate lineages leaving a highly reticulate signal within their genomes. Regardless, the single protein trees overall strongly support a single origin of Archaeplastida and likely a single primary plastid endosymbiosis in their common ancestor (Fig. 14; Price et al. 2012). Future genome projects that add more glaucophytes and other poorly sampled Archaeplastida lineages (e.g., prasinophytes) to the analysis are needed to validate the hypothesis of Archaeplastida monophyly.

Given the extent of gene sharing among algae, Price et al. (2012) investigated the "footprint" of non-cyanobacterial, prokaryotic HGT in the nuclear genomes of Archaeplastida. For this analysis, they constructed a database that included sequences from NCBI Refseq, *C. paradoxa* and the red algae *Calliarthron tuberculosum* and *Porphyridium purpureum* (Bhattacharya et al. 2013). These data were then queried using each *C. paradoxa*, *C. tuberculosum*, and *P. purpureum* protein, as well as those derived from two Viridiplantae (i.e., *Chlamydomonas reinhardtii* and *Arabidopsis thaliana*). The top five bacterial hits (BLASTP *e*-value ≤1E-10) were retained for each Archaeplastida query sequence and used as input for an automated phylogenetic tree-building pipeline (for details of procedure, see Price et al. 2012, supplement). Inspection of the maximum likelihood-generated trees turned up 444 non-cyanobacterial gene families shared by prokaryotes and Archaeplastida. Of these, 15 were present in all three Archaeplastida phyla. One such ancient HGT resulted in the transfer of a thiamine pyrophosphate-dependent pyruvate decarboxylase family protein involved in alcohol fermentation. This analysis turned up 60 other genes that are present in only two of the three phyla (i.e., 24, 10, and 26 genes in Glaucophyta-Viridiplantae, Glaucophyta-Rhodophyta, and Rhodophyta-Viridiplantae, respectively). More recent work has shown that HGT plays a key role in adaptation of algae to their environment and the impacts of this process will likely become more widely appreciated as additional complete algal

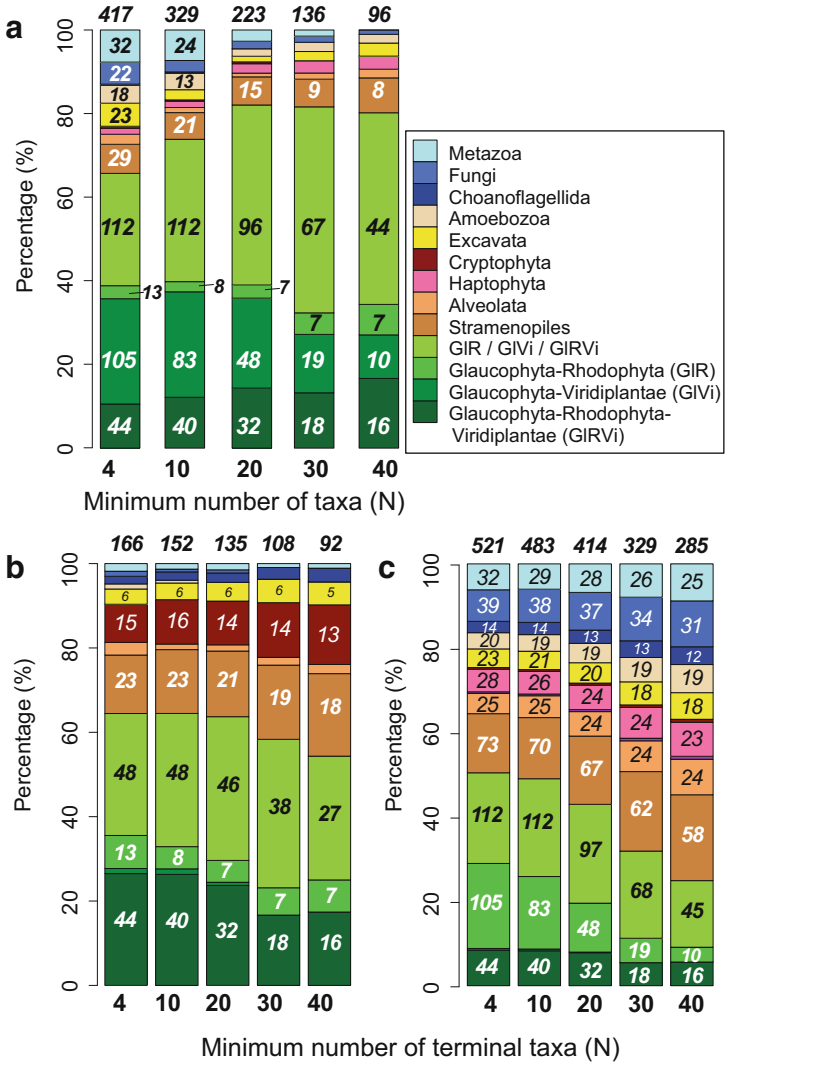

Fig. 14 Maximum likelihood analysis of single proteins derived from the *C. paradoxa* genome assembly (for details, see Price et al. 2012). **a** Percentage of single protein maximum likelihood trees (raw numbers shown in the bars) at bootstrap cutoff >90% that support the monophyly of glaucophytes solely with other Archaeplastida or in combination with non-Archaeplastida taxa that interrupt this clade. These latter groups of trees are explained by *red/green* algal EGT into the nuclear genome of chromalveolates (e.g., diatoms, haptophytes) and euglenids, respectively. For each of these algal lineages, the set of trees with different numbers of taxa (N) ≥4, ≥10, ≥20, ≥30, and ≥40 and distinct phyla ≥3 in a tree are shown. The Archaeplastida-only groups are Glaucophyta-Rhodophyta (GlR), Glaucophyta-Viridiplantae (GlVi), and Glaucophyta-Rhodophyta-Viridiplantae (GlRVi). Trees with evidence of EGT are shown as the single group, GlR/GlVi/GlRVi. **b** The same analysis done with *red* algae as the query to search for support for Archaeplastida monophyly. **c** The same analysis done with *green* algae as the query to search for support for Archaeplastida monophyly

genomes are analyzed (Qiu et al. 2013b; Schönknecht et al. 2013; Foflonker et al. 2015).

Evolution of the plastid translocon and metabolite transport: Important innovations that have been the subject of much study in algae and plants are the evolution of the protein import system for the plastid and the emergence of metabolic connections between the captured cyanobacterial endosymbiont and the host cell. A fundamental outcome of the cyanobacterium-to-plastid evolutionary transition in the Archaeplastida primary endosymbiosis was the establishment of protein translocons for protein targeting into the organelle (e.g., Gross and Bhattacharya 2008, 2009; Reumann et al. 2005; Sommer and Schleiff 2014). Components of the translocons at the outer and inner envelope membranes of chloroplasts (Toc and Tic, respectively) were known in other Archaeplastida and in chromalveolates (McFadden and van Dooren, 2004). The existence of an equivalent protein import system in *C. paradoxa* was suggested by immunological detection of epitopes in this alga using plant Toc75 and Tic110 antibodies and heterologous protein import assays (see section on Protein Import into Muroplasts; Steiner et al. 2005a; Yusa et al. 2008). Analysis of the genome of *C. paradoxa* turned up homologs of Toc75 and Tic110 that are OEM (outer envelope membrane) and IEM (inner envelope membrane) protein conducting channels, respectively, two Toc34-like receptors, as well as homologs of the plastid Hsp70 and Hsp93 chaperones and stromal processing peptidase (Price et al. 2012). These are likely to have formed the primordial protein translocation system in the Archaeplastida ancestor (Gross and Bhattacharya 2008, 2009). In summary, analysis of *C. paradoxa* genome data revealed the presence of the conserved core of translocon subunits derived from the cyanobacterial endosymbiont (i.e., Toc75, Tic20, Tic22), suggesting that the Toc/Tic system was likely to have been in place in the Archaeplastida common ancestor. Toc75 of glaucophytes and likely also of rhodophytes is closer than the homolog of Viridiplantae to the ancestral Omp85 of cyanobacteria in recognizing phenylalanine in the N-terminal part of the transit peptides (see also section on Protein Import into Muroplasts; Wunder et al. 2007). A dual function as receptor and pore is assumed (Steiner and Löffelhardt 2005). This phenylalanine requirement is no longer found in chloroplast import: Toc75 in Chlorophyta and Streptophyta has only retained the pore function, whereas the receptor function is taken over by a small family of proteins, e.g., Toc159. Likely, this went along with the need for import of certain abundant proteins (RuBisCO SSU, LHCPII). In addition, the Tic translocon appears to be more elaborate in land plants: a 1 Mda complex contains Tic20 (pore?), Tic56, Tic100, and Tic214 (Nakai 2015).

Another landmark trait linked to plastid establishment is the coordination of carbon metabolism between the host and plastid that relies on sugar-phosphate transporters. Previous work had shown that plastid-targeted sugar transporters evolved from existing host endomembrane nucleotide sugar transporters (NSTs) through gene duplication, divergence, and retargeting to the photosynthetic organelle (Weber et al. 2006; Colleoni et al. 2010). Analysis of the *C. paradoxa* genome turned up a surprising result in this respect. Price et al. (2012) found that although six endomembrane-type NST genes existed in *C. paradoxa*, there were no genes for

plastid-targeted phosphate translocator (PT) proteins. The search for the missing genes turned up two candidates that encode homologs of bacterial UhpC-type hexose-phosphate transporters. These genes were also found in other algal members of the Archaeplastida, but lost in plants. Both *C. paradoxa* UhpC homologs encode an N-terminal extension that could serve as a plastid targeting sequence. Surprisingly, both of these UhpC genes were derived via HGT in the Archaeplastida ancestor from parasites related to *Chlamydiae* and *Legionella* (Price et al. 2012). Support for the absence of typical NST-derived sugar transporters in the plastid of *C. paradoxa* was found in the analysis of the plastid permeome from this species. Using YFP-fusion constructs in *Nicotiana benthamiana*, Facchinelli et al. (2013) validated the capacity of the UhpC transit peptide to target to the chloroplast inner membrane in *N. benthamiana*, as well as the localization of the complete protein to this site for both *Chlamydiae*-derived transporters in *C. paradoxa*, as predicted by Price et al. (2012). Subsequent work done by Karkar et al. (2015), using the same approach, showed that the UhpC homologs in the red algae *Galdieria sulphuraria* and *C. merolae* are also targeted to the chloroplast inner membrane in *N. benthamiana*. These results demonstrate that the diversification of the PT gene family occurred in the red-green algal ancestor, with the glaucophytes relying on UhpC, a gene that is also retained by algal members of the Rhodophyta and Viridiplantae. Whether these data prove an early divergence of glaucophytes within Archaeplastida is unclear because PT gene loss in this lineage could also explain the current distribution. Regardless, these results bring to a close an intriguing, open question in Archaeplastida evolution and suggest that UhpC could have been the primordial sugar transporter in this supergroup (for details, see Karkar et al. 2015).

Small RNAs in Cyanophora paradoxa: RNAi (RNA interference) is a strategy found among eukaryotes to protect their genomes from the spread of self-replicating genetic entities such as transposable elements and viruses (e.g., Mallory and Vaucheret 2010). This pathway relies on the production of small RNAs (sRNAs) from double-stranded RNA (dsRNA). The initial RNAi signal may be amplified by the generation of multiple secondary sRNAs from a targeted mRNA. This reaction is catalyzed by RNA-dependent RNA polymerases (RdRPs), a phenomenon known as transitivity (Calo et al. 2012) that is particularly important in plants to limit the spread of viruses (Chen et al. 2010). The RNAi process in which sRNAs formed from perfect dsRNAs acting in *cis* by pairing to their cognate producing transcripts is referred to as the small interfering RNA (siRNA) pathway (Obbard et al. 2009), microRNAs (miRNAs) also represent a class of sRNAs widespread in eukaryote genomes that probably evolved from the ancestral siRNA pathway (Piriyapongsa and Jordan 2008). Gross et al. (2013) generated extensive sRNA data from *C. paradoxa* to characterize their genome-wide distribution and to gain insights into their potential functions. Given the monophyly of glaucophytes and Viridiplantae within the Archaeplastida, it was postulated that *C. paradoxa* could represent an ancestral form of the highly developed RNAi system found in plants such as *Arabidopsis thaliana*.

To establish the presence of a putative RNAi pathway in *C. paradoxa*, BLASTP analysis of the glaucophyte genome was done using, as queries, homologs of the

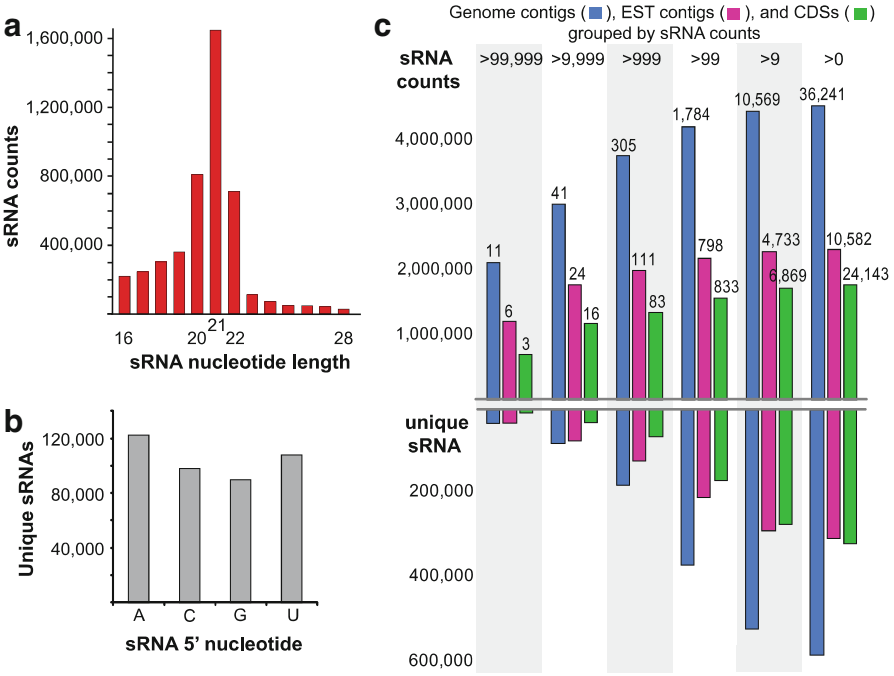

Fig. 15 Analysis of sRNAs from *C. paradoxa*. (**a**) Size distribution of redundant sRNAs in *C. paradoxa* showing the predominance of the 21 nt length class. (**b**) Composition of the 5′ nucleotide of unique sRNAs in *C. paradoxa*. (**c**) The results of mapping redundant (above the x-axis) and unique (below the x-axis) sRNAs to genomic contigs, EST contigs, and CDSs from *C. paradoxa*. The numbers on the top of the colored bars correspond to the number of genomic contigs (*blue*), EST contigs (magenta), and CDSs (*green*) that are associated with the sRNA counts shown at the *top* of the panel

A. thaliana Dicer and Argonaut proteins. These sequences were found as were several putative homologs of *A. thaliana* RdRP. Bioinformatic analysis of 4,739,151 sRNA reads derived from four *C. paradoxa* cDNA libraries showed that sequences had a predominant size of 21 nt (Fig. 15a) with overrepresentation of adenine and uracil in the first nucleotide (Fig. 15b) (Gross et al. 2013). Because *C. paradoxa* sRNAs mapped to over 70% of the EST contigs and to 75% of the predicted CDSs (Fig. 15c), Gross et al. (2013) concluded that sRNA production in this species was primarily associated with mRNA (exonic) sequences. A possible explanation for the significant levels that were found of transcript-derived sRNAs is through the production of secondary siRNA by RdRPs (present in the glaucophyte) during amplificatory cascades of the RNAi signal (for details, see Gross et al. 2013). This intriguing finding has however not been validated due to the lack of genetic tools in *C. paradoxa*. Given the postulated transitivity in *C. paradoxa* and its known presence in the fungus *Mucor circinelloides* (Calo et al. 2012), it is likely that a complex RNAi system was present in the ancestor of all eukaryotes.

In summary, nuclear genome data from glaucophytes have provided a myriad of important insights into the evolution of Archaeplastida. However, much of what has been learned is gleaned from a single draft assembly and several EST databases. As the *C. paradoxa* genome assembly improves, it will provide a valuable reference source for other glaucophyte complete genome projects. These are underway in different labs and become increasingly more tenable as sequencing costs continue to fall and better, long-read technologies are developed. Although we have touched upon some key aspects of glaucophyte genome evolution, we did not address several others that are rapidly advancing. One of these is the work led by the lab of J. Clark Lagarias on phytochrome function and evolution in algae. Analysis of glaucophyte phytochromes demonstrates that *C. paradoxa* (CparGPS1) has an unusual blue/far-red photocycle, whereas *Gloeochaete wittrockiana* (GwitGPS1) has a red/blue photocycle (Rockwell et al. 2014). This is in stark contrast to classical plant phytochromes that are associated with red/far-red photoreception that regulates gene expression for developmental pathways and the shade avoidance response (Rockwell et al. 2006). The surprising diversity of phytochromes in algae (Duanmu et al. 2014; Anders and Essen 2015), and in particular in glaucophytes, indicates that much still needs to be learned about how algae tune their light response to ambient conditions. In this regard, the sequence of a genomic clone of cyanophoropsin, a highly conserved homolog of fungal and bacterial rhodopsins, was described by Frassanito et al. (2010). This trait seems to be unrelated to the known photophobic response of *C. paradoxa* (Häder 1985) because uniform immuno-decoration of the muroplast envelope was achieved using specific antisera directed against an N-terminal recombinant peptide. Therefore, Frassanito et al. (2010) suggest the role of a light-driven proton pump, possibly in conjunction with bicarbonate import into the muroplasts (see section on CCM). Several, but not all, amino acid positions thought to be essential for this function are conserved. Interestingly, corresponding ESTs were overrepresented in low [CO_2] cDNA libraries, indicating that the cyanophoropsin gene is CO_2 responsive (Burey et al. 2007). In addition, a second form of cyanophoropsin was purified as a recombinant protein (Frassanito et al. 2013). Opsins localize to the muroplast envelope; the corresponding genes lack both N-terminal phenylalanine and a canonical stroma-targeting peptide as revealed by terminal amine labeling of substrates (TAILS; Köhler et al. 2015). It is therefore clear that glaucophyte genomes will provide exciting and novel insights into the broader story of algal evolution and help us understand how these taxa thrive in highly variable environments.

The 135.6 kb Muroplast Genome of *Cyanophora paradoxa* SAG 29.80

The list of genes of the completely sequenced muroplast genome of *C. paradoxa* (Stirewalt et al. 1995; Löffelhardt et al. 1997), given in Table 7, contains more than 60 genes that are nuclear encoded or missing in land plants. This gene content is typical for primordial plastids, i.e., those from algae devoid of chlorophyll *b*. The 192 muroplast genes rank between the 174 genes present on the 120 kb plastome

from the diatom, *Odontella sinensis*, and the 251 genes found on the 191 kb plastome from the red alga *Porphyra purpurea* (Reith 1995). With some exceptions, e.g., the *ndh* genes and *infA* (missing from all algal plastomes investigated thus far), *atpI*, or *accD*, the muroplast genome contains the standard set of chloroplast-encoded genes. In addition, the muroplast genome encodes many more ribosomal proteins, several enzymes involved in anabolic pathways other than photosynthesis, chaperones, (putative) transcription factors, and components of ABC transporters and the Sec preprotein translocase (Table 7). The most conspicuous feature of the gross organization of the muroplast genome is the 11.3 kb inverted repeat (IR), which corresponds to about half the size of land plant chloroplast IRs. Another obvious feature is the small intergenic spacer regions between muroplast genes. In a few cases (*orf299/orf244*, *ycf16/ycf24*, *atpD/atpF*, *psbD/psbC*) adjacent genes have been found to overlap by 3–16 bp. Moreover, only few noncoding regions that extend over several hundred bp are observed. Just one single intron has been identified: the 232 bp group I intron in the anticodon loop of $trnL^{UAA}$. These three features explain why muroplasts encodes around 50 genes more than land plant chloroplasts most of which even have slightly larger genomes. A restriction map of muroplast DNA from *C. cuspitata* (Kies-isolate; SAG 46.84) showed significant differences in size (about 10 kbp) and restriction pattern. However, the overall sequence identity to the Pringsheim isolate (SAG 29.80) was above 85% and 18 protein gene loci and the rDNA regions appeared to be conserved (Löffelhardt et al. 1997).

RNA genes: About half of the IR regions are occupied by the two rDNA units. The rDNA spacer is small, as is typical for chlorophyll *b*-less algae, and harbors *trnI* and *trnA* as in most plastids and prokaryotes (Löffelhardt et al. 1997). The *rnpB* gene, also present on the *P. purpurea* plastome, specifies the essential RNA component of RNaseP, a ribonucleoprotein responsible for 5′-processing of plastid tRNAs. This marks another distinction between primitive plastids and chloroplasts. In land plant chloroplasts, the enzyme activity is protein based only, whereas in *C. paradoxa* muroplasts an RNA component with strong similarity to bacterial counterparts is present – the protein component, if any, has not been found yet. In contrast to red algal RnpB, an RNA-only activity (as shown for bacteria) has been demonstrated for the muroplast RNA (Li et al. 2007). Addition of RnpA protein from *E. coli* considerably enhanced the activity, indicating a certain conformational instability of muroplast RnpB. A tmRNA combining properties of tRNAs and mRNAs that ameliorates problems arising from stalled ribosomes was also found to be encoded by a muroplast gene and shown to be processed by RNaseP (Gimple and Schön 2001). This is again typical for primitive organelles whose tmRNAs are examples of reductive evolution compared to their bacterial counterparts (de Novoa and Williams 2004). An RNA component of the algal plastid SRP, encoded on all sequenced rhodoplast genomes, could not be detected on muroplast DNA.

Muroplast gene expression: The codon bias of muroplast genes, likely a selection for translation efficiency, is more pronounced than that of other algae or land plants (Morton 1998). Putative promoter motifs can often be observed that are similar in both sequence and spacing to the canonical sequences from *E. coli* and other

eubacteria. Three muroplast ORFs (*ycf27*, *ycf29*, and *ycf30*), that are conserved among primitive plastid genomes, show significant sequence similarity to prokaryotic transcription regulatory factors of the OmpR and LysP classes. The occurrence of these putative regulators suggests that some transcriptional regulation occurs in muroplasts. *Ycf27* homologous response regulator genes (*rpaB*) appear to be confined to phycobiliprotein-containing organisms. Many genes show short poly-purine stretches complementary to the 3′ end of the cyanelle 16S rRNA (−CCUCCUUU-3′OH) at a distance of 7–12 bases upstream of the initiation codon. Typical ribosome binding sites (Shine-Dalgarno sequences) are AAGG, AGGA, GGAG, and GAGG. The gene arrangements observed suggest a predominance of polycistronic transcripts as reported for chloroplasts (e.g., the large ribosomal protein gene cluster) and cyanobacteria (e.g., phycobiliprotein gene clusters) which could be proven in several cases. Processing of the primary transcripts to smaller mRNAs seems to be rather common (Löffelhardt et al. 1997). The widespread distribution of a specific gene cluster (5′-*rpoB-rpoC1-rpoC2-rps2-atpH-atpG-atpF-atpD-atpA*-3′) strongly supports the hypothesis of a common origin of all plastid types. Three transcription units (*rpoBC1C2*, *rps2-tsf*, and *atpIHFGDAC*) that are widely separated on cyanobacterial genomes seem to have been fused together after the endosymbiotic event. This cluster is found with some variation in gene content, but never in gene order, in muroplasts and rhodoplasts as well as in land plant chloroplasts. The existence of this "diagnostic" cluster in plastids of different evolutionary levels can only be explained when a single primary endosymbiotic event is assumed (Kowallik 1994; Reith 1995; Löffelhardt 2014). In *O. sinensis*, this cluster is bipartite, and it is completely disintegrated in *Chlamydomonas reinhardtii*, which shows that there is no particular selection pressure to maintain or to reach this kind of gene arrangement.

A signature of primitive plastids devoid of chlorophyll *b* is that both subunits of RuBisCO are plastome encoded as first shown for *C. paradoxa* (Heinhorst and Shively 1983) and cotranscribed (Starnes et al. 1985). Interestingly, the *rbcLS* and *atpBE* genes are adjacent and divergently transcribed in muroplasts and land plant chloroplasts.

There are a few cases where the muroplast genome contains cyanobacterial genes and transcription units that are absent from the *P. purpurea* rhodoplast genome in spite of the 30% surplus in size and gene content of the latter. One of them is *groES-groEL*: the chaperonin-10 homolog is nucleus encoded in the red alga. Other examples are *crtE* (specifying geranyl-geranyl pyrophosphate synthase), *hemA* (glutamyl-tRNA reductase), and *orf244-orf299* encoding two components of an ABC transporter, likely for manganese, based on the significant sequence similarity to the cyanobacterial *mntA* and *mntB* genes (Bartsevich and Pakrasi 1995). The *orf333* upstream from muroplast *psbE* is found in this position in cyanobacteria, too, but is absent from all other plastid genomes. ORF333 is the product of a nuclear gene (*hcf136*) in *Arabidopsis thaliana* and is absolutely required for assembly/stability of functional PSII units (Meurer et al. 1998). A special case is *orf180* found only on muroplast DNA (in the *petA-psaM* intergenic region) and on the genome of the peculiar cyanobacterium, *Gloeobacter violaceus*. The gene product, symerythrin,

belongs to the ferritin-like superfamily (FLSF, Cooley et al. 2011). While its in vivo functions are still unknown, the recombinant protein displays oxidase and peroxidase activity. Other members of the FLSF (e.g., the rubrerythrins) have six or seven ligands to the diiron metallocenter, whereas symerythrin has eight ligands. Other unique features comprise the high internal symmetry of the crystal structure and the spontaneously formed carbon-carbon cross-link between a valine and a phenylalanine side chain. This led the authors to assume an ancestral role for this fold in the evolution of FLSF (Cooley et al. 2011). Recently, the muroplast DNA of *G. nostochinearum* was sequenced (B.F. Lang and G. Burger, unpublished) and was found to resemble that of *C. paradoxa* both in size and gene outfit. Interestingly, *orf180* was also detected, almost identical in sequence to the *Cyanophora* counterpart. In summary, such features of the plastome lend support to the often claimed "living fossil" status of glaucophytes, whereas the mosaic structure of the gene-rich nuclear genome of *Cyanophora* rather seems to contradict this view (Price et al. 2012).

Glaucophyte Mitochondrial Genomes

The complete mitochondrial DNAs (mtDNAs) of *C. paradoxa* (51.6 kbp) and *G. nostochinearum* (34.1 kbp) have been sequenced (Price et al. 2012). Glaucophyte mtDNAs do not stand out as particularly large or gene rich. Repetitive regions and larger intergenic distances in the *Cyanophora* metagenome account for the size difference. They encode the basic set of genes typical for animals and fungi, plus those characteristic of many protists and plants (i.e., close to a dozen coding for ribosomal proteins, a few extra subunits of the NDH and SDH complexes, and 5S rRNA). Recently, the mtDNA sequences of *Gloeochaete wittrockiana* (36 kbp) and *Cyanoptyche gloeocystis* (33.2 kbp) were published (Jackson and Reyes-Prieto 2014) with coding capacities strongly resembling those of the other two glaucophytes. Red and green algae share mtDNA-encoded TatC, a protein translocase component (see section on "Conservative Sorting"), and *ccm* genes specifying ABC transporters involved in cytochrome *c* biogenesis (Verissimo and Daldal 2014). Both these gene classes are absent from glaucophyte mtDNAs. In turn, green and glaucophyte algae share *rpl2*, *nad7*, and *nad9*, which are not present in red algal mtDNAs. Finally, glaucophytes possess a mitochondrion-encoded *nad11* that was lost by the two other groups. In conclusion, there is nothing at the level of mitochondrial gene complement that would specifically unite two of the three lineages.

Despite earlier claims likely caused by bacterial contaminants (Kiefel et al. 2004), no genes for mitochondrial division proteins of prokaryotic origin were found on the *C. paradoxa* genome. This is paralleled in green algae and plants, whereas mtMinD, mtMinE, and mtFtsZ were reported for rhodophytes and chromophytes (Leger et al. 2015). There is a single gene specifying (muroplast-targeted) TatC in the genome of *C. paradoxa* indicating the absence of the mitochondrial Tat pathway as, e.g., in land plants, where the AAA-ATPase Bcs1 assists mtRieske Fe-S protein in IM translocation and assembly into the cytochrome bc_1 complex (Wagener et al. 2011).

Interestingly, a contig for a Bcs1 homolog with a predicted mitochondrial localization was detected in the *Cyanophora* genome database (J.M. Steiner, unpublished). This would mean an advanced aspect of *Cyanophora* mitochondria, as primordial mitochondria (e.g., of jakobids) retained the proteobacteria-derived Tat pathway (Wagener et al. 2011).

Metabolic Pathways in the Cytosol of *Cyanophora paradoxa*

Starch metabolism: Early diverging phototrophic eukaryotes seem to play an important role in the conversion of cyanobacterial glycogen into the starch of green algae and land plants during evolution (Deschamps et al. 2008). Reserve carbohydrate granules have long been known to reside in the cytosol of glaucophytes (Kies 1992) and also of rhodophytes and algae derived through red algal secondary endosymbiosis. *C. paradoxa* starch showed a (high) amylose and amylopectin content with chain length distributions and crystalline organization similar to green algae and land plants that use ADP-glucose as the activated monomer for starch synthesis and temporary storage in the chloroplasts (Plancke et al. 2008). However, several starch synthase activities were found in *C. paradoxa* utilizing UDP-glucose, this time in analogy to rhodophytes that also synthesize their (more amylopectin-related) floridean starch in the cytosol. In addition, a multimeric isoamylase complex and multiple starch phosphorylases were demonstrated and of isoamylase: There is a correlation between the presence of starch and the debranching activity of isoamylase; those alpha-1,6-branches that impede the attainment of a crystalline structure are removed (Cenci et al. 2014). These results were obtained at the zymogram level and in some cases also at the gene level (Plancke et al. 2008). Transcription of a granule-bound starch synthase (responsible for amylose formation) was shown to be upregulated upon shift to low [CO_2] (Burey et al. 2007). Furthermore, the cytosolic transglucosidase DPE2 (disproportionating enzyme 2), transferring one glucose moiety from maltose (resulting from starch degradation by beta-amylase) to a cytosolic heteroglucan, could be demonstrated on *C. paradoxa* zymograms (Fettke et al. 2009). The *Cyanophora* Genome Project (http://dblab.rutgers.edu/cyanophora/home.php) (Price et al. 2012) allowed the identification of numerous putative carbohydrate metabolism enzymes using the Carbohydrate-Active enZymes (CAZy) database (Cantarel et al. 2009): about 84 glycoside hydrolases (GHs) and 128 glycosyl transferases (GTs), significantly more than in the green microalga *Ostreococcus lucimarinus* or the extremophilic red alga *Cyanidioschyzon merolae*, but less than in land plants. Many *C. paradoxa* CAZymes are involved in starch metabolism. Synthesis of the polysaccharide within Viridiplantae plastids relies on ADP-glucose-dependent enzymes of the GT5 family associated with glycogen synthesis in bacteria. The major *C. paradoxa* enzyme is phylogenetically related to the UDP-glucose-specific enzyme of heterotrophic eukaryotes (Cantarel et al. 2009) and has been partially purified from this alga (Plancke et al. 2008). This suggests the absence of ADP-glucose pyrophosphorylase in *C. paradoxa*. Surprisingly, another gene was found in the glaucophyte genome whose product is related to the

SSIII-SSIV (GT5) type of starch synthases in Viridiplantae. This gene is phylogenetically related to glucan synthases in chlamydiae, cyanobacteria, and some proteobacteria and is hypothesized to have played a key role in linking the biochemistry of the host and the endosymbiont. The SSIII-SSIV enzyme uses ADP-glucose in bacteria and land plants, suggesting that *C. paradoxa* or, rather, the common ancestor of Viridiplantae and glaucophytes may have used both types of nucleotide sugars for starch synthesis at the onset of the endosymbiosis. Cytosolic ADP-glucose is thought to arise from the cyanobacterial endosymbiont at that time via a sugar nucleotide transporter of host origin (Weber et al. 2006). A third player is thought to have contributed to this merging of the reserve carbohydrate synthesis pathways of host cell and endosymbiont: Chlamydiae, known for their intracellular lifestyle, might have supplied crucial enzymes and transporters to the cytosol and the endosymbiont/phagosome membranes during an earlier long-term, but transitory, infection. This "ménage a trois" could have been instrumental for the transition from glycogen of the heterotrophic host to starch of the eukaryotic phototroph (Ball et al. 2013): SSIII-SSIV (GlgA), isoamylase (presumably after gene duplication and some change in function of the bacterial direct debranching enzyme GlgX), and (at a later stage) the glucose-6-phosphate transporter UhpC likely represent the contributions (via HGT) from chlamydiae. Granule-bound starch synthase is of cyanobacterial origin (EGT), whereas the other enzymes stem from the metabolic repertoire of the host cell. New developments necessitated due to the glycogen-starch transition are glucan, water dikinase (GWD) and phosphoglucan, water dikinase (PWD), genes for which are also found on the *Cyanophora* genome. Degradation of the quasicrystalline starch granules by beta-amylases and phosphorylases is only possible after previous action of GWD and PWD (Cenci et al. 2014). Readers should note that the impact of *Chlamydiales* on Archaeplastida evolution and the validity of the ménage a trois hypothesis are considered controversial by some parties (e.g., Dagan et al. 2013; Deschamps 2014; Domman et al. 2015). More recent biochemical, phylogenetic, and genomic data however provide strong support for this model of Archaeplastida primary plastid establishment (see Ball et al. 2016a, b; Cenci et al. 2017; Gehre et al. 2016).

Biosynthesis of long-chain fatty acids and isoprenoids: De novo biosynthesis of fatty acids is compartmentalized in muroplasts as in plant chloroplasts. Elongation beyond C_{16} occurs in the cytosol with acetyl coenzyme A provided by the action of ATP citrate lyase (ACL). The long-assumed plastid localization of ACL was falsified for *C. paradoxa*, and, for the first time, a heterodimeric structure as in fungi and the prokaryote *Chlorobium tepidum* was proposed (Ma et al. 2001). This now applies for all plants as opposed to the large monomer observed in metazoa. cDNA and genomic sequencing of the gene for the catalytic subunit provided information about intron structure of nuclear genes: introns are numerous, in the size range of 53–65bp, with conserved border and (putative) branch point nucleotides (Ma et al. 2001; Bhattacharya and Weber 1997). The regulatory subunit is also present as evidenced by ESTs (http://tbestdb.bcm.umontreal.ca/searches/login.php).

The mevalonate pathway (missing in green algae), also dependent on acetyl coenzyme A provided by ACL, seems to be restricted to the cytosol of

C. paradoxa as shown by amplification of four selected genes (Grauvogel and Petersen 2007) and was confirmed later through the genome project.

Anaerobic Energy Metabolism

C. paradoxa was long considered an obligatory phototroph, and attempts to grow it on carbon sources as glucose or acetate were unsuccessful (Trench 1982). Therefore, it came as a surprise that the genome project revealed the potential for various fermentative metabolic pathways (Price et al. 2012). The respective gene repertoire is almost as extensive as that of *C. reinhardtii*, the best known model for this trait among green algae, and even exceeds that of picochlorophyta, whereas such genes are rare in red algae (Atteia et al. 2013). It remains to be seen if the corresponding enzyme activities, e.g., acetate:succinate CoA-transferase, hydrogenase (and maturation factors), pyruvate:formate lyase (and activating enzyme), and pyruvate: $NADP^+$ oxidoreductase, can be demonstrated in the appropriate compartments of the *Cyanophora* cell. Cytosol, plastids, and mitochondria are known to be involved in the anaerobic energy metabolism of algae (Atteia et al. 2013). The complex fermentative capabilities conserved between the distant relatives *C. paradoxa* and *C. reinhardtii* likely represent an evolutionarily advantageous combination of anoxic enzymes from the eukaryotic host and the cyanobacterial endosymbiont (Price et al. 2012).

Evolutionary History

No fossil remnants of glaucophytes are known, but their origin among the Archaeplastida is thought to date back to the Mesoproterozoic/Neoproterozoic boundary as that of rhodophytes (Butterfield 2000). Apart from the common possession of multilayered structures in members of the three algal groups mentioned, glaucophytes differ from prasinophycean green algae (flagella with scales, pellicular lacunae absent, intraplastidial starch), green algae (different kinetids and flagella movement, pellicular lacunae absent, intraplastidial starch), and euglenids (different pellicular structure, different type of mitosis, paramylon instead of starch as reserve polyglycan).

Phylogenetic Relationships

The phylum Glaucophyta as one of the three groups containing primary plastids contains all genera described by Kies (1992) based on morphological criteria (Table 2) and the presence of muroplasts. A concatenated phylogenetic analysis of plastid-encoded genes placed *C. paradoxa* and thus the glaucophytes on the first branch after the single primary endosymbiotic event (Martin et al. 1998; Rodríguez-Ezpeleta et al. 2005). This was corroborated by concatenated nuclear genes

(Rodríguez-Ezpeleta et al. 2005; Reyes-Prieto and Bhattacharya 2007a, b). Phylogenomics, made possible through the *Cyanophora* Genome Project, gave additional support (see above). Thus glaucophytes can be considered as direct descendants of the most ancient phototrophic eukaryotes, at least among the species known at present.

Phylogenetic relationships within the Glaucophyta have been investigated thoroughly in two independent studies (Chong et al. 2014; Takahashi et al. 2014). Based on concatenated and single genes of plastid (*psbA*) and mitochondrial (*cob* and *cox1*) origin, and the nuclear internal transcribed spacer (ITS) region, Chong et al. (2014) revealed that strains of *Glaucocystis nostochinearum* (or *Glaucocystis* species complex) were divided into six clades that possibly correspond to individual species (Fig. 8). The monophyletic group of *Glaucocystis* sp. complex was clustered together with the monophyletic *Gloeochaete wittrockiana* and *Cyanoptyche gloeocystis* clade. Five *Cyanophora* species were separated from the rest of the glaucocystophycean clade (see Fig. 8). Within the *Cyanophora* clade, *C. sudae* and *C. biloba* were clustered strongly and separated from the remaining *C. paradoxa* + *C. kugrensii* + *C. cuspidata* clades based on the *psa*B and ITS phylogenies (Takahashi et al. 2014). Although three new *Cyanophora* species were suggested based on morphological and molecular data (Takahashi et al. 2014), it still is a challenge to delimitate species in glaucophytes, because of the lack of authentic (Type) strain(s) and the simple morphology prevailing. However, using a combination of molecular and morphological data, the latter made possible through advanced EM methodology, Takahashi et al. (2016) confirmed the *Glaucocystis* clades proposed by Chong et al. (2014) and delineate six individual species (Fig. 8). Subtle, but significant differences in the peripheral ultrastructure of the cells, i.e., in the vesicle system underlying the plasma membrane (lacunae, cf. Fig. 7), were the key to this problem.

Acknowledgments The authors thank B. Franz Lang, Hideya Fukuzawa, and Steven Ball for helpful comments. W.L. is grateful to the Austrian Research Fund for 25 years of support.

Rhodophyta

3

Hwan Su Yoon, Wendy Nelson, Sandra C. Lindstrom, Sung Min Boo, Curt Pueschel, Huan Qiu, and Debashish Bhattacharya

Abstract

Rhodophyta, or red algae, comprises a monophyletic lineage within Archaeplastida that includes glaucophyte algae and green algae plus land plants. Rhodophyta has a long fossil history with evidence of *Bangia*-like species in ca. 1.2 billion-year-old deposits. Red algal morphology varies from unicellular, filamentous, to multicellular thalloid forms, some of which are sources of economically important products such as agar and carrageenan.

These species live primarily in marine environments from the intertidal zone to deep waters. Freshwater (e.g., *Batrachospermum*) and terrestrial lineages also occur. One of the major innovations in the Rhodophyta is a triphasic life cycle that includes one haploid and two diploid phases with the carposporophyte borne on female gametophytes. Red algae are also well known for their contribution to algal evolution with ecologically important chlorophyll-*c* containing lineages such as diatoms, dinoflagellates, haptophytes, and phaeophytes all containing a red algal-derived plastid of serial endosymbiotic origin. Analysis of red algal nuclear genomes shows that they have relatively small gene inventories of 6,000–10,000 genes when compared to other free-living eukaryotes. This is likely explained by a phase of massive genome reduction that occurred in the red algal ancestor living in a highly specialized environment. Key traits that have been lost in all red algae include flagella and basal body components, light-sensing phytochromes, and the glycosylphosphatidylinositol (GPI)-anchor biosynthesis and macroautophagy pathways. Research into the biology and evolution of red algae is accelerating and will provide exciting insights into the diversification of this unique group of photosynthetic eukaryotes.

Introduction

General Characteristics

The Rhodophyta (red algae) is a well-characterized and morphologically diverse lineage of photosynthetic protists. They range from unicells and uni- or multiseriate (arranged in rows) filaments, to large (up to 3 m) pseudoparenchymatous, branched or unbranched, terete (cylindrical) to foliose (blade-like) thalli, including crustose and erect forms, some of which are calcified (Figs. 1 and 2). More than 7,100 species are currently reported (www.algaebase.org). Diagnostic features of the red algae are: (1) plastids with accessory, water-soluble pigments allophycocyanin, phycocyanin, and phycoerythrin localized in structures termed phycobilisomes located on the outer faces of photosynthetic lamellae (thylakoids, Fig. 3b, c; other pigments include chlorophyll *a,* α- and β-carotene, lutein and zeazanthin); (2) thylakoids present as single lamellae (i.e., not stacked) in plastids (Fig. 3a–c); (3) lack of flagellated structures at any stage of the life history; and (4) food reserves stored as floridean starch [α-(1, 4)-linked glucan] in granules outside the plastid (Fig. 3a, b). Additional traits of some, but not all red algae include: (1) the presence of "pit connections" between cells (a misnomer because these are not connections between cells, rather plugs of proteinaceous material deposited in the pores that result from incomplete centripetal wall formation) (Fig. 3a, d); (2) mitochondria associated with the forming (cis) faces of dictyosomes (Golgi bodies) (Fig. 3e); (3) plastids surrounded by one or more encircling thylakoids (Fig. 3c); and (4) a complex life history composed of an alternation of two free-living and independent generations (gametophyte and tetrasporophyte) and a third generation, the carposporophyte, that occurs on the female gametophyte (terms are defined in the "Life Histories" section). The Rhodophyta currently consists of two subphyla and seven classes (Yoon et al. 2006).

Florideophyceae, the most species-rich class (6,751 spp.; 95% of all taxa), appears to be a monophyletic group characterized by the presence of tetrasporangia and a filamentous gonimoblast in most species (terms defined in the "Life Histories" section).

History of Knowledge

The process of describing and naming Rhodophyta (along with all plants and eukaryotic photosynthetic organisms) begins with Linnaeus, who placed taxa that currently belong to this phylum in three genera: *Conferva* (filamentous forms), *Ulva* (membranous forms), and *Fucus* (thalloid forms). Lamouroux was the first to use

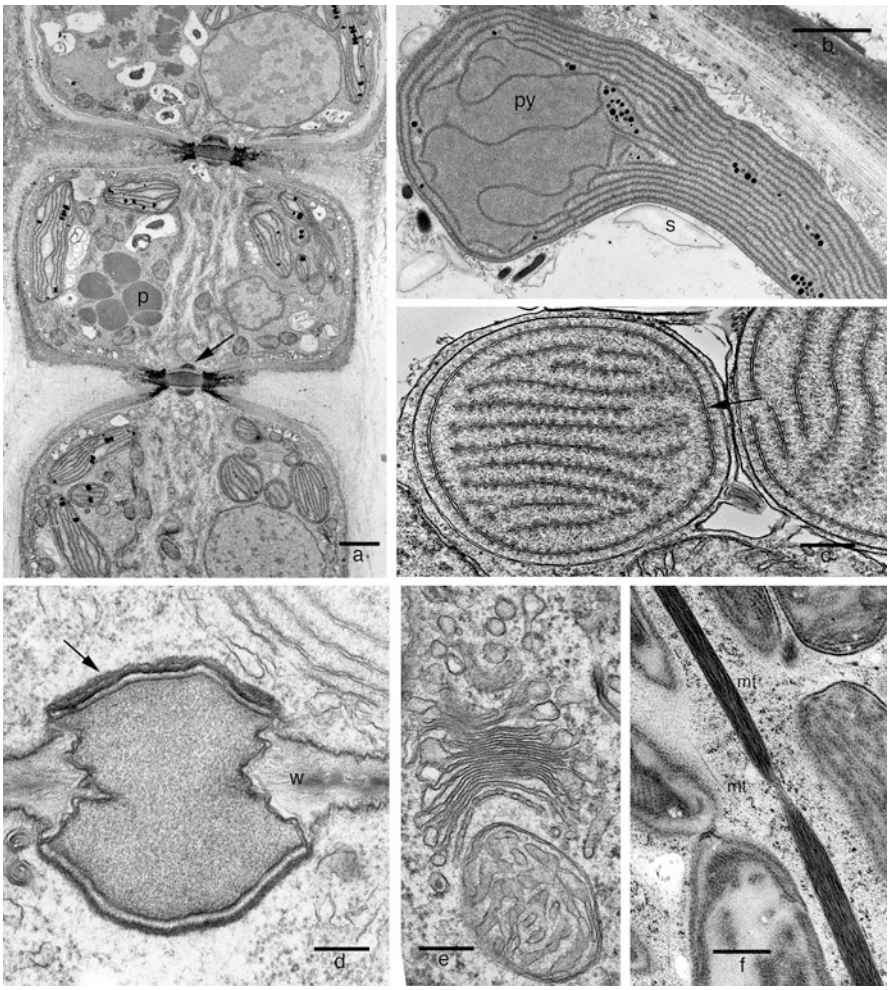

Fig. 3 (**a**–**f**) Thin-section electron microscopy of cellular features of red algae. (**a**) Multicellular epithallial filament of *Neopolyporolithon loculosum*. Cells are joined by pit plugs having dome-shaped outer caps (*arrow*). color to distinguish between groups of thallophytes, and he placed some red algal genera into an order "Floridées."

Red algae (particularly Florideophyceae) were not recognized as a monophyletic assemblage, however, until Harvey (1836) distinguished red, green, and brown algae (Rhodospermeae, Chlorospermeae, and Melanospermeae, respectively) as separate groups based on the spores being the same color as the parent thalli. Although this classification gained immediate acceptance, it was not until the elegant experiments of Haxo and Blinks (1950) that the direct link was established between the colors (presence of various accessory pigments) of algae and their photosynthetic action spectra.

During the nineteenth century, when European nations were sponsoring voyages to discover and explore new lands, plant and animal specimens were sent back to various scientific authorities. Thus, algal specimens were sent to C. A. and J. G. Agardh in Lund, F. T. Kützing in Leiden, P. C. Montagne in Paris, and W. H. Harvey in Dublin, as well as to numerous other algal systematists who published significant (and often magnificent) tomes. Their observations were restricted to morphological and anatomical features of taxa, with no clear understanding of how these features were related to the reproduction or life histories of the organisms.

Convincing documentation of sexual reproduction in red algae was provided by Bornet and Thuret, and further observations made independently by Schmitz and Oltmanns, linked morphological features with stages of sexual reproduction. With these discoveries, the criteria that formed the basis of the classification of the Florideophyceae for many years were established. By early in the twentieth century, a number of orders that are recognized today had been established, and by mid-century the voluminous works of one man, Harald Kylin (summarized in Kylin 1956), had set down an infraordinal classification scheme that was followed for about three decades. Over the past ca. 25 years, many more orders, families, and genera of red algae have been established (Schneider and Wynne 2007, 2013; Wynne and Schneider 2010).

The red algae are classified into the phylum Rhodophyta (Wettstein 1901), as one phylum of the supergroup Archaeplastida with two sister phyla, the Viridiplantae and Glaucophyta (Adl et al. 2005). The Rhodophyta has been traditionally classified into two classes, the Bangiophyceae and Florideophyceae (Gabrielson et al. 1985), or two subclasses, the Bangiophycidae and Florideophycidae (Dixon 1973). Based on cladistics and molecular phylogenetic studies, the Bangiophyceae has been identified as a paraphyletic group (e.g., Gabrielson et al. 1985; Müller et al. 2001; Oliveira and Bhattacharya 2000; Yoon et al. 2006). To reflect phylogenetic relationships, Saunders and Hommersand (2004) developed a revised classification system comprising two phyla (Rhodophyta and Cyanidiophyta), three subphyla (Rhodellophytina, Metarhodophytina, and Eurhodophytina), and five classes (Bangiophyceae, Compsopogonophyceae, Cyanidiophyceae, Florideophyceae, and Rhodellophyceae). This system was updated by Yoon et al. (2006), who inferred seven well-supported phylogenetic lineages in a multigene analysis. They proposed the Rhodophyta contain two subphyla, the Cyanidiophytina with a single class, the

Cyanidiophyceae, and the Rhodophytina with six classes (Bangiophyceae, Compsopogonophyceae, Florideophyceae, Porphyridiophyceae *classis nova,* Rhodellophyceae, and Stylonematophyceae *classis nova*). This seven-class system is now widely accepted for red algal classification. The system presented here and discussed in the "Classification" section represents a slight modification of the system proposed by Yoon et al. (2006, 2010).

Habitats and Ecology

Ecological Importance of Red Algae

Red algae can be found in many different environments – marine, freshwater, and terrestrial. The majority of red algae belong to the Florideophyceae, which are largely multicellular and nearly all inhabit marine habitats. Some species extend into estuarine environments and some are exclusively freshwater, for example, members of the Batrachospermales.

Although red algae rarely form canopies in subtidal communities, they play key roles in nearshore ecosystems. Species of red algae range from the upper reaches of intertidal shores (e.g., members of the Bangiales) to hundreds of meters in depth in clear tropical waters. As understory vegetation in kelp forests as well as turfs on intertidal shores, red algae provide habitat for a wide variety of organisms. This review supplements the earlier review of Gabrielson et al. (1990).

Calcified Red Algae

Calcified red algae are vital components of nearshore ecosystems. They can be found from intertidal shores to the deepest reaches of the euphotic zone and from polar to tropical latitudes (Foster 2001; Nelson 2009). Most calcified red algae belong to the orders Corallinales, Hapalidiales, or Sporolithales. Species in these orders are either geniculate (jointed or articulated) or nongeniculate (typically crustose). In tropical coral reef environments, crustose coralline algae reinforce the skeletal structure of corals, filling cracks and cementing together sand, dead coral, and debris, creating stable substrate, and reducing reef erosion (Adey 1998; Diaz-Pulido et al. 2007). In studying tropical coral reefs, Littler and Littler (2007) concluded that the presence of "massive corals and calcareous coralline algae relative to frondose macroalgae and algal turfs indicates a healthy spatially heterogeneous condition reflecting low nutrients and high herbivory," whereas high coverage of coralline algae suggests high herbivory levels and elevated nutrients, which can inhibit some corals.

Geniculate coralline algae are also widespread on hard substrata. They are sometimes referred to as ecosystem engineers to reflect the way their three-dimensional structure modifies the environment. Their complex, branched axes intermesh and thus resist wave action and disturbance and retain moisture when exposed at low tide, a particular advantage for intertidal species. These turfs provide

habitat and shelter from several of the stresses of intertidal life (e.g., desiccation, wave action, and predation) and, in addition, they provide surfaces for settlement of microphytobenthos and trap sediments for epiphytic filter-feeding taxa. Coralline turfs have been found to harbor high diversity, density, biomass, and productivity of mobile invertebrates (e.g., Cowles et al. 2009; Kelaher et al. 2004). Another ecosystem service provided by coralline algae is the release by some species of compounds that are critical to the settlement and morphogenesis of corals and molluscs (Morse et al. 1996; Roberts 2001; Tebben et al. 2015).

Rhodoliths are free-living coralline algae found in coastal habitats extending to depths of more than 200 m (Foster 2001; Nelson 2009), and they thrive in areas with sufficient water motion to inhibit burial by sediment but not so much as to remove them from their favored habitat (Foster 2001). Rhodolith beds (maërl) are extensive communities found on a wide variety of sediments, from mud to coarse sand. Foster (2001) argued that rhodolith beds may be one of earth's "big four" seaweed-dominated communities together with kelp forests, seagrass meadows, and nongeniculate coralline algae-dominated tropical reefs. Internationally recognized as unique ecosystems, new rhodolith beds continue to be discovered (Foster 2001; Konar et al. 2006; Teichert et al. 2012; Macaya et al. 2015). The three-dimensional structure of rhodolith beds creates microhabitats for diverse invertebrates and algae, including rare and unusual species, as well as serving as nursery grounds for some commercial species of fish (e.g., Hernández-Kantún et al. 2010; Kamenos et al. 2004a, b; Neill et al. 2015; Peña and Bárbara 2008b; Steller et al. 2003; Teichert 2014). Recognition of the ecological importance of these algal-dominated communities and the need for conservation has increased over the past decade (e.g., Barbera et al. 2003; Grall and Hall-Spencer 2003; Peña and Bárbara 2008a). Maërl has a long history of use as a soil additive in Europe, and commercial mining of rhodoliths is carried out in Europe and Brazil, despite concerns about the sustainability and impacts on ecosystem services (Briand 1991; Riul et al. 2008).

Recent studies indicate that rhodoliths and other coralline algae are at risk from the impacts of a range of human activities, such as physical disruption, reduction in water quality, alterations to water movement, and global climate change (e.g., McCoy and Kamenos 2015; Nelson 2009).

Invasive Species

There is increasing recognition of the potential ecological impacts of introduced species – for example, modifying the habitats they invade, displacing native species, altering food webs and community structure, and threatening native biodiversity. Compilations of introduced seaweeds have been published as well as regional surveys (e.g., Davidson et al. 2015; Miller et al. 2011; Nelson 1999; Williams and Smith 2007).

There have been serious consequences accompanying human-assisted introductions of certain red algae, with examples of both filamentous species, such as *Heterosiphonia japonica* (e.g., Newton et al. 2013; Schneider 2010; Sjøtun et al. 2008), and

large foliose species, such as *Grateloupia turuturu* (Araujo et al. 2011; D'Archino et al. 2007; Janiak and Whitlach 2012; Verlaque et al. 2005). Research has examined biological attributes that may determine the invasive nature of these species and their impacts on the receiving communities.

Both the movement of aquaculture species and ballast waters have been implicated in the spread of red algae. Molecular sequencing has been a useful tool in understanding the pathways and the timing of some introductions (Andreakis et al. 2007; Yang et al. 2008). In genera such as *Grateloupia* and *Gracilaria*, where identifying species using morphological characters can be problematic, molecular techniques as well as analyses of proteins and other compounds have proved valuable in distinguishing native from nonnative species (e.g., Kollars et al. 2015; Gavio and Fredericq 2002; Kim et al. 2010; Wilcox et al. 2007).

Biogeography

Studies continue to document the flora of some of the lesser-known areas of the globe (Harper and Garbary 1997; Hommersand et al. 2009; Klochkova and Klochkova 2001; Lindstrom 2006, 2009; Nelson and Dalen 2015; Selivanova and Zhigadlova 1997a, b, c; Wulff et al. 2009). Red algae are significant in these studies because they are generally both more numerous than either green or brown algae and more phylogenetically diverse due to their ancient history and wide environmental tolerances.

During the 1990s, biogeographic studies continued to focus on the role of physiological responses (particularly to temperature) in the distribution of red algae. Much of this work focused on Arctic, Antarctic, and tropical species (e.g., Wiencke et al. 1994 Bischoff-Bäsmann and Wiencke 1996; Bischoff-Bäsmann et al. 1997; Pakker and Breeman 1996). The role of temperature and area, particularly over geological time, was central to the thermogeographic model of Adey and Steneck (2001). This model has been used to explain the predominantly Pacific origin of the Arctic and Atlantic boreal seaweed floras (Adey et al. 2008) and was validated using subtidal seaweed assemblages in the northwestern Atlantic Ocean (Adey and Hayek 2011).

Molecular data are being used to look at the distribution and phylogeography of species (e.g., Gurgel et al. 2004; Montecinos et al. 2012) although phylogeographic patterns are not always evident in these data (e.g., Vis et al. 2012). Studies have also looked at patterns of recolonization in areas affected by Pleistocene glaciations (Hu et al. 2010; Lindstrom et al. 1997; Provan et al. 2005; Yang et al. 2009). Hommersand (2007) analyzed the Australian macroalgal flora in terms of global biogeographic patterns and in relation to vicariance events in the geological history of Australasia. He identified Australasia as "a center of origin and diversity for marine algae, especially the Rhodophyta." Molecular studies provided data to support the hypothesis that many lineages of red algae originated in the southern hemisphere, or at least extant members of lineages, are found there (e.g., Bangiales – Broom et al. 2004; Gelidiales and Gigartinaceae – Hommersand et al. 1994; Nelson

et al. 2011; Gracilariales – Gurgel and Fredericq 2004). Molecular sequencing has indicated that many species actually are species complexes, and the resolution of species boundaries not evident from morphological examination is permitting a clearer understanding of their divergent ecologies (Lindstrom et al. 2011; Boo et al. 2016a, b). The evolution of a domesticated red alga, *Gracilaria chilensis*, has also been studied using a combination of phylogeographic and population genetic tools (Guillemin et al. 2014).

Ocean Acidification, Global Warming, and Red Algae

The long-term ecosystem consequences of human-mediated changes in global climate (e.g., rising temperatures, increased levels of atmospheric carbon dioxide and resulting decreases in seawater pH, changes in UV radiation, and changes in ocean circulation and upwelling patterns) are being investigated. Harley et al. (2012) reviewed how multiple stressors may affect survival, growth, and reproduction of seaweeds in a changing climate: different responses of community members to these stressors may determine persistence or extinction. For turf-forming red algae, which rely on aqueous CO_2, elevated levels should differentially favor their growth, which in turn may enhance their competitive ability (Hepburn et al. 2011). Climate change may also drive shifts in seaweed distributions at both horizontal (geographical) and vertical (elevation) scales (Brodie et al. 2014; Harley et al. 2012). These changes may be stochastic rather than gradual as shown by Harley and Paine (2009).

Roleda and Hurd (2012) summarized the responses of seaweeds to ocean acidification and examined the underlying chemistry, physiological and community-level responses, and interactions with other stressors. The contribution of calcareous algae to global carbonate production was reviewed by Basso (2012) and by McCoy and Kamenos (2015), including the response of coralline red algae to marine acidification and rising temperature. These algae showed decreased net calcification, decreased growth and reproduction, as well as reduced abundance and diversity, leading to death and an ecological shift to dominance by noncalcifying algae. In some regions, the contribution of rhodolith beds to nearshore carbonate production is very significant. Pereira-Filho et al. (2012) calculated that the summits of several seamounts are covered with extensive rhodolith beds within the tropical southwestern Atlantic. These beds are responsible for 0.3% of the world's carbonate production, and Amado-Filho et al. (2012) recorded the production from Brazilian rhodolith beds to be comparable to the world's largest $CaCO_3$ deposits, describing these beds as "major $CaCO_3$ biofactories."

Calcareous organisms can provide insight into geological processes and have the potential to be used as indicators of paleoenvironmental conditions: rhodoliths and crustose coralline algae are particularly useful in this context because of their sensitivity to ecological changes reflecting their depositional setting (e.g., Adey et al. 2015; Frantz et al. 2000, 2005; Fietzke et al. 2015; Halfar et al. 2000, 2007, 2008, 2011; Kamenos et al. 2008).

The effects of ozone depletion and UVB radiation on algae have been summarized by Bischof and Steinhoff (2012). Because there are marked species-specific responses to UVB radiation, there may be significant ecological implications in the responses at a community or ecosystem level with changes in distributional patterns (latitude and depth) as well as succession patterns, trophic interactions, and species diversity. Studies of red algae in polar regions have shown that their distribution on the shore is related to their ability of cope with UVB-mediated damage to DNA. In red algae, mycosporine-like amino acids (MAAs) have been the focus of a number of studies examining their role as UV-screening substances. In general, cellular MAA concentrations in red algae have been shown to be positively correlated with UV dose.

Commercial Importance

Red algae continue to be an important component of seaweed aquaculture, representing about 33% of the harvested weight but nearly 50% of the value, which was about US $6.4 billion in 2012 (FAO 2014). *Eucheuma* spp., including *Kappaphycus*, were responsible for more than 5 million tons of harvested seaweed, and *Gracilaria* 2.7 tons, and *Porphyra* spp., including *Pyropia*, about 1.8 million tons. Production of all species showed significant increases from the 1990s. Major production areas include Korea, Japan, China, Indonesia, and the Philippines, with minor production occurring in Malaysia and Zanzibar. Buchholz et al. (2012) summarize the methods employed in cultivation of farmed red algae including both monoculture methods and integrated multitrophic aquaculture (IMTA–Chopin et al. 2008).

The majority of red seaweeds, either collected from the wild or farmed, are used in the production of human food (Buchholz et al. 2012; Pereira et al. 2012). Direct consumption as sea vegetables is important in the Asia Pacific region, and red algal hydrocolloids are used widely in the food and other industries. New applications are being developed for marine algal products, for example, in functional foods, medicine (as anti-inflammatory, antiviral, anticancer uses), as well as in cosmetics and cosmeceuticals, and as biomaterials in skeletal replacement or regeneration, including dental applications.

Seo et al. (2010) revealed a potential use of rhizoidal filaments in *Gelidium* as raw material for papermaking. The handsheets of *Gelidium* pulp had very high Bekk smoothness and opacity, which are essential properties for high-valued printing paper, when compared to those of wood pulp.

Novel Chemistry

Galloway et al. (2012) showed that different groups (phyla, orders, families) of marine macrophytes, including red algae, have distinct essential fatty acid signatures, and the signatures of red algae were more variable than those of brown,

particularly those in the orders Corallinales, Gigartinales, and Gracilariales. Because animals cannot synthesize these molecules and rely on plant sources, essential fatty acids are useful trophic markers for tracking sources of primary production through food webs.

Some red algae are known to produce secondary metabolites, which appear to play a key defensive role against both herbivory and fouling (e.g., Blunt et al. 2011; Dworjanyn et al. 2006; Oliveira et al. 2013). Amsler et al. (2009) found that chemical defenses against herbivory are very important in structuring Antarctic macroalgal communities but not the single Arctic community examined to date, and they suggested that this may be a consequence of the different evolutionary histories of these regions. Nylund et al. (2013) examined the costs and benefits of chemical defense in *Bonnemaisonia hamifera* and found that although costly in energetic terms, there were significant fitness benefits by protecting against harmful bacterial colonization. Lignin and secondary walls were reported in red algae by Martone et al. (2009), raising questions about the biosynthetic pathways and the convergent or deeply conserved evolutionary history of these traits.

Population Biology

Many of the ecological studies of red algae have focused on aspects of their biology in relation to their life histories and reproductive modes. Although little studied, vegetative reproduction via multicellular propagules is widespread in red algae, increasing local populations, and it may be that this is the way in which some human-mediated introductions are effected (reviewed by Cecere et al. 2011).

Differential responses to environmental factors by isomorphic life history stages have intrigued researchers who have grappled with the implications of the predominance of one phase of an alternating life cycle. A number of studies have modeled the impacts of changes in fertilization success and reproductive output on the abundance of isomorphic generations (e.g., Fierst et al. 2005; Scrosati and DeWreede 1999; Thornber and Gaines 2004). Guillemin et al. (2008) explored genetic diversity in the agarophyte *Gracilaria chilensis*, a species farmed extensively in Chile. Their results suggested that the farming practices favored asexual reproduction and reduced genetic diversity in the farmed stocks. A subsequent study showed that adult tetrasporophytes grew more rapidly than gametophytes under the same conditions. Guillemin et al. (2012) hypothesized that during domestication this difference led to selection of the tetrasporophyte now dominating commercial farms.

Molecular tools are providing new insights into aspects of the ecology and population dynamics of red algae enabling examination of connectivity between populations, as well as the genetic structure of populations at small spatial scales (Andreakis et al. 2009; Donaldson et al. 2000; Engel et al. 1999, 2004; Krueger-Hadfield et al. 2011).

Characterization and Recognition

Ultrastructure

Study of the fine structure of red algae began in earnest in the mid 1960s, and progress was recounted in a series of reviews in the early 1990s. The general features of red algal ultrastructure were reviewed in detail by Pueschel (1990), and knowledge of the fine structure of cell division was summarized by Scott and Broadwater (1990) in the same volume. Broadwater et al. (1992) reviewed the cytoskeleton and spindle. The fine structure of the unicellular red algae was surveyed by Broadwater and Scott (1994).

Although red algae have a typical eukaryotic cell structure (Fig. 3a), they possess a unique combination of cellular features. Their distinctive coloration stems from their water-soluble phycobilin accessory pigments, which are visible ultrastructurally as granules, called phycobilisomes, on the surface of the unstacked photosynthetic membranes of the plastids (Fig. 3b, c). Light energy captured by phycobilisomes is transferred to chlorophyll *a*, which is a constituent of the photosynthetic membranes. The presence of phycobilisomes on single photosynthetic membranes is a feature inherited from the endosymbiotic cyanobacteria that were the progenitors of red algal plastids. Also related to the primary endosymbiotic origin of red algal plastids is the absence of periplastid endoplasmic reticulum (PER) (Fig. 3c). Bounding membranes external to the two membranes of the plastid envelope are typical of many algal lineages and are considered remnants of secondary endosymbiotic acquisition of plastids from another photosynthetic eukaryote. The red algae, like the green algae and glaucophytes, which also became photosynthetic by cyanobacterial primary endosymbiosis, lack PER.

Red algae deposit starch as an insoluble carbohydrate reserve. Floridean starch differs from green-plant starch in being free in the cytoplasm (Fig. 3b), rather than in the plastids, and in consisting solely of amylopectin, without an amylose component. Amylopectin is an α 1–4 linked glucan with abundant α 1–6 linkages, similar to animal glycogen, but in light and electron microscopy the grains of floridean starch appear similar to those of green plants and unlike the fine granules of animal glycogen.

The crucial CO_2-fixing enzyme, ribulose-1,5-biphosphate carboxylase/oxygenase (RuBisCO), occurs throughout the stroma of plastids, appearing as small granules similar in size to plastid ribosomes. In many lineages of algae, dense aggregations of RuBisCO form visible structures termed pyrenoids (Fig. 3b). Only a small proportion of red algal species possess pyrenoids, but those that do are taxonomically widespread, occurring in some representatives of most of the presently recognized classes. Pyrenoids provide a variety of distinguishing features: number per plastid, location within the plastid, whether thylakoids penetrate the pyrenoid matrix (Fig. 3b), proximity to starch grains, and, in the Rhodellales, the peculiar feature of the pyrenoid is that it is deeply penetrated by an RNA-enriched projection of the nucleus (Waller and McFadden 1995).

One of the most distinctive features of the red algae is the absence of any form of flagellated motility. Centrioles, which have a microtubular substructure similar to

flagellar basal bodies and in some organisms give rise to flagella, are also absent from the red algae. The near universality of flagella or centrioles among eukaryotes and their absence in red algae was reasonably interpreted as evidence that the red algae diverged from the main line of eukaryotic evolution before the advent of eukaryotic flagellation. Molecular evidence provides a different explanation: these structures were lost by an ancestor of all living red algae. Although centrioles are absent, small, ring-shaped, or discoid structures with no structural similarity to centrioles are present at the poles of mitotic and meiotic spindles (Scott and Broadwater 1990).

Another intriguing ultrastructural feature of red algae is the variety of spatial associations that Golgi bodies form with other organelles (Broadwater and Scott 1994). The close association of the cis-face of Golgi bodies with mitochondria is decidedly the most common configuration in red algae (Fig. 3e). This arrangement contrasts strongly with the cis-Golgi being associated with the nuclear envelope, which is found only in some unicellular species. The association of Golgi with endoplasmic reticulum, the typical arrangement in eukaryotes, is also found, and cisternae of ER are often present near the mitochondrion-Golgi pairings, as well.

All but a few genera of multicellular red algae possess persistent intercellular connections, termed pit connections (Fig. 3a, d), which are the product of incomplete cytokinesis (Pueschel 1990). A structure called the pit plug is deposited within the connection, separating the cytoplasm of the two cells, but the cell membranes of the connected cells remain continuous along the sides of the pit plug. Pit connections are present in all members of the Florideophyceae and Bangiophyceae (although in the case of the latter, not in all life history stages) and some members of the Compsopogonophyceae. The proteinaceous plug core is the only universal element of pit plugs. The plug core may be separated from the adjacent cytoplasm by one or two cap layers of differing chemical composition (Pueschel and Cole 1982). In a multilayered plug cap, the cytoplasm-adjacent outer layer may be either a dome (Fig. 3a) or a thin plate (Fig. 3d), but both of these morphological types have similar cytochemical properties. A membrane, termed the cap membrane, may or may not be present, whether cap layers are present or not. The cap membrane and outer cap layer must have originated within the Florideophyceae because neither feature is found in other classes. Evidence for intercellular transport across pit plugs is largely circumstantial (Pueschel 1990), and compelling experimental proof of the function of pit plugs is not yet in hand.

The cytoskeleton is the most poorly known of typical red algal cellular constituents because it is composed mainly of microtubules and microfilaments, both of which are labile in conventional chemical fixation for electron microscopy. Freeze substitution provides a different preparative approach, and using this technique, Babuka and Pueschel (1998) demonstrated thick bundles of microfilaments and numerous cortical microtubules in axial cells of *Antithamnion* (Fig. 3f). Freeze substitution has been used extensively by Kuroiwa and associates (e.g., Miyagishima et al. 2003; Suzuki et al. 1995) to explore the role of ring-shaped structures, some actin – some not, in the division of plastids, mitochondria, and cells of *Cyanidium* and related genera. Light microscopic studies of fluorescently labeled

microfilaments and microtubules, often used in conjunction with specific cytoskeletal inhibitors, have demonstrated a role of one or both of these cytoskeletal elements in cytokinesis (Garbary and McDonald 1996), plastid movement (Russell et al. 1996), fertilization (Kim and Kim 1999; Wilson et al. 2002a, 2003), vesicle transport (Wilson et al. 2006), and the formation of pseudopodia in spores (Ackland et al. 2007). The rotation of plastids in the unicellular alga *Rhodosorus* is another striking example of subcellular movement, but the motive force is unknown (Wilson et al. 2002b). Using time-lapse microscopy, Pickett-Heaps et al. (2001) demonstrated that directional gliding motility is common and widespread in spores and among unicellular species of red algae. Mucilage secretion accompanies this movement, but the mechanism that generates directional motility remains to be elucidated.

Despite the ultrastructural characterization of the many diverse cellular inclusions found in red algal cells, we still have insufficient understanding of their functions. For example, protein bodies (Fig. 3a) are a prominent component of many vegetative cells. It has been proposed that these inclusions might serve as a seasonal nitrogen store (Pueschel 1992), but this idea has not been tested in red algae. Calcium oxalate crystals are common in higher plants and are present in some algal groups, including red algae (Pueschel 1995), but the physiological functions usually assigned to such inclusions in higher plants are unlikely to apply to the algae (Pueschel and West 2007). Progress has been made in the characterization of refractile inclusions that are associated with some kinds of specialized vegetative cells (Paul et al. 2006) and can form distinctive structures, such as the *corps en cerise* in cortical cells of *Laurencia* (Reis et al. 2013). These inclusions consist of halogenated sesquiterpenes, which can be transported to the thallus surface (Salgado et al. 2008) where they have a role in discouraging herbivory and fouling. In cortical cells of *Plocamium,* specialized vacuoles, dubbed mevalonosomes, have been demonstrated by ultrastructural enzyme localization techniques to contain enzymes of the mevalonate pathway (Paradas et al. 2015), whose products also have an antifouling function.

The greatest complexity of cell structure in red algae is found in reproductive cells and specialized vegetative cells. A large portion of the ultrastructural literature addresses the many subcellular changes associated with sporogenesis (Pueschel 1990). Although there is likely a phylogenetic signature in the fine structural details of sporogenesis, the taxonomically diverse survey work needed to explore this potential has not been pursued. The fine structure of the many kinds of specialized vegetative cells, such as rhizoids, gland cells, and hair cells, was studied early in the ultrastructural explorations of red algae (Pueschel 1990). Hair cells have continued to receive attention (Judson and Pueschel 2002; Oates and Cole 1994), as have some kinds of gland cells (Paul et al. 2006). Increased interest in the Corallinales has led to detailed examination of one of the most distinctive types of specialized cells in the red algae, the corallinalean epithallial cell. Although they are apical cells, the epithallial cells undergo terminal differentiation, senescence, and sloughing in a programmatic fashion (e.g., Pueschel et al. 1996). Intercalary meristematic cells divide to produce replacement epithallial cells. This highly unusual process is hypothesized to have an antifouling function or, alternatively, to be an adaptation

to frequent grazing. The fact that the walls of coralline algae are heavily calcified makes these epithallial dynamics all the more complex and interesting.

The discovery, description, and elucidation of phylogenetic affinities of new species of red algae are ongoing and for unicellular red algae, ultrastructural study continues to play a critical role in this endeavor. Given the simplicity of unicellular red algae and the paucity of structural features, one might expect to find molecularly distinct but structurally indistinguishable lineages. Instead, the several rhodophyte orders containing unicellular species possess a variety of distinctive ultrastructural characters. That these simple taxa should differ in their basic cellular features presumably reflects the antiquity of their evolutionary divergences. Scott et al. (2011) summarized the systematics of several of the orders containing unicellular red algae and their ultrastructural features. Compared to the diversity of cellular features of unicellular red algae, the basic features of typical vegetative florideophycean cells are relatively uniform.

Life Histories

The red algal life history is unique in having an additional third phase (i.e., a triphasic life history) in most Florideophyceae (except the Hildenbrandiales, Batrachospermales, and Palmariales). The "basic" biphasic life history is found in the early-diverged red algal lineages as well as in some florideophycean taxa. There are, however, numerous variations in the life histories of red algae.

The triphasic life history is an alternation of generations of three phases, the gametophyte, carposporophyte, and tetrasporophyte. It is generally called a "*Polysiphonia*-type" life history because it was first observed in the genus *Polysiphonia*. The triphasic life history is composed of haploid gametophytes (thalli that produce gametes), diploid carposporophytes, and diploid tetrasporophytes (thalli that typically produce four spores by meiotic division) (Fig. 4a). Gametophytes and tetrasporophytes are generally independent photosynthetic thalli, whereas the carposporophyte is diploid tissue that occurs on or within the haploid female gametophyte as a result of fertilization of the egg cell and subsequent development of the zygote.

Male gametophytic plants produce spermatia (= nonmotile sperm) from spermatangial initial cells. Female gametophytic plants produce carpogonial branches that are composed of a terminal carpogonium (= egg cell) with a trichogyne (a hair-like extension) and differing numbers of subtending cells depending on taxonomic group. Fertilization starts with attachment of spermatia to the trichogyne. Fusion of the gametic nuclei occurs in the carpogonium. The resulting diploid nucleus is either transferred, via an outgrowth from the carpogonium, to another cell (called the auxiliary cell), or remains in the carpogonium. In both cases, mitotic divisions of the diploid nucleus within a filamentous outgrowth (the gonimoblast) eventually result in the production of diploid carposporangia. Carpospores are released from the carposporangia and germinate to give rise to free-living diploid tetrasporophytes. Meiosis then occurs in specialized cells (tetrasporangial initial

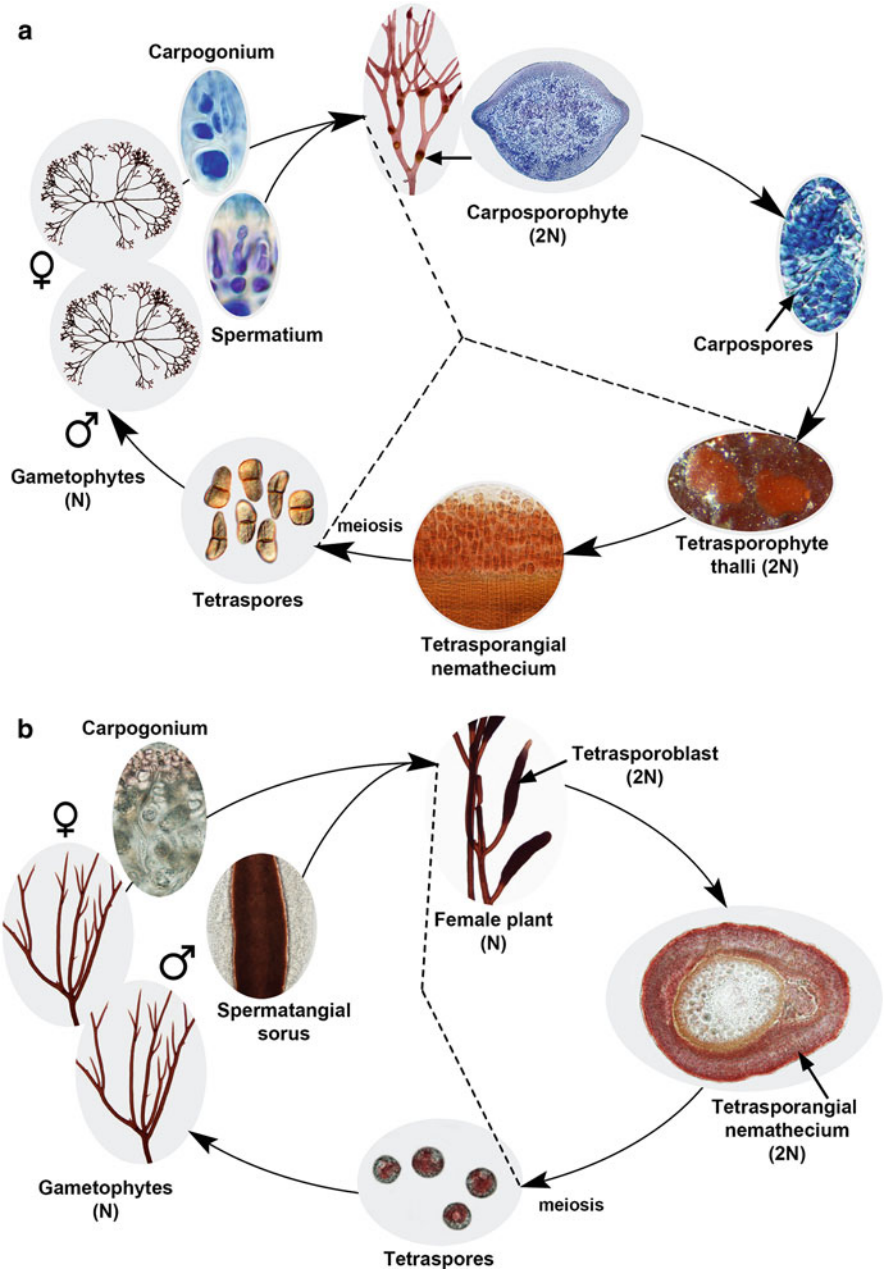

Fig. 4 (**a**, **b**) (**a**) Triphasic life history of *Ahnfeltiopsis catenata.* It shows branched gametophytes and a free-living crust attached to rock. (**b**) Tetrasporoblastic life history of *Pikea yoshizakii*. Tetrasporoblastic life history exhibits a truncated life history in which fertilized females produce tetraspores in nemathecia rather than carpospores in cystocarps

cells) in the tetrasporophyte, and the resulting tetrads of haploid spores are shed from the thallus. Individual spores germinate to give rise to gametophytes, completing the cycle.

The typical *Polysiphonia*-type life history includes isomorphic gametophytes and tetrasporophytes; however, in other red algae heteromorphic generations, in which the tetrasporophyte is morphologically distinct from the gametophyte, also occur. For instance, some species of Gigartinales have a heteromorphic life history in which sporophytes are crustose (see Fig. 4a). Heteromorphic generations also occur in the Nemaliales and Bonnemaisoniales, in which the tetrasporophyte is a minute branched filament. In some species of the Acrochaetiales, the tetrasporophyte is the more conspicuous phase, while the gametophyte is diminutive. The Palmariales are characterized by a life history in which male gametophytes and tetrasporophytes are the conspicuous macrophytes, and female gametophytes are microscopic and after fertilization are overgrown by the tetrasporophytes without benefit of a carposporophyte generation.

Several species of Gigartinales produce tetrasporoblasts and exhibit a truncated life history (Fig. 4b) in which fertilized females produce tetrasporangia in nemathecia rather than carposporangia in cystocarps, bypassing the free-living tetrasporophytic phase, for example, *Pikea yoshizakii* (Boo et al. 2016a). The tetrasporoblastic filaments are homologous to gonimoblast filaments, originating from auxiliary cells following diploid nucleus transfer, and, like the carposporophyte, are also borne on the female gametophyte. Tetrasporangia undergo meiosis, releasing tetraspores that germinate to produce gametophytes.

The biphasic life history is an alternation of generations of two phases: the gametophyte and sporophyte. Among reported sexual species in the Bangiales (Bangiophyceae) (Hawkes 1978), small colorless spermatia (previously referred to as β-spores) are produced (from 16 to 256 per parental cell) which, when released, may fuse with larger pigmented cells. Although formerly referred to as carpogonia, Nelson et al. (1999) concluded that the use of the terms "carpogonium" and "carpospore" is not appropriate for members of the Bangiophyceae, given the significant differences in the ontogeny of the female reproductive structures. The products resulting from this union are termed zygotospores (formerly known as α-spores) and most frequently germinate into the alternate conchocelis phase of the life cycle. The conchocelis phase in the Bangiales regenerates the gametophytic blades or filaments through conchospores (spores produced by the conchocelis phase). Although some species expressing this alternation of generations are reported to be sexual, others apparently are not. In *Pyropia yezoensis*, meiosis has been reported to occur upon germination of the conchospores, resulting in gametophytic thalli that are genetic chimeras (Ma and Miura 1984).

Asexual reproduction occurs in many red algal classes. It can occur through vegetative means (including simple cell division, fragmentation, and production of propagules) and through the production of spores. The term "archeospore" is applied when there is a single-cell product, and "monospore" where single spores are produced by an unequal cell division (Magne 1991). In the Bangiales, archeospores

are produced from conversion of vegetative cells in both the gametophytic and sporophytic phases and are an important means of reproduction. Endosporangia are produced in some members of the Bangiales. Some florideophycean red algae have apomictic (lacking meiosis) and apogamic (no fusion of gametes) life histories.

Evolutionary History

The fossil record of the red algae is meager (except for the Corallinales), due to the delicate or gelatinous nature of the vast majority of taxa. Even when thalli are preserved, it is rare that the minute reproductive structures on which the infraordinal classification is based also remain intact. Despite a growing range of Proterozoic fossils, few can be unambiguously assigned to an extant taxon.

There are, however, two exceptional cases of taxonomically resolved Proterozoic red algae. The first is *Bangiomorpha pubescens* from the Hunting Formation, Somerset Island, Arctic Canada (Butterfield 2000). This well-preserved modern *Bangia*-like fossil is generally considered as the oldest taxonomically known eukaryotic fossil (Fig. 5a–e). Large populations, with material ranging from a single cell to reproductively mature filaments, were embedded in a shallow-water chert/carbonate dated at 1174–1222 million years ago (Ma) (see Knoll 2011 for a review of the age constraints). Within this population, up to 2 mm long, unbranched multicellular filaments of uniseriate, multiseriate, and both uni/multiseriate habits (Fig. 5b, c) were found in clusters of up to 15 individuals (Fig. 5a) (see detail, Butterfield 2000). Two cells were usually paired in a uniseriate filament, suggesting transverse intercalary cell division. In multiseriate filaments, four to eight radially arranged wedge-shaped cells were usually identified in transverse cross-section (Fig. 5d). These transverse and radial intercalary cell division patterns are commonly found in species of modern filamentous Bangiales (e.g., Fig. 1h) and are conspicuously distinct from the apical cell division in other algae and filamentous cyanobacteria. Furthermore, *Bangiomorpha* contains spore-like, spheroidal cells within multiseriate filaments (Fig. 5e), indicating development of sexual reproduction in the ancestral red alga.

The second taxonomically resolved fossil red alga consists of anatomically preserved florideophyte fossils from the phosphorites of the late Neoproterozoic [570 (633–551) Ma] Doushantuo Formation at Weng'an, southern China (Condon et al. 2005; Xiao et al. 1998, 2004). Fossils in Doushantuo phosphorites preserved diverse three-dimensional cellular structures comprising cyanobacteria, acritarchs, animal embryos, and multicellular algae. These fossils provide key paleontological evidence about the early radiation of multicellular eukaryotes (Xiao et al. 2014). In the algal fossils, pseudoparenchymatous thalli exhibit specialized tissues including cell growth patterns (e.g., cortex-medulla differentiation, secondary pit connection between cells) and distinct reproductive structures (e.g., spermatangia, tetraspores and octaspores, and carposporangia, see Fig. 5f–i) that closely resemble key characters of Paleozoic relatives (Brooke and Riding 1998) and modern corallines (Xiao et al. 1998, 2004, 2014). Based on anatomical characters mapped on a molecular

(**h**, **i**) Carposporangia

phylogeny, Xiao et al. (2004) concluded that these fossils are stem groups that may have diversified into the crown group of Corallinophycidae in the Mesozoic Era. In addition, some Doushantuo algal fossils are related to the zygotosporangia of modern thallose Bangiales (Xiao et al. 1998, 2014), indicating diversification of the Bangiophyceae as well as the Florideophyceae during the Neoproterozoic Era or earlier.

More recently, crown groups of coralline fossils were reported from Mesozoic and Cenozoic sedimentary rocks (Aguirre et al. 2000, 2010). These species have been placed within the Sporolithales (136–130 Ma), Hapalidiales (115–112 Ma), and Lithophylloideae (65.5–61.7 Ma), providing additional time constraints on coralline and florideophyte evolution.

Divergence time estimation using relaxed molecular clocks usually provides an overview of the evolutionary timeline, despite the large degree of uncertainty associated with fossil constraints. To estimate a more reliable timeline, three fundamental requirements are critical: (i) a well-supported accurate phylogeny representing diverse lineages, (ii) reliable fossil calibrations, and (iii) robust molecular clock methods (Soltis et al. 2002). Several divergence time estimations indicated a Mesoproterozoic origin of red algae. For example, based on a phylogeny using six genes from 46 taxa, Yoon et al. (2004) estimated 1,474 Ma for the origin of red algae, after the primary endosymbiosis between a heterotrophic protist and a cyanobacterium sometime before 1,558 Ma. Parfrey et al. (2011) suggested approximately 1,500 Ma for the origin of red algae based on a 15-gene dataset from 88 eukaryotic taxa. Although they used multigene data from diverse eukaryotic phyla, both studies included only limited florideophycean taxa; therefore, they were not able to suggest a detailed timeline for the Florideophyceae, which includes ca. 95% of red algal species.

A comprehensive molecular clock analysis was recently published with special focus on the Florideophyceae (Yang et al. 2016) (see Fig. 6). This analysis was based on a robust seven-gene phylogeny including 91 red algal taxa representing all seven classes and 34 orders (i.e., 27 of 29 florideophycean and seven nonflorideophycean orders). Seven reliable fossils were used as constraint points: *Bangiomorpha,* Doushantuo and Mesozoic coralline fossils, and four land plants (i.e., 471–480 Ma for the liverwort and vascular plant split; 410–422 Ma for the fern and seed plant split; 313–351 Ma for the gymnosperm and angiosperm split, and 138–162 Ma for the monocot-eudicot split, see Magallón et al. 2013). This study suggests that the Florideophyceae diverged approximately 943 Ma, followed by the emergence of the five subclasses: Hildenbrandiophycidae (781 Ma), Nemaliophycidae (661 Ma), Corallinophycidae (579 Ma), and the split of Ahnfeltiophycidae and Rhodymeniophycidae (508 Ma).

This red algal evolutionary timeline was used to interpret the emergence of key morphological innovations (Fig. 6). The triphasic life cycle is the most distinctive feature of red algae, ancestrally present in nonhildenbrandiophycidean Florideophyceae (except the Palmariales and Batrachospermales). Because it is not possible to rule out secondary loss of the carposporophyte phase in the Hildenbrandiophycidae, Yang et al. (2016) suggested that the triphasic life cycle was enabled by the evolution of the carposporophyte sometime between the divergence of ancestral Florideophyceae (943 Ma) and the divergence of Nemaliophycidae (661 Ma). After the development of the carposporophyte (i.e., gonimoblast development on the female gametophyte), two distinct innovations evolved in the postfertilization development in diploid gonimoblast filaments. The first is found in the Corallinophycidae (except Rhodogorgonales), Ahnfeltiophycidae,

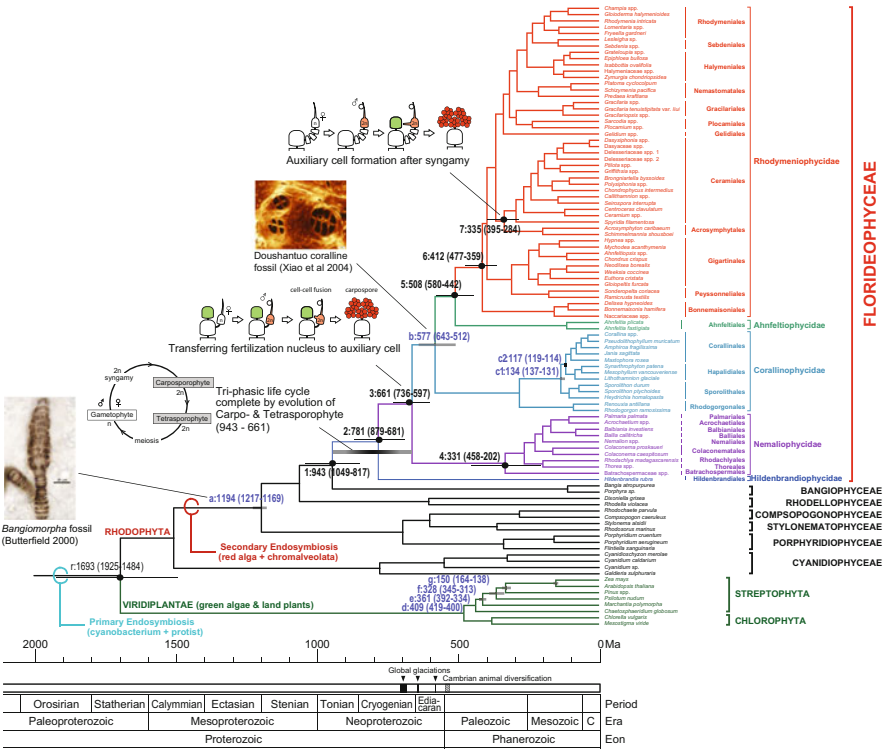

Fig. 6 Divergence time and evolution of the red algae. Primary and secondary endosymbiosis events are indicated with *cyan* and *red lines*, respectively. The three key evolutionary events are indicated with diagrams at the estimated evolutionary timeline. Triphasic life cycle, postfertilization "cell-to-cell fusion" mechanisms between carpogonium (fertilized egg) and an auxiliary cell, and the formation of an auxiliary cell after fertilization (syngamy) are indicated (Modified from Yang et al. 2016)

and Rhodymeniophycidae (661 Ma), where the zygotic nucleus and derivatives in the carpogonium move to an auxiliary cell by "cell-to-cell fusion" mechanisms followed by carposporophyte development, release of carpospores, and eventual sporic meiosis on the tetrasporophyte. The second innovation is only found in the Ceramiales (335 Ma) of the Rhodymeniophycidae, where an auxiliary cell is formed after fertilization (syngamy) followed by movement of the zygotic nucleus to the auxiliary cell. In addition within the Florideophyceae, especially in the Rhodymeniophycidae, there are numerous types of pre- and postfertilization cell-to-cell fusion mechanisms that have been used for ordinal diagnostic characters in florideophyte classification schemes (i.e., Hommersand and Fredericq 1990; Krayesky et al. 2009; Withall and Saunders 2006). The great diversity in pre- and postfertilization strategies in the Rhodymeniophycidae has resulted in the most successful subclass that comprises more than 70% of species richness in the entire Rhodophyta.

Evolutionary Relationships

The monophyly of Rhodophyta, Viridiplantae (green algae and land plants), and Glaucophyta, collectively referred to as the Archaeplastida (Adl et al. 2005), is supported by diverse molecular data (Chan et al. 2011; Hackett et al. 2007; Jackson and Reyes-Prieto 2014; Moreira et al. 2000; Rodriguez-Ezpeleta et al. 2005; Price et al. 2012; Reyes-Prieto and Bhattacharya 2007; Yoon et al. 2002b; Yoon et al. 2004), although a paraphyletic origin of these lineages cannot yet be ruled out (Parfrey et al. 2010; Yabuki et al. 2014; Yoon et al. 2008). However, because of the consistency between plastid and nuclear gene phylogenies, the single primary endosymbiosis hypothesis is widely accepted. This theory posits the origin of the plastid by acquisition of a cyanobacterium in the common ancestor of Archaeplastida >1,500 million years ago (see Fig. 6), followed by divergence of the greens, glaucophytes, and red algal lineages. These three major photosynthetic lineages share two-membrane-bounded plastids. Internal relationships (i.e., red-green monophyly vs. green-glaucophyte monophyly), however, are not fully resolved.

One of the most important evolutionary contributions of the red algae has been as a plastid donor through secondary endosymbiosis to the chlorophyll-*c* containing eukaryotic groups including the SAR group (Stramenopiles; Alveolates – dinoflagellates, apicomplexa, and ciliates; Rhizaria), cryptophytes, and haptophytes (Bhattacharya et al. 2004; Hackett et al. 2007; Yoon et al. 2002a, b) (see, e.g., ▶ Ciliophora ▶ Dinoflagellata ▶ Cryptophyta (Cryptomonads) and ▶ Haptophyta). Although the monophyly of these groups is still debated (Burki et al. 2016; Parfrey et al. 2011), plastid monophyly of the noncyanidiophycean red algal and chlorophyll-*c* containing lineages is strongly supported (Yoon et al. 2002a, b, 2004). Photosynthetic groups from these lineages have plastids bounded by three (i.e., peridinin-containing dinoflagellaes) or four (stramenopiles, cryptophytes, and haptophytes) membranes. Based on molecular clock analysis, Yoon et al. (2004) suggested 1,274 Ma as the date for the red algal secondary endosymbiosis (see Fig. 6).

Phylogenetic relationships between all major groups of Rhodophyta have been studied by Yoon et al. (2006), Le Gall and Saunders (2007), Verbruggen et al. (2010), and Yang et al. (2015). Based on a broadly sampled multigene phylogeny, with a focus on nonflorideophycean red algae, Yoon et al. (2006) identified several well-supported lineages, with the earliest diverged being the Cyanidiophyceae, and a strong monophyly of the Bangiophyceae and Florideophyceae. They proposed the seven-class system, although internal relationships among the four classes Compsopogonophyceae, Porphyridiophyceae, Rhodellophyceae, and Stylonematophyceae remain unresolved. In contrast, Le Gall and Saunders (2007) focused on the internal relationships of the Florideophyceae using combined EF2, SSU, and LSU rDNA sequences. They resolved five subclasses and established the subclass Corallinophycidae. Recently, Yang et al. (2015) largely resolved the internal relationships of the 12 orders of the Rhodymeniophycidae with a strong to moderately supported phylogeny based on

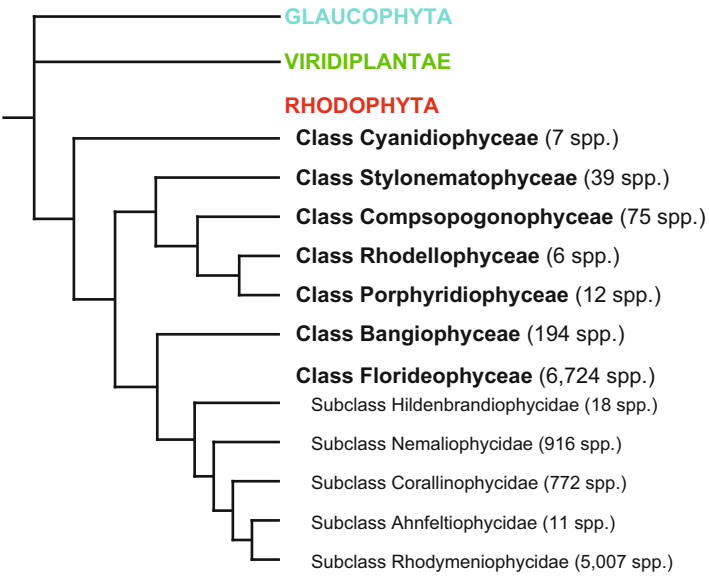

Fig. 7 Schematic phylogenetic relationships of the red algal classes and subclass based on Le Gall and Saunders (2007), Yoon et al. (2006), and Lee et al. (unpublished)

mitochondrial genome data. A more recent analysis using red algal plastid genome data from 45 species in all seven classes, 5 Florideophyceae subclasses, and 12 Rhodymeniophycidae orders resolved the four classes (i.e., Compsopogonophyceae, Porphyridiophyceae, Rhodellophyceae, and Stylonematophyceae) that diverged early (Lee et al., unpublished). After the divergence of the Cyanidiophyceae, the Stylonematophyceae diverged next, followed by the Compsopogonophyceae, and the Rhodellophyceae + Porphyridiophyceae clade (Fig. 7). Results from mitochondrial (e.g., Yang et al. 2016) and plastid genome analyses (Lee et al., unpublished) strongly suggest that organellar genome data can provide sufficient phylogenetic information to resolve most phylogenetic relationships in the Rhodophyta.

Genome Reduction in Rhodophyta

Although the red and green algal lineages putatively share a sister group relationship in the Archaeplastida (as described above), each has followed a vastly different path since their split. Genomes in the green lineage show dramatic expansion of gene families associated with the birth of land plants. In contrast, red algae likely have survived an ancient phase of extremophily (i.e., life in extreme environments such as volcanic hot springs) that resulted in extreme genome reduction (GR). This so-called hot start was followed by diversification into normal habitats and the origin of

multicellularity, without massive gene gains (Bhattacharya et al. 2013; Collén et al. 2013; Collén 2015; Nakamura et al. 2013).

GR is a hallmark of symbionts, intracellular pathogens, and parasites (Keeling and Slamovits 2005; McCutcheon and Moran 2012). The highly simplified gene inventory and reduced functions in these taxa precipitates an obligate association with a host (Keeling and Slamovits 2005; Moran 2002). In free-living organisms, GR is associated with reduced metabolic flexibility and life in specialized niches such as in oligotrophic [e.g., *Prochlorococcus* (Dufresne et al. 2003) and *Ostreococcus* (Derelle et al. 2006)] and extremophilic [e.g., Cyanidiophytina red algae (Qiu et al. 2013), *Galdieria sulphuraria* (Schönknecht et al. 2013) and *Cyanidioschyzon merolae* (Matsuzaki et al. 2004)] environments that are relatively invariant over time. Given the narrowing of genetic potential, GR presumably precludes subsequent taxonomic and ecological diversification. Intriguingly, red algae appear to provide a counter-example to this perspective. The ability of this lineage to diversify and adapt to novel mesophilic habitats, despite a highly reduced gene inventory, ultimately led to the rise of a remarkably successful branch of life that shows immense morphological diversity and complex life cycles (Saunders and Hommersand 2004). The available data suggest that GR in red algae provides a model for deciphering the lower limits of gene diversity in free-living taxa and potentially offers insights into how novel solutions evolved for promoting the diversity of Rhodophyta.

Evidence for Genome Reduction in the Red Algal Common Ancestor

Available complete genome data suggest that red algae encode only a modest gene inventory when compared to Viridiplantae, with extant species typically containing fewer than 10,000 genes, e.g., in the mesophilic unicellular red alga *Porphyridium purpureum* (Bhattacharya et al. 2013) and in the extremophilic unicellular red algae *C. merolae* (Matsuzaki et al. 2004) and *G. sulphuraria* (Schönknecht et al. 2013). Even red seaweeds such as *Chondrus crispus* (Collén et al. 2013) and *Pyropia yezoensis* (Nakamura et al. 2013), which are complex multicellular lineages and have sophisticated life cycles, contain a gene inventory comparable to their unicellular relatives (i.e., 9,606 and 10,327 putative genes, respectively). An analysis of gene family evolution under a phylogenetic framework that incorporated all available genomic data (e.g., novel transcriptomes from the Marine Microbial Eukaryote Transcriptome Sequencing Project; Keeling et al. 2014) is summarized in Fig. 8a. These results correlate the estimated number of core gene families and thallus morphology in each lineage and provide evidence for limited gene expansion in the derived, mesophilic lineages (Qiu et al. 2015). Fig. 8b shows the results of the analysis of orthologous gene families [using OrthoMCL (Li 2003)], based on Dollo parsimony (Farris 1977), and the estimation of gene family gains and losses under the same parameters as described in Qiu et al. (2015).

The results shown in Fig. 8 suggest that the net loss of genes was most severe in the stem lineage of red algae and in the common ancestor of the Cyanidiophytina.

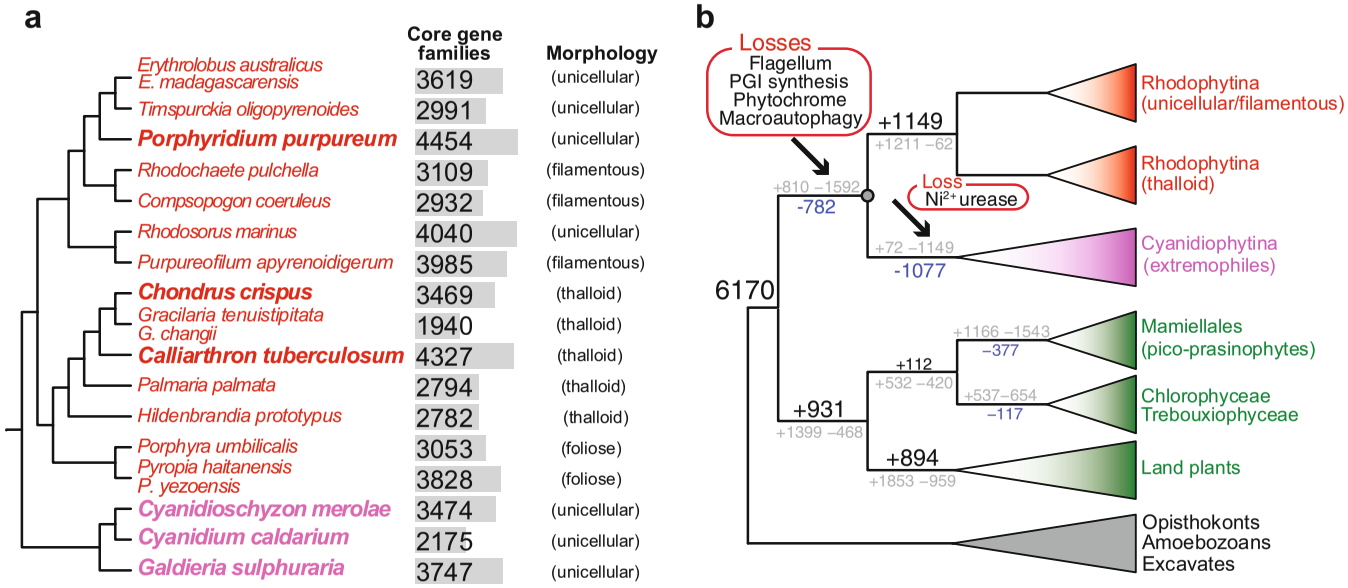

Fig. 8 (**a**, **b**) Genome-wide analysis of red algae. (**a**) The number of core gene families in red algal taxa for which genome or transcriptome data are available. A core gene family is defined as those present in the Cyanidiophytina or Rhodophytina ancestor, or earlier (for details, see Qiu et al. 2015). Using the number of core gene families as a measure, *Rhodosorus marinus* shows a coverage (e.g., 91%) that is comparable to that of *Porphyridium purpureum*, which has a completely sequenced genome. The approximate sequence coverage in other species is expressed likewise. Sequences from *Gracilaria tenuistipitata* and *Gracilaria changii* were pooled. The same was the case for *Pyropia yezoensis* and *Pyropia haitanensis* sequences. Taxa in boldface have complete genome sequences available. The tree topology of the mesophilic lineages is tentative and has no impact on the estimation of core gene families that have more ancestral origins. (**b**) Estimate of the number of gene family gains and losses (*gray* number at each branch) in *red* algae and Viridiplantae. Net gene family gains or losses are shown in *black* and *blue* text, respectively. Net gene family changes, when >600, are shown as proportionately sized numbers. The *arrows* indicate the two major phases of net gene loss in *red* algae. The major functional losses associated with each phase of genome reduction are also shown (for details, see Qiu et al. 2015)

Remarkably, about one-quarter (1,592/6,170, or 26%) of conserved algal "core" genes were lost in the red algal common ancestor. This is in contrast to the pronounced net gene gains in the Viridiplantae stem lineage (+931) and in the lineage leading to land plants (+894; Fig. 8b). Although we expect these numbers to change as more genomes are added to the analysis, the most compelling comparison is between the stem lineages of red and green algae. The Rhodophyta ancestor would have to gain ca. 1,700 genes on this branch to achieve the expansion found in Viridiplantae. The large gene gains at the root of mesophilic red algae (+1,149) needs to be interpreted with caution because some of these genome assemblies are highly fragmented (i.e., leading to over-estimation of gene numbers) and there are contamination issues associated with the EST data included in the analysis (Qiu et al. 2015).

Functions Lost in the Red Algal Ancestor

The impact of GR on red algae is most obviously manifested in the absence of flagella and basal bodies. Other notable losses in the red algal stem lineage include light-sensing phytochromes, glycosylphosphatidylinositol (GPI)-anchor biosynthesis, macroautophagy pathways (Qiu et al. 2015), and then subsequent loss of the nickel-dependent urease pathway in the Cyanidiophytina common ancestor (Qiu et al. 2013) (Fig. 8b). Interestingly, flagella and the GPI-anchoring function are preserved in parasites such as *Trypanosoma* species and *Giardia lamblia* (Das et al. 1994) that also underwent drastic GR. This observation suggests a differential impact of GR in cells adapted to different lifestyles, i.e., intracellular pathogens versus free-living cells. Whereas flagella loss is relatively common in eukaryotes, GPI anchoring is a highly conserved function and plays critical, perhaps indispensible roles in a wide variety of organisms (Kawagoe et al. 1996; Lillico et al. 2003; Takeda and Kinoshita 1995), as is the case for macroautophagy (Mizushima and Levine 2010). It is currently unknown how red algae cope with the loss of these conserved functions.

Classification

Here we follow the seven-class system (Yoon et al. 2006) of the Rhodophyta (see Table 1 and Fig. 7) and describe the basic diagnostic characters and classification status for each class based on the previous review (Yoon et al. 2010).

Cyanidiophyceae is a group of asexual, unicellular red algae that thrive in acidic (pH 0–4) and high-temperature (25–55 °C) conditions around hot springs and/or acidic sulfur fumes (Pinto et al. 2003). This is the first group to diverge, and members contain the ultrastructural character of a Golgi-ER association. The class Cyanidiophyceae contains one order Cyanidiales, two families Cyanidiaceae and Galdieriaceae, and three genera *Cyanidium*, *Cyanidioschyzon*, and *Galdieria*, based on morphological characters. Molecular phylogenetic studies, however, have revealed great hidden diversity in this lineage (Gross et al. 2001; Pinto et al. 2003;

Table 1 Current taxonomic system of the red algae according to Yoon et al. (2006, 2010) and Le Gall and Saunders (2007)

Kingdom Plantae Haeckel
Phylum Rhodophyta Wettstein
Subphylum Cyanidiophytina Yoon, Müller, Sheath, Ott, et Bhattacharya
Class Cyanidiophyceae Merola, Castaldo, De Luca, Gambardella, Musacchio, et Taddei
Order Cyanidiales Christensen
Subphylum Rhodophytina Yoon, Müller, Sheath, Ott, et Bhattacharya
Class Bangiophyceae Wettstein
Order Bangiales Nägeli
Class Compsopogonophyceae Saunders et Hommersand
Order Compsopogonales Schmitz in Engler et Prantl
Order Erythropeltidales Garbary, Hansen, et Scagel
Order Rhodochaetales Bessey
Class Florideophyceae Cronquist
Subclass Hildenbrandiophycidae Saunders et Hommersand
Order Hildenbrandiales Pueschel et Cole
Subclass Nemaliophycidae Christensen
Order Acrochaetiales Feldmann
Order Balbianiales Sheath et Müller
Order Balliales Choi, Kraft, et Saunders
Order Batrachospermales Pueschel et Cole
Order Colaconematales Harper et Saunders
Order Entwisleiales Scott, Saunders, et Kraft
Order Nemaliales Schmitz
Order Palmariales Guiry et Irvine
Order Rhodachlyales Saunders, Clayden, Scott, West, Karsten, et West
Order Thoreales Müller, Sherwood, Pueschel, Gutell, et Sheath
Subclass Corallinophycidae Le Gall et Saunders
Order Corallinales Silva et Johansen
Order Hapalidiales Nelson, Sutherland, Farr, et Yoon
Order Rhodogorgonales Fredericq, Norris, et Pueschel
Order Sporolithales Le Gall, Payri, Bittner, et Saunders
Subclass Ahnfeltiophycidae Saunders et Hommersand
Order Ahnfeltiales Maggs et Pueschel
Order Pihiellales Huisman, Sherwood, et Abbott
Subclass Rhodymeniophycidae Saunders et Hommersand
Order Acrosymphytales Withall et Saunders
Order Bonnemaisoniales Feldmann et Feldm.-Maz.
Order Ceramiales Oltmanns
Order Gelidiales Kylin
Order Gigartinales Schmitz
Order Gracilariales Fredericq et Hommersand
Order Halymeniales Saunders et Kraft

Order Porphyridiales Kylin ex Skuja
Class Rhodellophyceae Cavalier-Smith
Order Dixoniellales Yokoyama, Scott, Zuccarello, Kajikawa, Hara, et West
Order Glaucosphaerales Yang, Scott, Yoon, et West
Order Rhodellales Yoon, Müller, Sheath, Ott, et Bhattacharya
Class Stylonematophyceae Yoon, Müller, Sheath, Ott, et Bhattacharya
Order Rufusiales Zuccarello et West
Order Stylonematales Drew

Yoon et al. 2002a, b) from comprehensive sampling in Italy (Ciniglia et al. 2004), Yellowstone National Park, Japan, and New Zealand (Skorupa et al. 2013; Toplin et al. 2008), Iceland (Ciniglia et al. 2014), and Taiwan (Hsieh et al. 2015). As Yoon et al. (2010) suggested, taxonomic revision in the Cyanidiophyceae is required at the order, family, and genus levels.

Compsopogonophyceae is a group of multicellular but simple filamentous, blade, and tubular red algae. It is characterized by having a Golgi-ER association and floridoside as the low molecular weight carbohydrate (LMWC) (Broadwater and Scott 1994; Karsten et al. 2003). *Rhodochaete* and *Compsopogon* contain pit plugs with a simple plug core without a cap or membrane (Scott et al. 1988). The class Compsopogonophyceae is classified into three orders: one freshwater order, Compsopogonales, with two families Boldiaceae and Compsopogonaceae, and two marine orders, Erythropeltidales and Rhodochaetales, with 14 genera. The presence of sex was reported from two sister taxa *Erythrotrichia* and *Rhodochaete* (Hawkes 1988; Magne 1960, 1990), and packets of spores may be indicative of sexual reproduction in *Pyrophyllon* and *Chlidophyllon* (Nelson et al. 2003).

Porphyridiophyceae is a group of unicellular red algae that contain a single branched or stellate plastid without a peripheral thylakoid, a Golgi association with ER/mitochondria (Scott et al. 1992), and floridoside as a LMWC (Karsten et al. 2003). This class has a single order Porphyridiales, one family Porphyridiaceae, and four unicellular genera *Erythrolobus*, *Flintiella*, *Porphyridium*, and *Timspurckia*.

Rhodellophyceae is a class that includes the unicellular red algae *Corynoplastis*, *Dixoniella, Glaucosphaera*, *Neorhodella*, and *Rhodella* and contains three orders Dixoniellales, Glaucosphaerales, and Rhodellales (Scott et al. 2011; Yokoyama et al. 2009; Yoon et al. 2006). Dixoniellales and Rhodellales contain mannitol as the LMWC. The LMWC for the Glaucosphaerales is unknown (Karsten et al. 2003). *Dixoniella*, *Glaucosphaera*, and *Neorhodella* have a Golgi-nuclear association,

differing from *Corynoplastis* and *Rhodella*, which have a Golgi-ER association (Scott et al. 1992, 2011).

Stylonematophyceae comprises diverse morphological forms of unicellular, pseudofilamentous, and filamentous taxa with thick mucilaginous walls and cells lacking pit plugs. A Golgi-ER association and digeneaside and sorbitol as LMWCs are diagnostic characters for this group (Broadwater and Scott 1994; Karsten et al. 2003) although digeneaside is missing in *Chroodactylon*, and dulcitol is present in *Rhodospora*. A single stellate plastid with a pyrenoid is found in most taxa. This class has two orders, Stylonematales and Rufusiales, two families, Stylonemataceae and Rufusiaceae, and 14 genera (*Bangiopsis, Chroodactylon, Chroothece, Colacodictyon, Empselium, Goniotrichopsis, Kylinella, Neevea, Purpureofilum, Rhodaphanes, Rhodosorus, Rhodospora*, *Rufusia,* and *Stylonema*) that are all reported from marine habitats.

Bangiophyceae has either simple unbranched filaments or leaf-shaped foliose thalli, and most species live in the marine environment. The Bangiales includes the most highly valued seaweed aquaculture crops in the world (i.e., *Pyropia*, previously known as *Porphyra*). A biphasic life cycle is common in this group, with a macroscopic gametophyte alternating with a microscopic conchocelis phase. The conchocelis phase in the Bangiales has pit plugs with a single cap layer but no cap membrane (Pueschel and Cole 1982). The class Bangiophyceae includes one order Bangiales, one family Bangiaceae, and 12 currently recognized genera with ca. 130 species. The real diversity, however, is likely underestimated, and further genera need to be formally described (Sutherland et al. 2011).

A sister group relationship of the Bangiophyceae and Florideophyceae has been suggested based on numerous morphological and molecular data including features of the reproductive cells, Golgi association with ER/mitochondria, the presence of pit connections, and the presence of group I introns (Gabrielson et al. 1985; Gabrielson et al. 1990; Freshwater et al. 1994; Ragan et al. 1994; Oliveira and Bhattacharya 2000; Müller et al. 2001; Yoon et al. 2002b; Yoon et al. 2004; Yoon et al. 2006).

Florideophyceae includes around 6,700 species that are mostly macroscopic; they are the most morphologically and genetically diverse of all red algal classes. The triphasic life cycle comprising a carposporophyte, tetrasporophyte, and a gametophyte phase is common in this group. Five subclasses are recognized (Hildenbrandiophycidae, Nemaliophycidae, Corallinophycidae, Ahnfeltiophycidae, and Rhodymeniophycidae) with 29 orders that are distinguished by molecular data, ultrastructural features (i.e., pit plug connection between neighboring cells including number of cap layers and membranes), and reproductive development (i.e., pre- and postfertilization processes) (see review by Saunders and Hommersand 2004).

The subclass **Hildenbrandiophycidae** contains a single order the Hildenbrandiales, with two genera *Hildenbrandia* and *Apophlaea*, characterized by pit plugs with a single cap layer covered by a membrane (Pueschel and Cole 1982). Although zonately and irregularly divided tetrasporangia have been reported, there are no reports of recognizable gametophytic reproductive structures (carpogonia or spermatangia) or a sexual life history. The **Nemaliophycidae** is characterized

by the presence of pit plugs with two cap layers. Ten orders are recognized: Acrochaetiales, Balbianiales, Balliales, Batrachospermales, Colaconematales, Entwisleiales, Nemaliales, Palmariales, Rhodachlyales, and Thoreales. The **Corallinophycidae** is characterized by pit plugs with a domed outer cap layer and calcified thalli. It contains four orders: the Corallinales, Hapalidiales, Rhodogorgonales, and Sporolithales. The **Ahnfeltiophycidae** includes two orders the Ahnfeltiales and Pihiellales that are characterized by having naked pit plugs lacking caps and membranes (Maggs and Pueschel 1989). The **Rhodymeniophycidae** is the most taxon-rich (ca. 5,000 spp.) red algal subclass and is divided into 12 orders: Acrosymphytales, Bonnemaisoniales, Ceramiales, Gelidiales, Gigartinales, Gracilariales, Halymeniales, Nemastomatales, Peyssonneliales, Plocamiales, Rhodymeniales, and Sebdeniales. All have pit plugs covered by a membrane only (Pueschel and Cole 1982).

Summary

Red algae occupy a wide variety of habitats and play important economic and ecological roles on our planet. They remain poorly studied at the genetic level but have a rich history of morphological, biochemical, and life history analyses. Ultimately all of these diverse areas of science will need to unite to provide comprehensive understanding of the features that make red algae unique members of the tree of life. As an example of recent advances, the explosion of genomic data has significantly changed our views of red algal evolution. Rather than being typical photosynthetic members of the Archaeplastida, we now recognize Rhodophyta as a distinct group that does not share the expected large gene inventory with Viridiplantae and Glaucophyta. In fact, they appear to have shed about one-quarter of the ancestral gene set, leading to nuclear genome reduction. This finding may be explained by an ancient adaptation to an extremophilic environment such as in the vicinity of hot springs: this is the so-called hot start hypothesis for Rhodophyta. Despite this surprising revelation about their early evolution, which is expected to result in severely reduced taxonomic diversity [i.e., extant Cyanidiophytina are species depauperate; 6–10 species/lineages (Reeb and Bhattacharya 2010)] and further habitat restriction, the Rhodophytina ancestor managed to re-emerge, diversify into a variety of mesophilic environments, and develop multicellularity and a complex triphasic life cycle. If this hypothesis is correct, then understanding how this feat was achieved remains a major unanswered question to be addressed by future researchers.

Zygnematophyta

4

John D. Hall and Richard M. McCourt

Abstract

The Zygnematophyta are among the most diverse green algae, with a variety of thallus types (filaments, unicells, colonies), cell wall structure (one to several layers, with varying degrees of ornamentation), and approximately 4,000 described species. The group lacks flagella at all stages of the life cycle. Several types of asexual spores are produced. Sexual reproduction, when present, involves conjugation or the union of two haploid vegetative protoplasts (individual cells of filaments or unicells) to form a zygospore, which undergoes meiosis to produce a new haploid thallus upon germination. Almost exclusively freshwater, these algae are common in ponds, lakes, and streams, in surface mats, or as phytoplankton or benthic growths. Many, but not all, are found in oligotrophic to mesotrophic waters of moderate to low pH, although the diversity of habitats occupied spans a wide range and may be quite specific for individual species. The fossil record extends at least to the Carboniferous. Recent analyses have placed this group as the sister taxon to land plants, despite the dramatic differences in morphology, life cycles, and reproduction. The group includes the well-known *Spirogyra* and numerous beautiful unicellular forms known as desmids, many of which have elaborate external ornamentations (e.g., spines, granules, large lobes). The conjugating green algae are important as ecological indicator species and for the ecological services they provide.

●●**Gonatozygaceae** (*Gonatozygon*)

Introduction

The Zygnematophyta, here considered a phylum, is equivalent to the class Zygnematophyceae in the botanical literature. The group comprises those freshwater green algae with two unique characteristics: sexual reproduction by conjugation and absence of flagellate (mastigote) cells in the life cycle. The phylum contains some of the most beautiful microscopic organisms known (Fig. 1). The elegance of their microscopic cellular architecture is obscured by their macroscopic appearance as floating pond scums, green planktonic masses, and slimy films on the surfaces of plants and other substrates.

The Zygnematophyta is usually divided into two groups (considered two orders of the class Zygnematophyceae): Desmidiales and Zygnematales (Table 1). The order Zygnematales traditionally included the families Zygnemataceae and Mesotaeniaceae (Mix 1972). The family Zygnemataceae (14 genera, over 800 species) included filamentous algae with cell walls that lack a median incision or pores. The

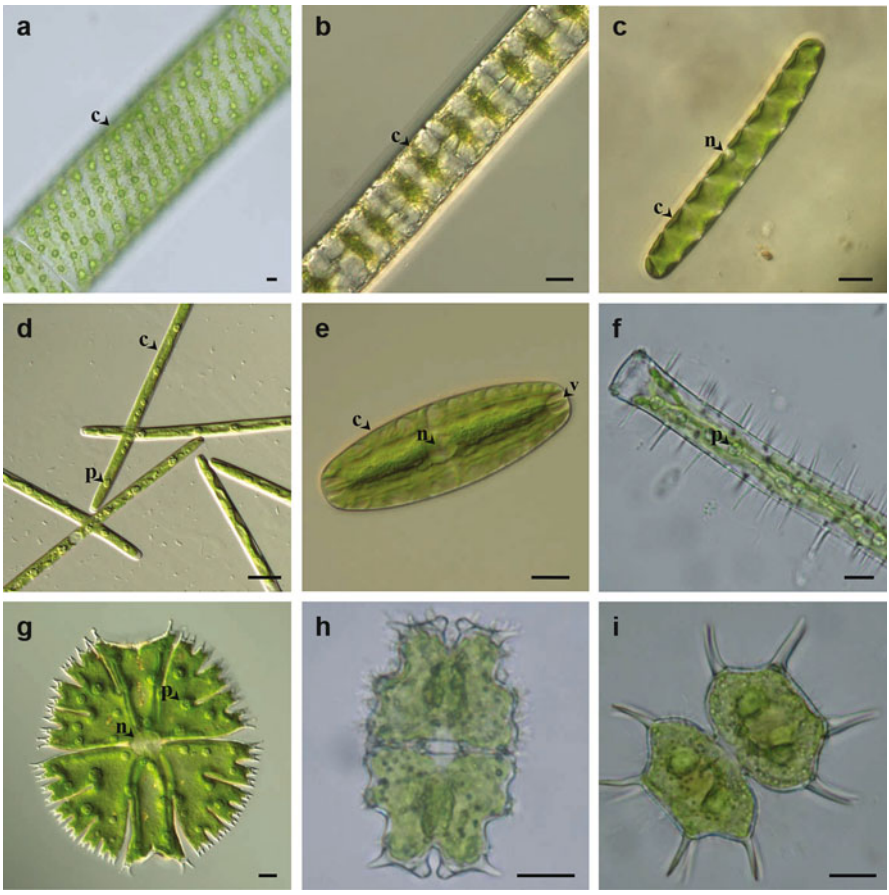

Fig. 1 Structural diversity in the Zygnematophyta. (**a**) *Spirogyra* sp.; (**b**) *Zygnema* sp.; (**c**) *Spirotaenia condensata*; (**d**) *Roya obtusa* var. *montana*; (**e**) *Netrium digitus*; (**f**) *Gonatozygon aculeatum*; (**g**) *Micrasterias rotata*; (**h**) *Euastrum evolutum* var. *glaziovii*; (**i**) *Xanthidium cristatum var. hipparquii.* Structures: *c* chloroplast, *n* nuclear region at site of isthmus between semicells, *p* pyrenoid, *v* apical vacuole. Scale bar = 10 μm in each micrograph

family Mesotaeniaceae contained the saccoderm desmids and was the smallest family (8 genera, approximately 100 species). Molecular phylogenetic studies indicate that the families of the Zygnematales are not monophyletic (McCourt et al. 2000; Gontcharov et al. 2003; Hall et al. 2008a). Zygnematales are generally oblong, rod shaped, or cylindrical, and the smooth cell wall lacks pores; the primary wall is a homogeneous piece, lacking a median constriction. The Desmidiales (41 genera, 3,500+ species) contains the placoderm desmids, which are divided into four families, the Closteriaceae, Gonatozygaceae, Peniaceae, and Desmidiaceae, the latter being the largest of the four families (36 genera, 3,000 species, 12,000 subspecific taxa) (Gerrath 1993; Hall and Delwiche 2007). Most placoderm desmids

[c]Dubious genera reported only once from India

are unicellular, but filamentous and colonial species are known. Placoderm cell walls have pores and may be intricately ornamented. Each cell consists of two mirror-image parts called semicells that are joined at a narrow midregion or isthmus where the nucleus is located (Fig. 1g). Chloroplasts and other nonnuclear cell contents are divided equally between semicells. The structure of semicells is often complex, with two, three, or more planes of symmetry. The number of lobes on a semicell on end view determines its degree of radiation, e.g., biradiate semicells have two corners, triradiate have three, and so on.

Because of their intriguing structure and reproduction, the zygnematophytes have been extensively studied since the mid-nineteenth century. Research continues in many areas of zygnematophycean biology. In this review, we focus on seminal works and literature published in the last 30 years. Investigators tend to

specialize on one of the three traditional families, a fact reflected in treatments in monographs and books. Reviews and monographs on filamentous Zygnematales (Zygnemataceae) include Transeau (1951), Randhawa (1959), Hoshaw (1968), Kadlubowska (1972, 1984), and Rundina (1998). Major references on unicellular Zygnematales (Mesotaeniaceae) and Desmidiales are *A Synopsis of North American Desmids* (six volumes, Prescott et al. 1972, 1975, 1977, 1981, 1982; Croasdale et al. 1983), Růžička (1977, 1981), Brook (1981), Förster (1982), Croasdale and Flint (1986, 1988), Croasdale et al. (1994), Palamar-Mordvintseva (2003, 2005), Coesel and Meesters (2007), and Brook and Williamson (2010).

Members of the Zygnematophyta have not been exploited for economic use in any major way. A few species have been used in fish aquaculture, and natural populations are abundant enough that one can infer an important role in natural food webs. Some studies suggest that green algae in general and *Spirogyra* in particular may be useful for the detection and recovery of certain metals from contaminated waterways (Gupta et al. 2001; Singh et al. 2007; Rai et al. 2008). Members of the conjugating green algae, including *Spirogyra*, *Mougeotia*, and the Desmidiales, have been used as indicators of trophic status and water quality (Jarnefelt 1952; Rawson 1956; Brook 1965; Coesel 2001).

Biogeography, Habitats, and Ecology

Zygnematophytes are restricted almost entirely to freshwater, although a few species have been collected from brackish waters. Many conjugating green algae are minute, have large geographic ranges, and are able to survive in many marginal habitats; however, biogeographic patterns do exist. Krieger (1937) proposed that many desmids were part of geographic groups and recognized ten continental-scale geographic areas with distinct desmid floras. Coesel (1996) considered this hypothesis in light of modern distributional data and concluded that there are regional floras, although the Arctic/Alpine flora seems to be mostly determined by a minimum average temperature. The apparent existence of regional desmid floras may be the product of insufficient sampling in some regions. However, many conspicuous species characteristics of a particular area are known only from less-studied regions (such as tropical Asia, Africa, and Australia) and, presumably, would have been noticed in areas with a longer history of investigation (such as Europe and North America) if those species existed there (Tyler 1996). Hundreds of local, regional, and national floras documenting the distribution of zygnematophytes have been published. A search of online databases will reveal many of the most recently contributed books and papers. Older floras are referenced in taxonomic treatments and reviews (e.g., Kadlubowska 1984; Prescott 1984).

Zygnematophytes occur in a wide variety of habitats, ephemeral pools, ponds, lakes, streams, rivers, marshes, and bogs, and on every continent. A considerable number of artificial habitats have been colonized by zygnematophycean species. In fact, the widespread occurrence of reservoirs, cattle tanks, roadside ditches,

irrigation canals, and other water impoundments has probably had a significant but unknown effect on the distribution of many species. Within a given habitat, species often show preference for microhabitats. Planktonic species occupy the water column, either permanently as euplankton or temporarily as tychoplankton after being dislodged from the substrate. Relatively few desmid species are truly planktonic. Most conjugating green algae are benthic or periphytic and grow on surfaces or occasionally attached to substrates by means of rhizoids or mucilage. Rhizoids that attach to substrate may be present in all of the filamentous Zygnematales (e.g., *Mougeotia*, *Spirogyra*, and *Zygnema*). Epibiotic species grow on the surfaces of the submerged leaves and stems of plants, especially on plants with highly dissected leaves such as *Utricularia*. Epibionts and species that live in water near plants make up the periphyton.

Some zygnematophytes thrive in habitats subject to extreme physical conditions. For example, some species of saccoderm desmid genera *Ancylonema*, *Cylindrocystis*, and *Mesotaenium* occur on snow and ice. *Cylindrocystis* has also been found in desert crust communities (Lewis and Lewis 2005). Placoderm desmids can be found in Alaskan tundra pools as well as the Antarctic Peninsula and some sub-Antarctic islands, in which freezing temperatures are tolerated for long periods. The filamentous *Zygogonium* is found in very acid pools and rivers (pH < 3) (e.g., Zettler et al. 2002).

Although zygnematophytes occur in a wide variety of habitats, species show distinct preferences for certain habitats characterized by water chemistry and productivity. A generalization often made is that desmids prefer slightly acidic waters (pH 4–7), such as pools in acid peat bogs. Brook (1981) pointed out that, although this generalization is true, a number of species are common in alkaline waters. Acidic habitats support desmid species with the greatest ornamentation and morphological complexity. Generalizations about the distribution of the Zygnemataceae are difficult to make because of the paucity of comparable field measurements. A series of more than 250 collections of *Spirogyra, Zygnema*, and *Mougeotia* from sites across the USA in spring 1982 showed that the temperature and pH of the sites were remarkably uniform at the time of collection (ca. 20 °C and pH 6, in spring season), but this may have been a correlation, rather than a cause (McCourt et al. 1986).

Considerable attention has been devoted to the chemistry and productivity of desmid habitats (Brook 1981). Whereas most placoderm desmids, especially planktonic species, are characterized as oligotrophic (occurring in water of low productivity, low pH, high levels of free CO_2, and low levels of bicarbonate), some species commonly occur in eutrophic waters (high productivity, high pH, low levels of free CO_2, and high levels of bicarbonate). Oligotrophic species requiring high levels of free CO_2 for photosynthesis may be outcompeted in eutrophic lakes by eutrophic species that are able to use bicarbonate directly for photosynthesis (Brook 1981). Desmid assemblages have not been definitively linked to chemical properties of water bodies. Factors controlling local distribution of conjugating green algae remain largely speculative.

Nonetheless, the occurrence of distinct assemblages of desmids in particular water types has led to the effective use of assemblages as general indicators of trophic status and water quality (Brook 1981; Coesel 2001, 2003). Researchers have classified desmid communities into associations, i.e., assemblages, characterized by predictable combinations of species. Heimans (1969) noted that, although it is useful to categorize species as oligotrophic or eutrophic, more than one factor such as pH or eutrophy is involved, and a species' response to these multiple factors may change from one region to another. Coesel (1982) studied desmid assemblages in the Netherlands. He used principal components analysis to categorize over 200 species in quaking fen and lowland marsh habitats into ecologically relevant clusters of species. Cluster composition was affected by pH, successional stage of the *Sphagnum* mat in the fen habitat, oligotrophic or eutrophic nature of water, and rapidity with which these factors changed in water-filled depressions in the *Sphagnum* mat.

Coesel (2001) proposed an index for the use of desmids as biological indicators of conservation value of sites in the Netherlands. This index (scaled from 0 to 10) takes into consideration more information about the species than presence or absence. Species richness, the presence of rare taxa, and the presence of taxa indicative of habitat maturity are included in the calculation of the conservation value of a particular habitat. So sensitive are the desmids to environmental parameters that the desmid flora will sometimes change before there are noticeable differences in the macroflora of a degraded habitat (Coesel 2003).

Little is known about the ecology and habitat preferences of filamentous Zygnematales. For a brief review of published work, see Hoshaw (1968). Filamentous Zygnematales are widely distributed but less frequently reported than other green algae because they often occur in ephemeral pools and because species identification relies on characteristics of the infrequently encountered zygospores. Pessoney (1968), in an unpublished dissertation, described reproduction of *Spirogyra*, *Zygnema*, and *Mougeotia* in temporary, semipermanent, and permanent ponds near Austin, Texas, USA. Conjugation occurred mostly in spring and was more frequent in temporary ponds that were flooded and dried in 2 weeks than in more permanent bodies of water. *Spirogyra* species tended to dominate the pools and showed the highest incidence of conjugation of the three genera.

Species of zygnematophytes are often widely distributed. Individual cells, filaments, or zygospores may be dispersed by currents, wind, insects, water birds, or other agents. Vegetative cells and spores may be carried in the gut of water birds or in mud attached to their feet. Several types of desiccation-resistant spores and cells are produced by zygnematophytes (zygospores, parthenospores, and akinetes). Rewetting of dried mud samples as much as 10 or 20 years old is a common means of starting or recovering cultures, which suggests that spore banks may persist in natural habitats over long periods of time.

Little is known of the role of Zygnematophyta in freshwater ecosystems outside of their role as primary producers. The extent and variety of the animals that graze on them are poorly known. Available data suggest that desmids are an important food source for zooplankton and possibly benthic microinvertebrates (Coesel 1997). It has

been demonstrated that grazing induces physical changes in some species of the genus *Staurastrum* (Wiltshire et al. 2003), which implies a complex relationship between these algae and the herbivores that feed on them.

Conjugating green algae are also subject to parasitism. Chytrids, other fungi, and oomycetes are known to parasitize desmids and filamentous Zygnematales and may have significant effects on algal populations (Kadlubowska 1999; see Kagami et al. 2007 for a review on chytrids). Filamentous Zygnematales are also among the preferred hosts of the parasitic dinoflagellate *Cystodinedria* (Carty 2003).

Zygnematophytes are not immune to the adverse impact of human activities. Hoshaw (1968) remarked on the destruction of habitats of the Zygnemataceae. A number of studies have documented long-term declines in natural desmid populations due to pollution and subsequent eutrophication, development of forests that shade out macrophytes that harbor periphyton, and decreased pH of waters subject to acid rain (e.g., Coesel et al. 1978; Van Dam and Buskens 1993).

Characterization and Recognition

General Features

Unicells and unbranched filaments are the most common forms in the Zygnematophyta, but colonial forms are also known. A single nucleus is usually located in the center of the cell. From one to several axile or sometimes parietal chloroplasts occur in a single cell. Chloroplast shapes range from asteroid (*Cylindrocystis* and *Zygnema*, Fig. 1b) to laminate (*Gonatozygon*, *Mesotaenium*, *Mougeotia*, and *Roya*, Fig. 1d, f) to ribbon-like (*Spirogyra* and *Spirotaenia*, Fig. 1a, c). An axile, ridged chloroplast (stellate) is found in many desmids including *Netrium* (Fig. 1e), *Closterium*, and *Penium*. Species of Desmidiaceae contain some of the largest and most elaborate chloroplasts known among the green algae. Their chloroplasts are often ridged, lobed, and highly dissected. Chloroplasts of most species contain thylakoids stacked as in plants; other species lack grana-like structures or have only rudimentary grana. Pigments include those typical of green algae and embryophytes, i.e., the descendants of a common ancestor that includes all green algae and embryophytic plants: chlorophylls *a* and *b*, β-and γ-carotenes, and several xanthophylls including loroxanthin (Donohue and Fawley 1995). Chloroplasts usually contain one or more pyrenoids (Fig. 1d, g) around which starch is stored.

Cell walls of the Zygnematophyta consist of at least three layers: an outer layer of variable composition depending on species (mucus or an amorphous pectic substance), a primary wall composed of irregularly arranged microfibrils beneath the outer layer, and an innermost layer composed of ribbon-like bands of cellulose microfibrils (Fig. 2). Many placoderm desmids shed the primary wall and retain the secondary wall as the outer covering. Ornamentations such as granules, spines, and verrucae may occur in the outer layer only or in the primary and secondary walls.

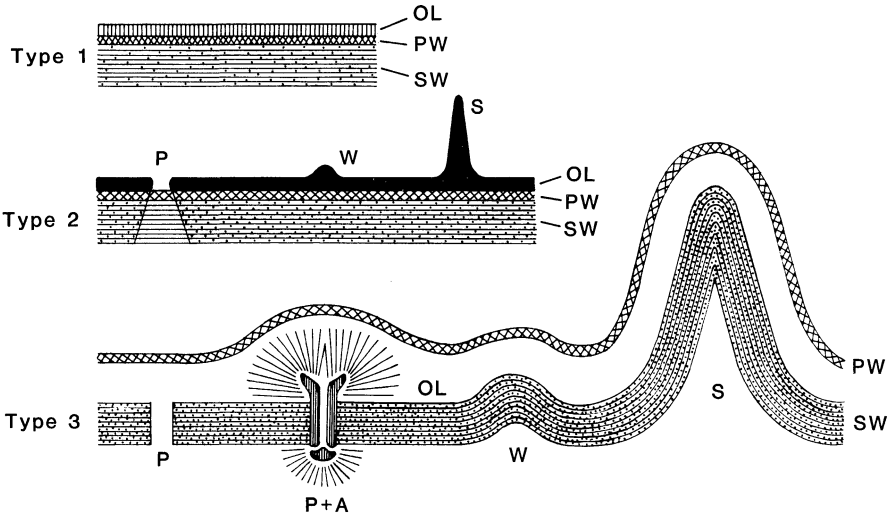

Fig. 2 Cell wall structure of the Conjugaphyta. Wall types *1*, *2*, and *3* are described in Table 2. Structures: *OL* outer layer, *PW* primary wall, *SW* secondary wall, *P* pore, *P+A* pore apparatus, *S* spine, *W* wart (After Mix 1975)

Cell wall pores are of fundamental importance in classification, although their function is not clear. Pores may be absent (Zygnemataceae, Mesotaeniaceae) or present (Desmidiales). If present, pores may penetrate only the outer layer (Closteriaceae, Gonatozygaceae, Peniaceae) or extend completely through the secondary wall (Desmidiaceae). Pores through the secondary wall in some desmids may be differentiated into a complex pore apparatus, with a lined pore channel and a "spider web" of fibrous material at the inner opening (Neuhaus and Kiermayer 1981). Extrusions of fibrous mucilage from the external openings of the pores are visible under the light microscope.

Classification and Taxonomy

Work on mitosis, cytokinesis, and kinetid (flagellar apparatus) ultrastructure in the green algae resulted in major restructuring of systematics of the green algae at the class level and reinterpretation of their presumed relationship to ancestors of land plants. Mattox and Stewart (1984) proposed the establishment of five classes in the Chlorophyta. They placed the Zygnematales (= Zygnematophyceae) in the class Charophyceae (= Charophyta) on the basis of the presence of a primitive phragmoplast in *Spirogyra*, types of enzymes for glycolate and urea metabolism known for a few genera, and the similarities of the group to *Klebsormidium*, an obviously charophycean genus (Pickett-Heaps 1975). We follow the classification of Lewis and McCourt (2004) for the class-level relationships and the classification of Mix (1972), with some modification, at the family level. The Zygnematophyta are one of several

green algal groups that are monophyletic with embryophytes and one of the major lineages of the Chlorobionta, which itself is one of the main lineages of the Archaeplastida (Adl et al. 2012; McCourt 2016). Although recent studies have changed our view of the green algal sister taxon to embryophytes (see discussion below), the working classification proposed by Lewis and McCourt (2004) is still a reasonable one.

The Zygnematophyta are part of a lineage of green algae, known as Charophyta (Karol et al. 2001), equivalent to Streptophyta of other authors (e.g., Wickett et al. 2014), that contains some green algae plus all land plants (McCourt et al. 2004; Leliaert et al. 2012). Early molecular studies with broad taxon sampling and several genes showed the conjugating green algae to be more distantly related to land plants than either the Charophyceae or Coleochaetophyceae (Karol et al. 2001). However, later work with many genes, albeit with fewer taxa, supported zygnematophytes as the sister group (Turmel et al. 2006, 2007). Most recently, the latter hypothesis has garnered strong support from several recent phylogenomic analyses so that the strongly supported consensus is that a filamentous zygnematophyte-like ancestor gave rise to the Zygnematophyta and its sister taxon, all embryophytes (Wickett et al. 2014; Ruhfel et al. 2014). The implications of the latter relationship are profound in regard to the origin of a land flora and the likely morphological and physiological traits of early land-colonizing green algae (Delwiche and Cooper 2015; Davis et al. 2014; deVries et al. 2016). Taxon sampling in larger phylogenomic analyses has been, however, limited (only two zygnematophytes are included in Wickett et al. 2014). Delwiche and Cooper (2015) noted this problem of taxon sampling and suggested that further studies might provide alternative topologies. Davis et al. (2014) also commented that "In some cases, however, high support for relationships should be interpreted cautiously because conflicting topologies are supported by other data. Key examples include the previously mentioned sister groups of land plants . . ." Thus, although the consensus currently is that the zygnematophytes are the sister group to land plants, the issue is not quite a settled question.

Within the zygnematophytes, relationships among the numerous genera are becoming clear, but traditional taxonomy has not been supported by molecular work (Gontcharov et al. 2003, 2004; Hall et al. 2008a). For example, it is not clear if the Zygnematales is a monophyletic group and there is some evidence that the Desmidiales may include *Netrium* and *Roya*, genera not previously recognized as part of this lineage (Gontcharov et al. 2003, 2004; Hall et al. 2008a). There is some evidence that species of the genus *Spirotaenia* may not belong to the conjugating green algae (Gontcharov and Melkonian 2004). Although phylogenetic position of this genus is uncertain, it shares many of the characteristics of other zygnematophytes including reproduction by conjugation and will be treated as a member of the group.

Classification within the conjugating green algae is somewhat unsettled, and structural synapomorphies have not been found for many of the lineages discovered in molecular phylogenetic studies (e.g., Gontcharov and Melkonian 2008). There is some evidence that chloroplast shape may be an important phylogenetic

Table 2 Cell-wall characteristics of the Zygnematophyta

Zygnematales	Type 1. Mesotaeniaceae and Zygnemataceae	1. Cell wall one homogeneous piece
		2. Primary wall not shed
		3. Outer hyaline (mucus) layer smooth
		4. Ornamentations weak or absent
		5. Pores absent
Desmidiales	Type 2. Closteriaceae, Gonatozygaceae and Peniaceae	1. Cell wall may be formed of several segments, which are divided by very slight constrictions
		2. Primary wall not shed
		3. Compact, structured outer layer (warts, spines, and ridges originating from outer layer)
		4. Ornamentations strong and variable
		5. Pores or pore-like gaps only in outer layer
	Type 3. Desmidiaceae	1. Cell wall formed of two segments divided by a marked constriction (isthmus)
		2. Primary wall shed
		3. No continuous outer layer but mucilaginous envelope originating from pore organs from secondary wall
		4. Pores in secondary wall

After Brook (1981)

characteristic (McCourt et al. 1995; Hall et al. 2008a), but groups within the Zygnematales have not been formally circumscribed.

Before differences in cell wall characteristics were revealed, three families of conjugating green algae were recognized: Desmidiaceae, Mesotaeniaceae, and Zygnemataceae. The traditional Desmidiaceae is equivalent to the Desmidiales in this treatment, and species in this group are often referred to in general literature as the "placoderm desmids." Conversely, the Mesotaeniaceae in earlier literature were called the "saccoderm desmids." It is important to recognize that the saccoderm desmids and Zygnemataceae are not natural groups, but rather groupings based on growth habitat (saccoderms are unicellular and zygnemataceans are filamentous). The order Zygnematales as defined here includes those species formerly assigned to the families Zygnemataceae and Mesotaeniaceae. They share the trait of a simple cell wall, but this is likely a primitive trait that does not diagnose a monophyletic group. Nevertheless, the current classification is based primarily on characteristics of the cell walls. These characteristics are outlined in Table 2.

The taxonomy of the Zygnematophyta has involved the descriptions of numerous morphological species. Among the characters distinguishing species in this diverse group of algae are radiation, cell wall ornamentation, cell dimensions, chloroplast number and form, details of cell division and the conjugation process, as well as zygospore color and ornamentation. Intraspecific polymorphisms and aberrant forms are numerous, especially among placoderm desmids (Brook 1981).

The correlation between morphological species and biological species is not clear. Watanabe and Ichimura (1982), working with *Closterium*, have shown the existence

of several ecologically and sexually isolated mating groups within a single morphological species or species complex. This and other studies (Ichimura 1983) suggest that, although a species of *Closterium* may appear to be widely distributed, crossing experiments reveal that reproductively isolated mating groups are restricted to much smaller areas, and several biological species may be involved. In our own studies of the Gonatozygaceae, we have found that some morphological species constitute distinct phylogenetic lineages although reproductive isolation has not been demonstrated (Hall unpub.).

Although the *Closterium* studies imply the existence of more biological species than are presently described, research on polyploidy in desmids and *Spirogyra* has indicated that perhaps too many species have been described because of morphological variation within a polyploid species complex (polyploid derivatives from a single clone). Polyploidy has been reviewed by Nichols (1980). Placoderm desmids display changes in cell volume and degree of radiation associated with ploidy changes (Pickett-Heaps 1983). Clonal cultures of *Spirogyra* have been reported to develop filaments of three or more distinct widths that are the phenotypic expression of euploid increases in chromosome number (Allen 1958; Hoshaw et al. 1985, 1987). Variations in ploidy of *Spirogyra* and the morphological changes associated with them have undoubtedly led to excessive numbers of species descriptions (over 400 species). At the same time, it is likely that cryptic genetic variation may have led to underestimates of species diversity in other genera. The nature of diversity in species of these algae remains a fertile area of research.

Reproduction

A cardinal feature distinguishing the Zygnematophyta from other chlorophytes is sexual reproduction by conjugation involving the fusion of non-flagellate gametes. Asexual reproduction is by fragmentation, cell division, akinetes, and parthenospores. These types of reproduction have been observed either in natural populations or in laboratory cultures.

Conjugation was first observed nearly 200 years ago, but only during the twentieth century were the events adequately interpreted (Fritsch 1935; Randhawa 1959). Investigations of cultures have provided data on the events of entire sexual cycles. Observations have been made of stages from cell or filament pairing to zygospore germination.

Sexual cycles (Figs. 3 and 4) consist of conjugation (the physical joining of cells or filaments and subsequent union of gametes to form a zygote), formation of a thick-walled zygospore, a period of zygospore dormancy, and germination of the zygospore to produce vegetative cells. Sexual cycles of the conjugating algae are haplobiontic. They display zygotic meiosis; growing cells are haploid; and meiosis occurs in the zygote, the only diploid cell in the sexual cycle. Strains of species may be homothallic (conjugation is intraclonal) or heterothallic (conjugation is interclonal between plus and minus mating types). A great deal of work has focused on molecular mechanisms involved in mating-type determination in *Closterium* (Hirano et al. 2015; Sekimoto et al. 2014).

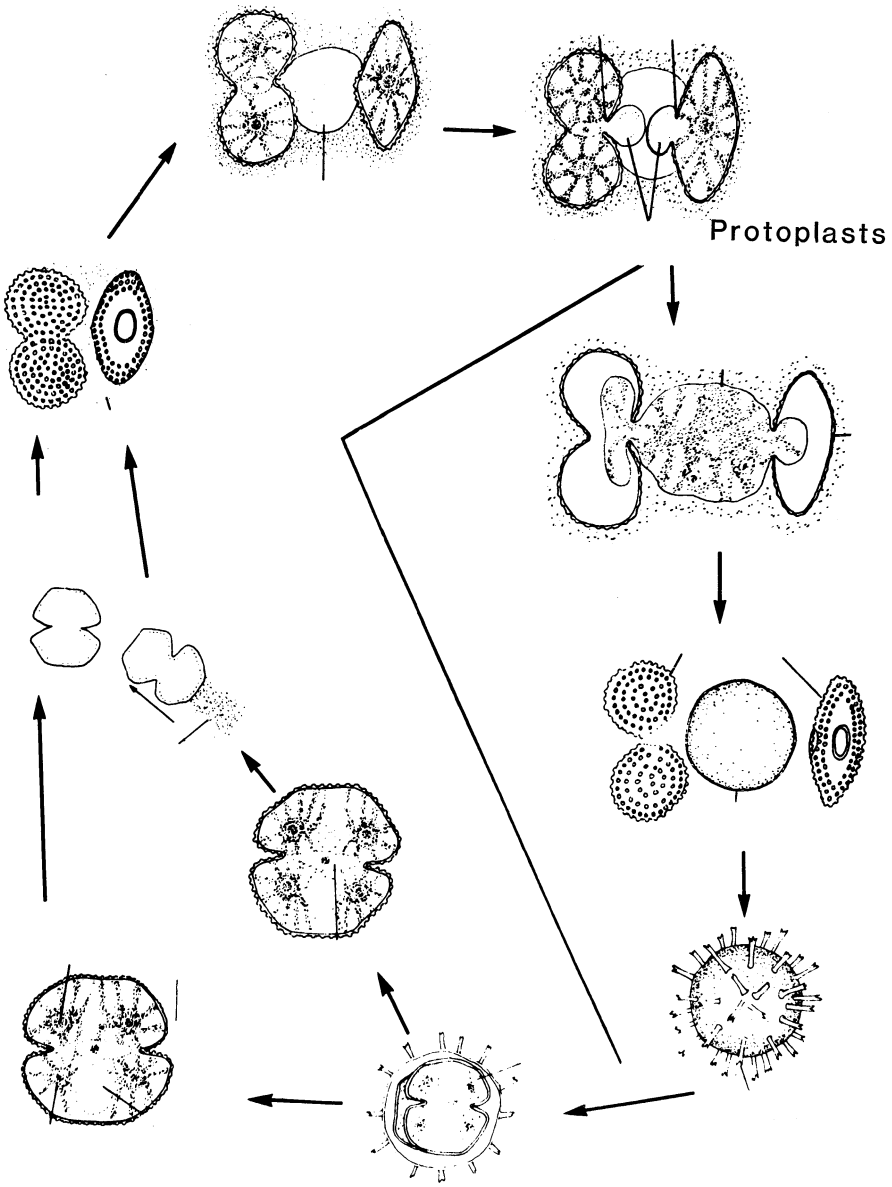

Fig. 3 *Cosmarium* life cycle (After Lee 1980)

Laboratory strains of placoderm and saccoderm desmids have been induced to conjugate by increasing carbon dioxide in the atmosphere surrounding cells (Starr 1964) and by suspending cells in a low-nitrogen medium (Biebel 1973). Brandham (1967) described the movement of *Cosmarium botrytis* cells to form

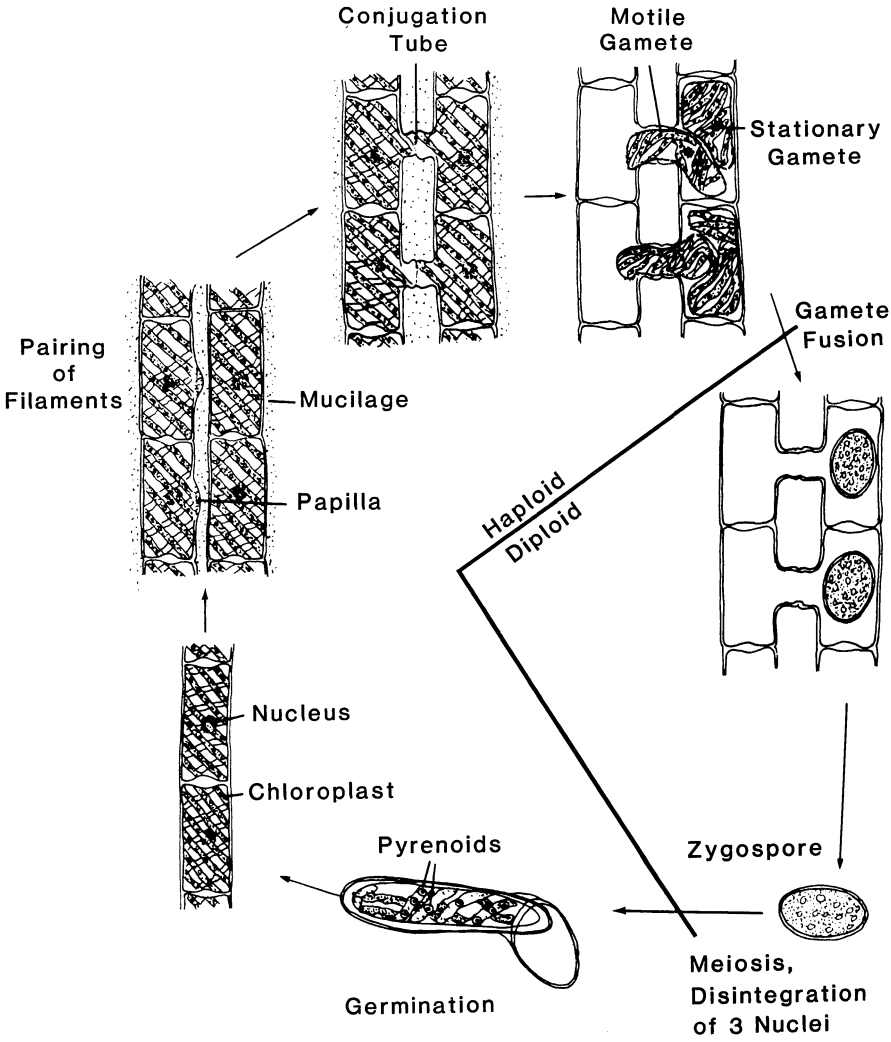

Fig. 4 *Spirogyra* life cycle (After Lee 1980)

pairs; this movement suggests the action of a sexual pheromone. Pheromones were long thought to be involved in initiating sexual reproduction. Hoshaw (1968) reported evidence that a sexual pheromone produced by one mating type of *Zygnema circumcarinatum* facilitated conjugation. A fragment of a gene encoding a putative pheromone thought to be involved in the induction of sexual reproduction has been identified in *Closterium* (Tsuchikane et al. 2003; Fukumoto et al. 2003).

It seems that optimal conditions for conjugation vary from species to species. Filamentous Zygnematales often conjugate when filaments are transferred to nutrient-poor conditions, such as the surface of a 1.2% tap water agar. We have found that freshly collected filaments spread on agar conjugate more readily than filaments from cultures. Scalariform conjugation involves the movement of filaments into a paired ladder-like arrangement after which outgrowths from adjacent cells (papillae) join to form a conjugation tube. In Zygnemataceae with lateral conjugation, a short curved tube joins adjacent cells in a single filament.

Many different mating systems are known among the conjugating green algae. Gametes of saccoderm and placoderm desmids usually leave parent cells and meet in a conjugation vesicle or tube. In conjugation of filamentous Zygnematales, cells of the filament function as gametangia and form isogametes or anisogametes (see glossary in Hoshaw 1968). One gamete may move to the opposite cell, or both gametes may move into and fuse in the conjugation tube. Physiological anisogamy occurs when one isogamete moves and the other isogamete remains stationary, as happens in most species of *Spirogyra* (Hoshaw 1968). Gamete directionality is not fixed. That is, filaments may contain some cells that act as a gamete donor and others that act as a gamete recipient.

The zygospore wall is composed of three major wall layers: exospore (outermost), mesospore (middle), and endospore (innermost). These layers may themselves be multilayered. DeVries et al. (1983) reported the presence of sporopollenin in the two mesospore layers of *Spirogyra hassallii* along with cellulose and/or pectin in exospore and endospore layers. Walls of zygospores are smooth or ornamented and may be black or shades of yellow, brown, or blue.

Meiosis in the placoderm desmid *Pleurotaenium* occurs in the zygospore immediately before germination (Blackburn and Tyler 1981). In contrast, meiosis in *Spirogyra crassa* occurs early in zygospore formation, even before the wall matures (Godward 1966). Zygospore germination involves the rupture of the exospore and mesospore with the emergence of one to four germlings (single cells or the first cell of a filament). The endospore becomes the cell wall of germlings, or cleavage of the single remaining protoplast from meiosis may occur within the endospore during the formation of two, three, or four germlings (Biebel 1973). Chloroplasts from only one gamete survive in germlings, even in homothallic isogamous species where the gametes are genetically identical. In all species of *Spirogyra* studied and some species of *Zygnema*, in which only one gamete moves, chloroplasts persisting in the zygospore and resulting progeny are those of the stationary gamete (Biebel 1976).

Conjugation has infrequently been observed in natural populations of placoderm and saccoderm desmids. In some species, asexual spores are known. Brook (1981) described two types of akinetes formed asexually by placoderm desmids. The protoplast either emerges from the cell to form a spore or secretes a thick wall inside the original cell wall. Akinetes form in many filamentous zygnematalean species by

the second method. A parthenospore is similar to an akinete but forms when gametangial cells form spores without gamete fusion. Less commonly observed are akinetes, thick-walled vegetative cells, which in *Zygnema* form most readily under conditions of high light (6,500 lux) and low nitrogen (Pessoney 1968).

Photomovement of Chloroplasts and Cells

Mougeotia and *Mesotaenium* are useful experimental organisms in the study of phytochrome-mediated movements of chloroplasts (Haupt 1982). The laminate chloroplast moves within the cell to display its maximum surface area or face toward low-intensity white light, whereas in high-intensity white light, the chloroplast aligns itself with the edge profile toward the light. Presumably these motions optimize photosynthetic performance and minimize damage to the photosynthetic apparatus. *Mougeotia* has advantageous features for such research, with its cells each containing a single large chloroplast that can be partially irradiated with microbeam illumination. Unlike chloroplast movements in other organisms, chloroplast orientation in *Mougeotia* proceeds to completion in darkness after exposure to brief light flashes, allowing the processes of light perception and response to be studied separately (Haupt 1982, 1983).

Phytochrome in the peripheral cytoplasm appears to be the photoreceptor pigment in both the low and high light-intensity responses, but the action spectra are very different. Low-intensity white light (or red light) striking the cell from one side transforms red-absorbing phytochrome (P_r) to the far-red-absorbing active form (P_{fr}) more effectively on front and rear cell surfaces than on the flanks. A higher concentration of P_{fr} builds up in the front and rear cortical cytoplasm, and the chloroplast edges move as if repelled by high P_{fr} levels so that the flat surface of the chloroplast turns toward the light. In high-intensity light, the same P_f-P_{fr} gradient is set up, but an additional blue-light photoreceptor in the cortical cytoplasm somehow acts as a switch in the reaction chain; the chloroplast edges, instead of being repelled by high P_{fr} levels, are attracted to them, whereby the edge profile of the chloroplast is displayed to the light. Actin microfilaments are believed to move the chloroplast edge touching the cortical cytoplasm, and calcium apparently plays a key role in the transduction chain. Many details of this process remain unknown, but progress has been made toward a greater understanding of phytochrome signaling in *Mougeotia* and *Mesotaenium* (see Wagner 2001, for details). In particular, full-length phytochrome-coding sequences have been cloned from *Mesotaenium* and *Mougeotia*. In addition, a new photoreceptor, neochrome (similar to the *Adiantum* phy3), has been identified from *Mougeotia scalaris* (Suetsugu et al. 2005). This molecule seems to be the product of the fusion of portions of phytochrome and phototropin genes.

Placoderm and saccoderm desmid cells have long been known to be capable of gliding or somersaulting movements. It has been shown that gliding movement is effected by the localized excretion of mucilage, usually from the apices (Oertel et al.

2004; Rogers-Domozich et al. 1993). Some filamentous Zygnematales, such as *Spirogyra*, are also capable of a gliding motility (Kim et al. 2005).

Cytomorphogenesis

Placoderm desmids, particularly members of the genus *Micrasterias*, have been valuable in research on cytomorphogenesis, the process of growth and differentiation of their elaborately structured cell walls following cell division. Several features make *Micrasterias* especially useful in this research (Kiermayer 1981; Meindl 1993). The cells are relatively large (200–300 μm in diameter), easily centrifuged to produce enucleate semicells, and easy to observe without staining. Experimental production of enucleate, polyploid, or aneuploid cells has shown effects of the nucleus and cytoplasm on differentiation.

Micrasterias cells are typically biradiate, each semicell comprising a polar lobe flanked by two wings (lateral lobes), which are incised and differentiated at the edges in a species-specific pattern. In *M. denticulata*, following mitosis and septum formation at the isthmus, each semicell generates an adjoining mirror image of itself in about 16 h (Kiermayer 1981; Meindl 1993). The septum swells outward under the influence of turgor pressure, the polar lobe and wings begin to form, and the chloroplast flows into the forming semicell and eventually divides into two, but the two halves stay joined as semicells at the isthmus (Fig. 5).

Although all conjugating green algae are thought to use some variation of centripetal cell division, members of the group display a number of interesting and unusual cell division characteristics. In the placoderm desmid *Staurastrum* (*Pleurenterium*), after cytokinesis, the nucleus moves out of the isthmus into the developing semicell. The nucleus is then moved by means of a microtubular system in a circular motion. After most of the semicell has formed, the nucleus then returns to its place in the isthmus of the cell, a process termed nuclear migration (Meindl

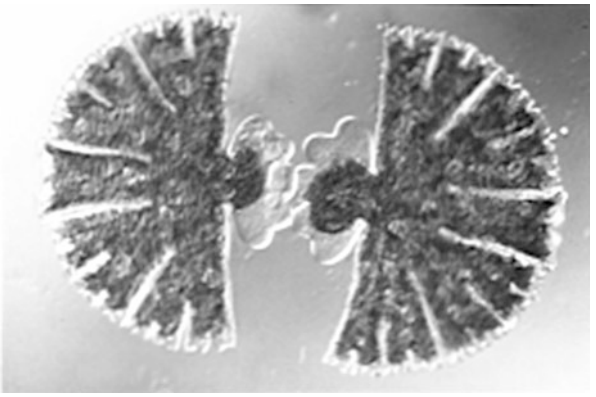

Fig. 5 Early stage in semicell regeneration following cell division in *Micrasterias denticulata*. × (Photomicrograph courtesy of Dr. J. D. Pickett-Heaps, University of Colorado)

1986). Many of the molecular players in this process have been identified (e.g., Holzinger and Lütz-Meindl 2002).

In addition to cytological differences in cell division, some filamentous placoderm desmids display different patterns of cell division. The existence of replicate folds on the cross wall of species of *Desmidium* and *Bambusina* have long been known (Hauptfleich 1888). It was also discovered that *Onychonema* had an unusual mode of cell division that involved the delay of mitosis and the formation of a division vesicle (Krupp and Lang 1985). Additional differences in cell division among filamentous desmids are now known. Hall et al. (2008b) proposed that characteristics of cell division may be a valuable systematic character in filamentous Desmidiaceae.

It is worth noting that among charophytes (=streptophytes), the Zygnematophyta are the only group for which transformation protocols have been developed (Abe et al. 2011 for *Closterium*; Sorensen et al. 2014 for *Penium*; and Vannerum et al. 2010, 2011 *Micrasterias*). These protocols may prove valuable in using zygnematophytes as model systems.

Nuclear Cytology and Genetics

The most significant features of nuclear cytology in Zygnematophyta are (1) the presence during mitosis of stainable material derived from the nucleolus and known as nucleolar substance, (2) the presence of a complex interphase nucleolus, and (3) the absence of a localized centromere on the chromosomes of some species. In *Spirogyra*, large, complex nucleoli have been observed at interphase or prophase (Godward 1966). In *Spirogyra*, *Sirogonium* (Hoshaw and Wells 1982), and *Zygnema* (Harada and Yamagishi 1980), new nucleoli are organized by nucleolar-organizing chromosomes, which possess long secondary constrictions called nucleolar-organizing regions. Placoderm and saccoderm desmids also possess nucleolar-organizing chromosomes and nucleolar substance (Godward 1966; Brook 1981).

According to Godward (1966), *Spirogyra* metaphase chromosomes are of three types: (1) minute dot-like chromosomes in which the centromere position cannot be observed, (2) chromosomes with localized centromeres, and (3) polycentric chromosomes. In some genera such as *Zygnema* and *Mougeotia*, only dot-like chromosomes have been reported. Chromosomes in most saccoderm and placoderm desmids are small (less than 1.5 μm long). The parallel separation of chromatids at anaphase in most species suggests the presence of polycentric chromosomes.

Godward (1966) summarized data on chromosome numbers in the Zygnematophyta. Chromosome numbers in growing cells of saccoderm desmids range from 20 to 592, in placoderm desmids from 9 to 220, and in Zygnemataceae from 4 to 94. Considerable intraspecific variation in chromosome numbers has been reported (Brook 1981).

The genetics of the group was reviewed by Biebel (1976). He noted that their potential for genetic studies has rarely been exploited. Inheritance of genes for mating type and zygospore structure has been demonstrated. Selective abortion of

meiotic products in a zygospore results in incomplete, unordered tetrads. Recessive lethal alleles have been found in *Cosmarium turpinii* that are expressed in the homozygous condition in diploid zygospores but not in haploid vegetative cells.

Maintenance and Cultivation

Laboratory investigations of the conjugating green algae often begin with cultures from one or more of the world's culture collections, thereby bypassing the steps of collection and isolation of experimental organisms. If organisms directly from nature are desired, plankton and periphyton samples frequently contain desmid species, and filaments of the Zygnemataceae occur suspended in submerged masses or as surface scums that permit easy collection by hand. Once collected, cells or filaments can be isolated into unialgal culture by one of the methods described in Stein (1973) and Andersen (2005).

Many growth media are available; formulae and suggestions have been provided by Hoshaw (1968), Stein (1973), Starr (1978), and Andersen (2005). Strains obtained from culture collections often have the growth medium designated. For isolation and early growth, biphasic soil-water medium (Starr 1978) is often preferred; addition of a small quantity of peat is necessary to lower the pH for some species. For organisms requiring soil extract, we have found that we can grow many of these species in axenic conditions by adding 40 mL/L of filter-sterilized soil extract to sterile Bold's basal medium (see Stein 1973, for formula). Most placoderm desmids grow well in general defined medium with the addition of B vitamins. After a suitable growth medium is selected, cultures of Zygnematophyta will often produce luxuriant growth after 2–4 weeks in stationary culture under 40-watt cool-white fluorescent lamps of 50 $\mu Em^{-2}\ s^{-1}$ intensity on a 16:8 h light-dark cycle at 15–20 °C.

Fossil Record

Until the late twentieth century, fossil zygospores of conjugating green algae were largely ignored or identified as form taxa of non-zygnematalean spores (Van Geel 1979). Although fossil zygospores have been used to reconstruct ancient climates and aquatic habitats, a major hindrance to their use in reconstructing past climates is the general lack of knowledge of the ecology of extant species (Ellis and Van Geel 1978). Nevertheless, fossil zygospores provide information independent of pollen records (Van Geel and Van der Hammen 1978). The presence of these algal zygospores (usually *Mougeotia* and *Spirogyra*) at a site implies the past presence of shallow, stagnant, mesotrophic habitats subject to warming temperatures in spring that induce conjugation (Van Geel 1978; Van Geel and Van der Hammen 1978; Jarzen 1979). The presence of fossil desmids in deposits suggests the former presence of slightly acid swamp waters (Tappan 1980). An exception to this is the presence of *Oocardium*, one of the few desmids that prefer limy waters, in which it forms calcareous tubules called tufa (Bradley 1974).

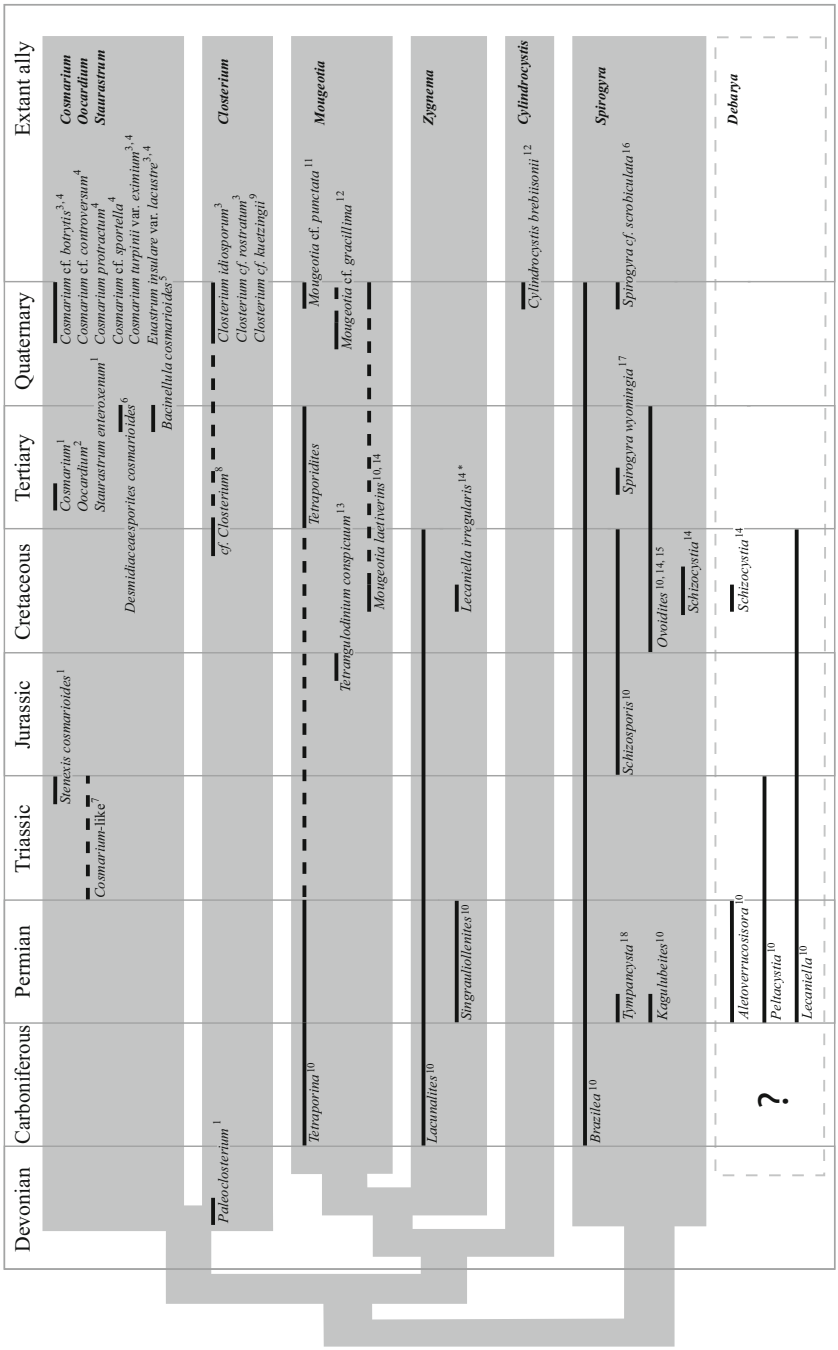

Fig. 6 (continued)

One of the most commonly reported fossil zygospores is that of *Debarya glyptosperma* (Van Geel and Van der Hammen 1978; Ellis and Van Geel 1978), reported originally as the form taxon *Peltacystia* (Van Geel 1979). The commonness of these distinctly keeled zygospores in deposits would not be predicted based on current distribution and abundance of this species, which, although found on every continent, is quite rare. The explanation for this is all the more elusive because, being rare, *Debarya* is not well known ecologically. Based on fossil evidence, *D. glyptosperma* in the Colombian Andes was restricted to cold to cool high-mountain climates (Van Geel and Van der Hammen 1978).

The fossil record of the Zygnematophyta is incomplete but extends to the middle Devonian (Fig. 6; Table 3). Because zygnematalean vegetative cells are fragile, most fossils are those of zygospores, which are usually necessary to identify living as well as fossil Zygnematophyta to species. The oldest zygnematalean fossils are Carboniferous zygospores of *Mougeotia* (reported as the form taxon *Tetraporina*), *Brazilea*, and *Lacunulites*. The phylogenetic placement of some fossil Zygnematophyta is less certain. *Paleozygnema spiralis* has been reported from Cretaceous amber in Germany (Dörfelt and Schäfer 2000). Both vegetative filaments and spores were preserved in the amber. The spore has a superficial spiral pattern similar to early stages of spore formation in *Spirogyra.* Placement of this taxon is uncertain. Based on the supposed phylogenetic affinities of the fossils to modern taxa, it can be deduced that all major lineages of the Zygnematales had diverged before the Carboniferous (Fig. 6; Table 3).

The oldest reported desmid fossils are vegetative cells of *Paleoclosterium leptum* from the middle Devonian. Fossils with obvious affinities to the Desmidiaceae do not appear until the Triassic. Extant genera of the Desmidiaceae (sensu stricto) do not appear until the Tertiary. This late appearance of Desmidiaceae in the fossil record is congruent with the derived placement of the group in molecular phylogenies (McCourt et al. 2000; Gontcharov et al. 2003; Hall et al. 2008a). Similarly, the filamentous nature of the oldest zygnematophycean fossils is congruent with the proposal of Delwiche and Cooper (2015) that the ancestor of charophyte (=streptophyte) algae and embryophytes was a filamentous taxon, most likely a branched one (see their Fig. 3).

Fig. 6 Fossil record superimposed on phylogenetic tree (After Hall et al. 2008a). Branching order based on Hall et al. 2008a. Phylogenetic position of *Debarya* is not known; however, it is thought to be closely related to *Mougeotia*. The placement of the *Debarya* lineage is unknown. *Debarya* is thought to be most closely related to *Mougeotia*. A "?" indicates the point of uncertainty. Sources used for fossil dates are indicated by the *superscript*. *1* Tappan 1980; *2* Bradley 1974; *3* Van Geel et al. 1981; *4* Van Geel et al. 1989; *5* Weyland 1963; *6* Hunger 1953; *7* Schmidt et al. 2006; *8* Waggoner 1994; *9* Van Geel and Van der Hammen 1978; *10* Van Geel 1996; *11* Van Geel 1976; *12* Van Geel 1978; *13* Schrank 2005; *14* Zippi 1998; *15* Hofman and Zetter 2005; *16* Van Geel et al. 1989; *17* Bradley 1970; *18* Afonin et al. 2001. Only new or particularly interesting fossils are referenced; many more fossils including many species within the form genera are known. * There is some disagreement as to the placement of *Lecaniella*, but Zippi (1998) indicates that this fossil belongs to the Zygnemoid lineage rather than the *Debarya* lineage

The affinities of fossils to extant taxa are rarely known with certainty. Mapping the reported fossils on the phylogeny of extant lineages in light of our incomplete understanding of affinities is somewhat bold, but if taken at face value, it suggests that most of the lineages of extant Zygnematales are very ancient.

Our understanding of evolution in the group has been much affected by molecular phylogenetic studies. It is clear that the traditional families Mesotaeniaceae and Zygnemataceae are not natural groups and that the order Zygnematales may be paraphyletic with respect to the Desmidiales. We now hypothesize that the

Desmidiales are a monophyletic group unto themselves that share a common ancestor with some unicellular and filamentous Zygnematales (as opposed to being derived from one or more unicellular zygnematalean lineages as was often proposed). Among the Desmidiales, most colonial and filamentous forms seem to belong to one or two major lineages, implying few transitions between these two growth habits (McCourt et al. 1995; Gontcharov et al. 2003; Hall et al. 2008a). Among the Zygnematales, however, there have been several transitions between the unicellular and filamentous forms. Although the direction of such transitions is not certain, lineages related to the conjugating green algae (Klebsormidiophyceae and Coleochaetophyceae) comprise filamentous or multicellular organisms, which is the inferred growth habit of the ancestor of conjugating green algae. Continued studies of evolution in the conjugating green algae and related lineages will provide greater insight into the origin and early diversification events in this group.

Acknowledgments This chapter is dedicated to Dr. Robert W. Hoshaw, who coauthored the chapter in the first edition of this book.

Charophyceae (Charales)

5

Richard M. McCourt, Kenneth G. Karol, John D. Hall, Michelle T. Casanova, and Michael C. Grant

Abstract

The charophytes, or stoneworts, are a group of green algae with six extant genera in one family, distributed worldwide in freshwater ponds and lakes. They are among the green algal groups most closely related to land plants and exhibit a complex thallus, with multinucleate internodal cells joined at nodes comprising smaller, uninucleate cells giving rise to whorled branchlets. Two genera (*Chara, Nitella*) contain most of the described species, with a third (*Tolypella*) containing several dozen taxa. The remaining genera have one or a few species. Reproduction is oogamous, with sperm and eggs produced in separate multicellular structures. The thallus is haploid; the zygote is the only diploid cell in the life cycle, and meiosis is followed by the development of a resistant spore. Thalli and spores

are often encrusted with calcium carbonate. Such spores are abundant in the fossil record of the Charales, which extends to the Upper Silurian, and many genera and families have become extinct. These algae provide important ecosystem services, for example, as colonizing species, as biological agents for producing water clarity, or as the base of the food web. Charophytes are important for the study of evolution of embryophyte development, growth meristems, and cell biophysics. As one of the green algal groups most closely related to land plants, the rich charophyte fossil record may reveal clues regarding the earliest algae that invaded the land.

Summary Classification

- **Charales**
  - **Characeae** *Chara*, *Lamprothamnium*, *Lycnhothamnus*, *Nitella*, *Nitellopsis*, *Tolypella*

Introduction

Charophytes are large, parenchymatous green algae (Fig. 1) that grow in fresh and occasionally in brackish water. Although less common than aquatic bryophytes or tracheophytes, charophytes are the ecologically dominant benthic macrophyte in some habitats. Charophytes are relatively large for green algae and can grow up to a half meter or more in height, in lush meadows and freshwater ponds, lakes, and flowing waters. The term "charophyte" used here applies to members of the order Charales, which contains extant and fossil taxa (Feist et al. 2005).

Charophytes have a complex thallus with an upright, stemlike main axis punctuated by whorls of branchlets (Fig. 1). Rhizoids anchor the thallus in sandy or muddy substrates. Thalli of some genera (notably *Chara*, *Lamprothamnium*, and *Tolypella*) accumulate calcium carbonate externally and have a musky odor. Worldwide in distribution and occasionally abundant in submerged areas, these macroscopic green

algae have been well studied for several centuries by biologists (e.g., Allen 1888, 1889; Braun and Nordstedt 1882; Corillion 1972) .

Six extant genera in the family Characeae and order Charales are recognized; two additional orders and a large number of genera and families are known from the fossil record (Table 1). Two extant genera are common: *Chara* and *Nitella*, each with several hundred species. Of the other four genera, *Tolypella* and *Lamprothamnium* are the most common and diverse, with approximately 16 and 7 species, respectively. A monograph by Wood and Imahori (1965) synonymized numerous species in *Chara* and *Nitella* and recognized only 19 species in *Chara* and 50 in *Nitella*, with numerous subspecific taxa. Wood's taxonomic arrangement has not been widely adopted due to experimental work showing that the earlier taxonomy reflected

[b]Extinct

species-level differences in terms of reproductive isolation (e.g., Grant and Proctor 1972; Proctor 1975; McCracken et al. 1966). Therefore, earlier species names are commonly used in the current literature.

The charophyte thallus is composed of basal rhizoids, with an upright axis consisting of alternating internodes and nodes. Due to their large size and apparent complexity, charophytes may be mistaken for bryophytes or certain aquatic angiosperms (e.g., *Ceratophyllum*) in the field. Charophytes lack the diploid sporophyte generation and multicellular embryos of bryophytes and vascular plants (Graham and Wilcox 2000). However, their plantlike structure, complex asymmetric sperm, and large, protected egg cells (described below) led earlier workers to see them as intermediate in complexity between green algae and embryophytes (Bold and Wynne 1978; Smith 1950). This intermediate position was clarified by molecular studies that show charophytes to be one of several groups of green algae that are more closely related to land plants than they are to the rest of the green algae (Karol et al. 2001; Lewis and McCourt 2004; McCourt et al. 2004; Turmel et al. 2006).

Charophytes fulfill a number of ecological roles in both permanent and temporary water bodies (van den Berg et al. 1998). They are primary producers, sometimes the dominant photosynthesizers in aquatic ecosystems (Schwarz et al. 1999; Porter 2007). Stands of charophytes provide habitat for epiphytic algae, invertebrates (Hawes and Schwarz 1996; James et al. 1998), and structural refuges for zooplankton (Kuczyńska-Kippen 2007) and juvenile vertebrates (fish and frogs). Charophytes

are often early colonizers and water clarifiers (Casanova et al. 2002), and they are directly consumed by a number of arthropods (beetles, amphipods; Proctor 1999) and snails (Elger et al. 2004), fish (Lake et al. 2002), and water birds (Schmieder et al. 2006). In deep lakes they can be the deepest growing plants (Dale 1986; Schwarz et al. 1999). Charophyte communities in temporary wetlands are commonly species rich (Casanova and Brock 1999a) occurring as individual plants (Casanova and Brock 1999b), although monospecific, continuous "beds" or "meadows" are also common (Stross et al. 1988; Pelechaty et al. 2010).

Charophyte life histories are haplobiontic, with one free-living haploid vegetative phase. After meiosis in the zygote, the haploid oospores germinate and produce a protonema, which differentiates into axes, branchlets, and rhizoids at the first node. The rhizoids grow downward (Kiss and Staehelin 1993), anchoring the thallus axis in the sediment, and the axes grow upward (Andrews et al. 1984). Sexual reproduction may be initiated either as soon as possible after germination (e.g., *Chara muelleri,* Casanova and Brock 1999a) or in response to environmental cues (e.g., *Chara australis,* Casanova 1994). Life histories can be annual or perennial (Casanova and Brock 1999a), with annual species most frequently occurring in habitats subject to periodic drying (Blindow 1992a, b) or freezing (Schwarz et al. 1999). However, some species (e.g., *Chara braunii*) with an annual life history occur in areas exposed to long-term flooding (Casanova and Brock 1999b).

Practical applications for charophytes include management of water quality (through encouragement of charophyte colonization) and as an indicator of water regime requirements in riparian and wetland ecosystems (Casanova 2011). Because their large cells are easy to observe and manipulate, charophytes have been useful as model organisms for studies of cell membrane potential and cytoplasmic streaming (Tazawa et al. 1987; Tazawa and Shimmen 2001; Raven and Brownlee 2001; Yamamoto et al. 2006).

Habitats and Ecology

Charophytes are primarily freshwater plants, but they are occasionally abundant in brackish areas, both in contemporary habitats (Shepherd et al. 1999) and in ancient ones, as shown in the fossil record (Soulié-Märsche 1999; 2008). These algae usually occur in quiet or gently flowing waters, from very shallow (several cm) to deep (>10 m (30 m in clear lakes such as Tahoe)), so long as light and oxygen levels are adequate. Some have been found in swiftly flowing rivers (personal obs.), but such occurrences have been rarely noted in the literature. Habitats are typically alkaline (hard water), although some species are known from mildly acidic waters. Rhizoids are usually anchored in sandy substrates mixed with gravel. The upright portions of plants are buoyant and exhibit a characteristic whorled pattern when viewed from above (Casanova 2009).

The family Characeae, which contains all living charophytes, is worldwide in distribution, but individual species range from restricted endemics to broadly

distributed taxa. In general, dioecious taxa are narrowly distributed or endemic, whereas monoecious taxa are usually widely distributed (Proctor 1980).

Autecological studies predominated in the early literature, in which species distributions were characterized by environmental parameters (e.g., temperature, light, depth, water quality characteristics) (Hutchinson 1975). Interspecific interactions have not been investigated as thoroughly, but competitive effects of vascular plants and algae on charophytes have been suggested (Stross 1979; Stross et al. 1988). In fact, Martín-Closas (2003) hypothesized that charophytes dominated freshwater floras after the Permian until angiosperms evolved and came to dominate freshwater habitats from the Lower Cretaceous until the present.

Nutrients are absorbed by charophytes through their rhizoids and photosynthetic thallus (Kufel and Kufel 2002), and charophyte communities can be a significant store of nitrogen in small water bodies (Rodrigo and Alonso-Guillén 2008). Uptake by charophytes removes nutrients from the water column that would otherwise be available for growth of other algae (van den Berg et al. 1998; Siong et al. 2006). In addition, some species have an allelopathic effect on the growth of certain microalgae (Blindow and Hootsmans 1991; Pakdel et al. 2013). Early reports by Forsberg (1964) that even low concentrations of phosphorus were toxic to charophytes have not been supported by subsequent studies (Blindow 1988) and the decline of charophytes following eutrophication can be explained largely by decreases in water clarity and competition with angiosperms (Blindow 1992a).

Susceptibility or resistance to predation has been shown to determine the presence or absence of charophytes in various permanent and ephemeral habitats (Mann et al. 1999; Proctor 1999). A number of studies have investigated the marked zonation of charophytes in lakes, a pattern where charophytes grow in a discrete band with distinct upper and lower depth limits. Studies have invoked light, competition, and herbivory as the controlling factors that set the depth limits (Schwarz et al. 1999, 2000).

Charophytes are well adapted to the submerged aquatic environment. For example, the evolutionary significance of the multinucleate giant cells of charophytes has been explained as a shade-tolerance adaptation (Raven et al. 1979) by which cytoplasmic streaming in giant cells of charophytes optimizes transport of nutrients to various parts of the thallus, analogous to the phloem-like system of transport that evolved in kelps or other large algae.

Characterization and Recognition

The charophyte axis has a distinctive node-internode structure. Internodes consist of so-called giant cells, which are multinucleate. Nodes comprise several, smaller, uninucleate cells that give rise to whorls of leaflike organs of limited growth called "branchlets," and secondary axes (branches of unlimited growth), which also exhibit the node-internode construction. A single apical meristematic cell occurs on each axis tip, the latter exhibiting a pattern of growth and branching similar to the apical meristem of higher plants (Fig. 2) (Cook et al. 1998; Pickett-Heaps 1975; Clabeaux

Fig. 2 Apical meristem of *Chara*, longitudinal section. Large intermodal cells show a clear, central vacuolar region; lateral branchlets arise from peripheral cells at nodes. (Photograph courtesy of Dr. Martha Cook, from a specimen from Ward's Natural Science)

and Bisson 2009). Internodes are composed of giant cells, which are multinucleate with numerous ellipsoidal plastids distributed in the cytoplasm surrounding a large central vacuole. The cytoplasm streams actively lengthwise around the cell periphery. Internodal cells may be naked or covered by a single-celled layer of thin cortical cells that grow upward and downward from nodal cells to cover the internodes. Some corticating cells project outwardly as spines. Cortication is common among species of *Chara*, incomplete in the rare genus *Lychnothamnus*, and absent in *Lamprothamnium, Nitella*, *Nitellopsis*, and *Tolypella*. Shape and numbers of ranks of cortical cells are important in delineating species in *Chara* (Wood and Imahori 1965; Casanova 2005).

Nodes consist of several uninucleate cells produced through cytokinesis of 1–3 central cells that give rise to a series of peripheral cells (Cook et al. 1998), with adjacent cells connected by true plasmodesmata. These peripheral cells are initials that give rise to branchlets 3–10 cells in length or to secondary axes that exhibit the node-internode structure of the main axis. Peripheral cells are also the initials for the cortical cells and for stipulodes. Stipulodes are single cells that subtend branchlet whorls at nodes. They may be short and blunt or long and tapering, and they occur in one or two tiers. Stipulodes are present in *Chara*, *Lamprothamnium*, and *Lychnothamnus* in the tribe Chareae and absent in *Nitellopsis* and the Nitelleae (see "Classification" section below).

Growth occurs through division of an apical cell at the tips of the main axes or secondary branches. A single cutting face of the apical cell produces an alternation of internodal cells and nodal initials. The nodal initials develop into the nodes through the cytokinetic pattern described above. While the apical region in charophytes

(Fig. 2) is superficially similar to the apical meristems of higher plants (Pickett-Heaps 1975; Clabeaux and Bisson 2009), the single cutting face is simpler than meristematic development in higher plants (Cook et al. 1998). Cook et al. (1998) interpreted the presence of plasmodesmata and pattern of cytokinesis as a parenchymatous organization of nodal tissue. In this interpretation the internodes and cortical cells are filamentous in construction, whereas the nodes are parenchymatous plates, similar to the earliest histogenetic tissues of plant apical meristems. Homology of these tissues in Charales and higher plants is open to question.

Branchlet morphology differs greatly among genera (Fig. 1). *Chara, Lamprothamnium*, and *Lychnothamnus* produce whorls of branchlets that are essentially monopodial and do not branch dichotomously. Branchlets in *Nitella* are generally not monopodial, and they bifurcate one or several times at the nodes. *Tolypella*, the third common genus, exhibits clusters of branchlets and stalked reproductive structures in clusters at nodes that have the appearance of a bird's nest.

Asexual reproduction occurs through growth of erect axes from nodes on the rhizoids, and through contracted starch-filled branches (Casanova et al. 2007; Casanova 2009), and tubercular, starch-filled outgrowths of the rhizoids called bulbils (Fritsch 1948; Casanova 1994), which may fall away and germinate separate from the thallus.

Sexual reproduction is oogamous. Oogonia and antheridia are the female and male gametangia, respectively, which include gamete-producing cells and associated vegetative cells. Each oogonium contains a single large egg cell, whereas sperm are produced in filaments with numerous antheridial cells, packed inside a spherical antheridium (Pickett-Heaps 1975; Graham and Wilcox 2000). Smith (1950) interpreted the oogonia and antheridia as single-celled structures, each within a larger structure of modified sterile vegetative filaments. He and some authors used the terms "globule" for the male and "nucule" for the female sexual structures, although the more common terms used are antheridia and oogonia, or oosporangia, respectively. Oogonia and antheridia occur on the branchlets at nodes and may be associated with small sterile cells and can be enveloped in mucous. The oogonia are oblong, 200–1000 μm long by 200–600 μm wide. Sexual structures are easily visible with a hand lens or even with the naked eye. Thalli may be dioecious or monoecious. In monoecious species, the two kinds of reproductive structure may occur at the same node (conjoined) or different nodes (sejoined) on the same branch. Sexual structures are relatively easy to remove for experimental crossing studies of monoecious and dioecious species (McCracken et al. 1966; Grant and Proctor 1972).

The egg is surrounded by five jacket cells that spiral in a left-handed (sinistral) twist from the base to the apex, which consists of one or two tiers of cells that form a corona (Fig. 3). The Chareae have one tier of coronal cells, the Nitelleae two. The mature oospore (Fig. 4) displays a basal pentagonal cell and in some genera one or two additional basal cells.

Male antheridia are spherical and range from 200 to 1500 μm in diameter, often bright orange in color. The outside of the antheridium is composed of four or eight shield cells, inside of which is a cluster of modified multicellular filaments, each cell of which produces one sperm. Sperms have two flagella attached slightly below the

Fig. 3 Apex of *Chara* oogonium (female sexual structure) with single tier of five coronal cells. Note spiral jacket cells and transparent sperm swimming around apex. (M. E. Cook)

apex of an asymmetric, helically twisted cell reminiscent of sperm cells in mosses and liverworts (Renzaglia and Garbary 2001).

Sperm cells are liberated when the shield cells separate. Sperm gain access to the egg cells through slits between jacket cells near the apex of the globules (Fig. 3). The zygote and inner jacket cell walls thicken, and the outer parts of the jacket cells fall away leaving an oblong, spiral-embossed spore, which may germinate immediately or go through a period of dormancy (Casanova and Brock 1996). Upon germination, a main axis and a rhizoidal initial are produced, which develop into the mature thallus (Fritsch 1948).

The Characeae possess large chromosomes (Fig. 5) that are relatively easy to stain and count during mitotic cell divisions (Casanova 1997). Young antheridia provide the best material for chromosome observation, but rhizoid squashes can also be successful. Chromosome numbers vary widely in all genera. Counts between 8 and 77 have been published as observed values within *Chara* and *Nitella* (Guerlesquin 1984; Bhatnager 1983). On the basis of this multiplicity of published numbers, both Bhatnager (1983) and Guerlesquin (1984) have attempted to identify the basic or ancestral chromosome numbers for the group. Not surprisingly, the plethora of reported chromosome counts has resulted in basic chromosome number(s) for Characeae of 3, 5, 6, 7, 8, or 11. Grant (1990) hypothesized that a single base, or ancestral, number of $n = 14$ is adequate to explain all extant chromosome numbers in the genus *Chara* and that aneuploidy is either extremely rare or absent. He noted that reported chromosome numbers in *Chara* were invariably multiples of 14, i.e., 14, 28, 42, or 56, in natural populations. Estimates of chromosome numbers in *Nitella* range from 3 to 27, almost invariably multiples of 3 or 9, so the basic

chromosome number is likely to be 3. Grant (1990) also argued that the cytogenetic mechanism and evolutionary history of this group cannot be well understood until chromosome numbers are established and that chromosome counts must be stable and correlated with biological species and not the result of an aberrant cell division product. Further karyotypic work on the Characeae is clearly needed. Grant and Proctor (1972, 1980) postulated that polyploidy is adaptive as a mechanism for producing (and masking harmful) genetic variation in self-fertilizing monoecious species, in contrast to dioecious species, which generally possess half the number of chromosomes. In dioecious species, genetic variation maintained through outbreeding may enhance survival in habitats that vary from one generation to the next (e.g., in temporary wetlands), and in polyploid monoecious species, variation in enzyme activity (through multiple copies of enzymes) is likely to enhance survival during the life of a single plant or population (e.g., in permanent habitats) (Casanova 1997). Grant and Proctor (1972, 1980) suggested that sexual reproduction functions as a mechanism of dispersal and drought avoidance in addition to its role in genetic recombination.

Classification

The genus *Chara* was erected by Vaillant in 1719 for several living species of this genus and formally recognized by Linnaeus (1753) as one of several genera of algae. Understanding of the relationship of the Charales to other green algae and land plants has undergone considerable revision in recent years (reviewed in McCourt et al. 2004; Becker and Marin 2009). The relatively complex morphology and reproduction of charophytes has been long known and led Smith (1950) and others (Margulis et al. 1990, in the first edition of this book) to view the group as a class (Charophyceae) separate from the rest of the green algae (Chlorophyceae). Some workers preferred to elevate the group to division status (e.g., Charophyta of Bold and Wynne 1978). Research on cell ultrastructure and flagellar insertion (Mattox and Stewart 1984), along with molecular phylogenetic studies (McCourt et al. 1996, 1999; Meiers et al. 1999; Karol et al. 2001; Sakayama et al. 2002; 2004a, b, 2005a, b), supported the monophyly of extant members of the group, regardless of rank. In addition, the monophyly of the fossil and extant members of the Charophyceae is well supported (Feist et al. 2005). Figure 6 depicts a consensus molecular phylogeny for the genera of extant Charales (Karol et al. 2001) and also shows the occurrence record of fossils for the major lineages since the origin of the group in the Silurian (dates from Feist et al. 2005). Note that some sister lineages of the extant Charales occur much earlier in the fossil record (Early Devonian) but have since become extinct.

Feist et al. (2005) summarized the history of classification of the charophytes and proposed a classification including both fossil and extant taxa in the phylum (=division) Charophyta, with the single class Charophyceae. Living charophytes are included in the family Characeae in the order Charales, along with five families of extinct taxa known primarily from fossil spores (gyrogonites), with few vegetative

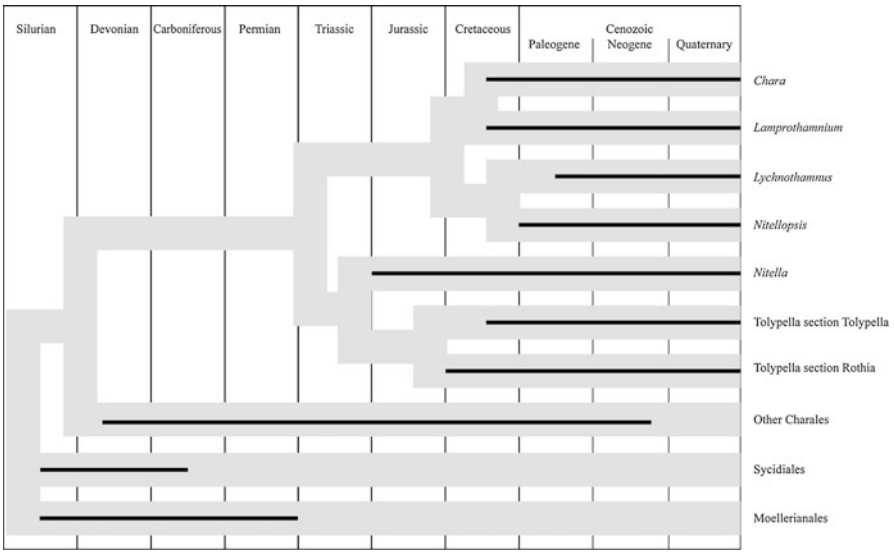

Fig. 6 Phylogenetic relationships of genera in the Charales, and ranges of fossil ages of extant genera and several extinct taxa. The black bars indicate the ages of the earliest known fossils for taxa, as well as fossil ages for extinct taxa in the Charales and the extinct Orders Sycidiales and Moellerinales. Relationships of extant taxa based on molecular phylogenetic studies (McCourt et al. 1999; Meiers et al. 1999; Karol et al. 2001). Fossil ages and phylogenetic relationships of fossil taxa based on Feist et al. (2005). (R. M. McCourt and J. D. Hall)

thalli in the fossil record (but see Kelman et al. 2004). Two additional orders of fossil taxa (Fig. 6) are also included in the Charophyceae (Feist et al. 2005).

Lewis and McCourt (2004) proposed a classification of green algae that assigned extant charophytes to the class Charophyceae in a clade containing several other orders of green algae plus embryophytes or land plants. A separate clade comprises the remaining members of the traditional Chlorophyta. This division of the green algae into two evolutionary lineages, one of which contains several smaller groups (► Chlorokybophyceae, Klebsormidiophyceae, Coleochaetophyceae, by Cook and Graham) and the other larger clade of conjugating green algae (► Zygnematophyta, by Hall and McCourt), was originally based on ultrastructural morphology of flagellar roots and types of mitosis, as well as features of glycolate metabolism (Mattox and Stewart 1984). The hypothesis of two major clades has been strongly supported by molecular data (McCourt et al. 1996; Karol et al. 2001; Becker and Marin 2009). In this scheme, the green algae *sensu lato* do not constitute natural group, and some green algae are clearly more closely related to embryophytes than to other green algae (i.e., Charophyta sensu Karol et al. 2001). A classification of charophytes of this chapter is shown in Table 1.

The evolutionary relationship of Charales to embryophytes remains unresolved (Graham 1993; Lewis and McCourt 2004; Turmel et al. 2006; Becker and Marin 2009). Karol et al. (2001) performed a phylogenetic analysis on a broad sample of

35 green algae and embryophytes using four genes (two plastid, one mitochondrial, one nuclear, ~5000 bp) and found strong support for the hypothesis that the Charales are the sister group (i.e., closest living relatives) of land plants. This hypothesis has been challenged by a study of entire plastid genomes from a smaller number of green algae and land plants (Turmel et al. 2006). The latter study used 76 genes from the complete plastid genomes of nine green algae and embryophytes (~48,000 nt) and found strong support for the hypothesis that conjugating green algae (see ► Zygnematophyta) constitute the sister group to embryophytes. These alternate hypotheses of the embryophyte sister taxon would lead to very different sets of assumptions about the common ancestor of embryophytes and their nearest green algal relative, since the Zygnematophytes are simpler in morphology and reproduction than the charophytes and lack mastigote cells entirely (McCourt et al. 2004). Some of the implications of the sister status of Zygnematophytes and embryophytes are explored in Wodniok et al. (2011).

Additional data with more taxa and more sequence data (including organellar genome data) may resolve this interesting question with significant implications for the evolution of land plants and the origins of their adaptations to a dry habitat.

Maintenance and Cultivation

Charophytes present some unique challenges for cultivation due to their size, life cycle, and, in some cases, dioecy. The erect thallus and rhizoid system often require larger culture vessels (liter sized or more) for the development of adult morphology. The effort needed for culturing charophytes depends on the uses to which they will be put and the length of time the cultures will need to be maintained. Short-term cultures for physiological studies (Beilby and Shepherd 2006), chromosome assessments (Casanova 1997), teaching exercises, or morphological studies (Casanova 2009) can be simply obtained from field-collected material kept in rainwater on a windowsill. Longer term cultures for genetic vouchers or clonal reproductive studies are more difficult to maintain. Because epiphytes are frequent, axenic cultures are difficult to establish from vegetative material. Unialgal cultures (i.e., with a single species of eukaryotic algae and possible bacterial contamination) can be obtained through germination of surface sterilized spores in defined media. However, material for microscopic observation and molecular studies can usually be obtained from branch tips that are relatively free of epiphytes.

Proctor (personal communication) developed a successful means of growing what he termed “clones” (isolates from single vegetative thalli or oospores) in seminatural conditions in a greenhouse. In this method, wide-mouth one-gallon (3.8 L) glass jars are filled to a depth of 3 cm with autoclaved or steam-sterilized alkaline sandy-loam soil. Jars with sandy loam are filled with steamed or filter sterilized water free of chlorine and metal residue from copper pipes. Field-collected sprigs of vegetative branches brushed or manually cleaned of epiphytes are then planted in the sandy loam using clean large forceps or gloved hands. After several weeks, it will be apparent if the sprig has successfully anchored itself in the sediment

with rhizoids. Epiphytes or algal cells associated with the field-collected sprigs may infest some cultures, but the Proctor reported (personal communication) that these often die back without any special treatment. While not always successful, this technique can yield long-lived (>20 years) clonal cultures that require little more than indirect sunlight on a window sill. Such cultures are readily used in the classroom.

The National Institute for Environmental Studies in Japan (NIES; http://mcc.nies.go.jp/) has reported success in growing charophytes in defined media and provided illustrated instructions on culture methods. Watanabe (2005) has also provided methods for *ex situ* cultivation of threatened algal species and included media for Charales.

Evolutionary History

The Charales are exceptional among green algae in having an extensive fossil record, rivaled only by the Dasycladales of the Ulvophyceae (Berger and Kaever 1992; Taylor et al. 2009). Some taxa of both groups deposit calcium carbonate as part of the thallus, which facilitated formation of fossils of vegetative and, in particular, reproductive structures (spores). In Charales, the oogonium is often enveloped by a calcium carbonate "shell" (most *Nitella* and some *Chara* species are exceptions). Fossils resulting from these types of reproductive structures are called gyrogonites, which are often more elaborate in structure than spores of extant Characeae (Fig. 7). Gyrogonites range in size from a few hundred μm to several mm in size. Although some vegetative thalli may be calcified, such as the well-known *Paleonitella* found in the Early Devonian Rhynie chert (Kidston and Lang 1921), gyrogonites are much

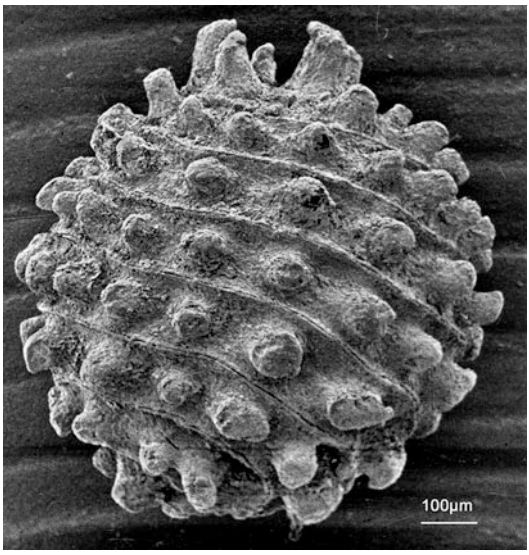

Fig. 7 Gyrogonite of *Maedleriella angusta* Feist-Castel, a species from the Middle Eocene of Southern France (From Feist-Castel 1972)

more common in the fossil record. Therefore, gyrogonite morphology is the basis for most of the taxonomy and stratigraphy of fossil Charales (Feist et al. 2005).

Morphology of gyrogonites provides a rich source of data: shape, dimensions, apical structure, presence and absence of pores, morphology of membranous coverings that occur in some groups, occurrence of a variety of bumps, tubercles, or other ornamentations on the outer surface (Feist et al. 2005). The earliest gyrogonites from the late Silurian and Early Devonian exhibit greater morphological variation than oospores or more recent or extant taxa. The pattern of spiraling of the jacket cells (also called spiral cells) apparently reversed in the Early Devonian (ca. 370 mya) from dextral to sinistral, and the number of jacket cells decreased over time such that all extant taxa now have five sinistral jacket cells, although occasionally spores with six cells are found (M. Casanova, personal observation).

Between the upper Silurian and the present day, charophytes have gone through several periods of diversification and extinction (Grambast 1974). Diversity was greatest during the Devonian, with a secondary peak in diversity in the Late Jurassic and Early Cretaceous (Feist et al. 2005). Since the Miocene, diversity has declined (Grambast 1974) so that only a single family (Characeae) with six genera survives today. Feist et al. (2005) provided a comprehensive overview of the fossil record and evolutionary history of the group.

Acknowledgments The authors acknowledge the National Science Foundation, grants DEB 1020948 and 1036478, for support in writing this chapter. We sincerely thank Dr. Michelle T. Casanova, who reviewed the manuscript and provided several figures. This material is based in part on work performed while R. M. McCourt worked at the U.S. National Science Foundation. Any opinion, findings, and conclusions or recommendations expressed in this material are those of the authors and do not necessarily reflect the views of the National Science Foundation.

Chlorokybophyceae, Klebsormidiophyceae, Coleochaetophyceae

6

Martha E. Cook and Linda E. Graham

Abstract

The freshwater and terrestrial green algal lineages discussed in this chapter include the scaly flagellate *Mesostigma*, the sarcinoid form *Chlorokybus*, the unbranched filamentous members of the Klebsormidiophyceae, and the branched filamentous members of the Coleochaetophyceae. The lineages discussed here, together with two other green algal lineages (Charophyceae and Zygnematophyceae) and the land plants (embryophytes), form a monophyletic group known as Streptophyta or Charophyta. The streptophyte algae share cytological and biochemical characteristics with plants and may shed light on the evolution of plant features. Of special interest is the evolution of mechanisms associated with the transition from freshwater to dry land, a topic currently being energized by whole-genome analyses. Metagenomic studies of these organisms have revealed surprising features that might also have characterized the microbiomes of early streptophytes.

Summary Classification

●**Streptophyta** (Charophyta)
●●**Mesostigmatophyceae** (*Mesostigma*)
●●**Chlorokybophyceae** (*Chlorokybus*)
●●**Klebsormidiophyceae** (e.g., *Klebsormidium*, *Entransia*)
●●**Coleochaetophyceae** (e.g., *Coleochaete*, *Chaetosphaeridium*)

Introduction

The green algal lineages discussed in this chapter include simple freshwater or terrestrial forms distinguished by their close relationship with land plants (embryophytes). The clade Streptophyta (also known as Charophyta) includes embryophytes along with their close green algal relatives, known informally as streptophyte algae or charophyte algae (Bremer 1985; Lewis and McCourt 2004). These algae were originally termed charophycean algae (Mattox and Stewart 1984). The orders Chlorokybales, Klebsormidiales, and Coleochaetales were placed in the class Charophyceae by Stewart and Mattox (1975; Mattox and Stewart 1984) on the basis of a distinctive set of cytological and biochemical characters. These algae form flagellate reproductive cells that are rather similar to spermatozoids of land plants in ultrastructural details. Neither these reproductive cells nor plant spermatozoids have eyespots (which are often present in green algal swarmers). Both have a multilayered structure (MLS) associated with their flagellar apparatus. However, unlike land plant sperm but like motile cells of certain other green algae, charophycean swarmers are typically covered with many small, square scales and

bear similar scales as well as hairs on the flagella. At cytokinesis, members of these charophycean orders have a persistent interzonal spindle, and the genera *Coleochaete* and *Chaetosphaeridium* produce a phragmoplast and cell plate similar to those of land plants (Brown et al. 1994; Cook 2004a; Doty et al. 2014; Marchant and Pickett-Heaps 1973). Streptophyte algae also have peroxisomes and photorespiratory enzymes similar to those of land plants (Frederick et al. 1973). For these and other reasons, streptophyte algae (including the lineages that are the subject of this chapter as well as Zygnematophyceae and Charophyceae (orders Zygnematales and Charales of Mattox and Stewart (1984); see ▶ Charophyceae (Charales) and ▶ Zygnematophyta)) are believed to be closer to the ancestors of land plants (embryophytes) than are other green algae. Cytological (Melkonian 1989; Rogers et al. 1981), biochemical (Iwamoto and Ikawa 2000; Schwender et al. 2001), and molecular (Kim et al. 2006; Nedelcu et al. 2006; Petersen et al. 2006; Rodríguez-Ezpeleta et al. 2007; Simon et al. 2006) evidence indicates that the former prasinophyte *Mesostigma viride* is also a member of the streptophyte algae.

Mesostigma viride Lauterborn is the only member of the Mesostigmatophyceae (Lewis and McCourt 2004; Marin and Melkonian 1999). Likewise, the only member of the Chlorokybophyceae is the single species *Chlorokybus atmophyticus* Geitler (Bremer 1985). Klebsormidiophyceae includes the species *Entransia fimbriata* Hughes (Karol et al. 2001; McCourt et al. 2000; Sluiman et al. 2008; Turmel et al. 2002), the species *Hormidiella attenuata* Lokhorst (Lokhorst et al. 2000; Sluiman et al. 2008), and *Klebsormidium* (Silva et al. 1972) with approximately 20 species currently described (Lokhorst 1996; Novis 2006; Rindi et al. 2008; Škaloud 2006; Sluiman et al. 2008). In addition to these filamentous klebsormidialian forms, some recent studies have indicated that the genus *Interfilum* Chodat, which includes three species composed of unicellular aggregations or cell packets, nests within the genus *Klebsormidium* (Mikhailyuk et al. 2008, 2014; Novis and Visnovsky 2011; Rindi et al. 2011), a condition that will likely require renaming of at least some species of *Klebsormidium* (Novis and Visnovsky 2011; Rindi et al. 2008). Coleochaetophyceae encompasses *Chaetosphaeridium* Klebahn with six species (Thompson 1969) and *Coleochaete* de Brébisson with approximately 20 species currently described (Cimino and Delwiche 2002; Delwiche et al. 2002; Printz 1964). Additional genera are hypothesized to belong to Klebsormidiophyceae and Coleochaetophyceae but have not been sufficiently well studied for accurate systematic placement at this time. The lineages of green algae discussed in this chapter are generally of no particular economic importance. However, in view of their close relationship to land plants, they may well provide excellent simple systems for the study of more complex physiological and reproductive processes of plants, including the transition of aquatic algal ancestors to dry land (Bowman 2013; Delwiche and Cooper 2015; Graham 1984, 1985, 1993, 1996; Graham and Kaneko 1991; Graham et al. 2000).

Habitats and Ecology

The genera included here occupy a variety of freshwater and terrestrial habitats. *Mesostigma viride* is a freshwater flagellate. The sarcinoid form *Chlorokybus atmophyticus*, as its name indicates, has been isolated from terrestrial habitats (Škaloud 2009). *Klebsormidium* travels through the air and occupies diverse freshwater and terrestrial habitats, including biological soil crusts (Mikhailyuk et al. 2015) and urban settings, especially at the base of humid walls and in the shade of tall chimneys (Rindi et al. 2008). Some species of *Klebsormidium* occur in acid mine drainage environments (Brake et al. 2014; Novis 2006) and have been proposed for use in removing metals from these environments (Orandi and Lewis 2013). Surveys of biodiversity within *Klebsormidium* reveal a correlation between phylogeny and particular types of habitat (Mikhailyuk et al. 2015). However, attempts to distinguish different lineages of *Klebsormidium* based on morphology alone have not been successful because some features (e.g., the ease of filament fragmentation) can vary with differing environmental conditions, including light, temperature, humidity, and growth medium (Rindi et al. 2008; Škaloud 2006; Škaloud and Rindi 2013). *Interfilum* occurs on soil, including alpine soil crusts and outcrops (Mikhailyuk et al. 2008; Novis and Visnovsky 2011). *Hormidiella attenuata* has been cultured from the surface of nutrient poor soil in a xeromorphic forest and in a sugar cane field (Lokhorst et al. 2000). *Entransia fimbriata* has been collected near the edge of a small lake formed by damming a river (Hughes 1948) and from a *Sphagnum* bog, in the extension of the lagg into the mat (Cook 2004b). *Coleochaete* and *Chaetosphaeridium* are generally attached to macrophytes or inorganic substrates in nearshore ponds and lakes.

Terrestrial members of the algal lineages discussed here have adapted to the stresses of life on land, including desiccation and higher levels of UV light. The terrestrial form *Chlorokybus* has UV-absorbing amino acids not present in the aquatic *Mesostigma* (Jobson and Qiu 2011). Similarly, aquatic *Entransia fimbriata* lacks UV-absorbing amino acids present in other members of the Klebsormidiophyceae, which may occur in aeroterrestrial habitats (Kitzing and Karsten 2015). Furthermore, the UV-absorbing amino acids of *Klebsormidium* and *Interfilum* have an identical absorption peak that is only slightly different from that of *Hormidiella* (Kitzing and Karsten 2015). These results are consistent with the topology of Mikhailyuk and coauthors (2008), in which *Interfilum* nests within *Klebsormidium*, *Hormidiella* is the sister group to *Klebsormidium*, and *Entransia* is the first to diverge in that lineage. Strains of *Klebsormidium* that occur in alpine soil crust resist desiccation by maintaining a high solute level (Kaplan et al. 2012) and in some cases by maintaining turgor pressure with flexible cells walls that buckle (Holzinger et al. 2011). Even when plasmolyzed, these taxa exhibit little change in cellular structure (Holzinger et al. 2011; Kaplan et al. 2012; Karsten and Holzinger 2014). *Interfilum* is more resistant to desiccation when forming packets of cells than

when in the form of single cells protected by mucilage, presumably due to surface area to volume ratio (Karsten et al. 2014). Likewise, when grown on agar or on quartz sand in a humid environment, some species of *Coleochaete* form packets or clumps of cells similar to *Chlorokybus* or *Interfilum*, rather than the flat discs that occur in a typical aquatic habitat (Graham et al. 2012). Additionally, in such an aeroterrestrial environment, the cell walls produce autofluorescent compounds and are resistant to degradation (Graham et al. 2012).

Characterization and Recognition

Morphology

Mesostigma (Fig. 1a) is a scaly unicellular flagellate with a prominent eyespot (stigma) located in the center of the chloroplast near the flagellar basal bodies (Rogers et al. 1981). The chloroplast includes two prominent pyrenoids surrounded by starch (Manton and Ettl 1965) and several superficial pyrenoids (Rogers et al. 1981). *Chlorokybus* (Fig. 1b) occurs as packets of cells (a sarcinoid thallus). Each cell has a single chloroplast with a prominent pyrenoid surrounded by a starch sheath and a peripheral superficial pyrenoid (Rogers et al. 1980). Members of the Klebsormidiophyceae (Figs. 1c–e) are either packets of cells (*Interfilum*, not shown) or unbranched filaments that may be distinguished from each other by differences in filament or chloroplast structure. *Hormidiella* exhibits a short basal transparent stalk (Lokhorst et al. 2000) (Fig. 1e), while filaments of *Entransia* (Cook 2004b) and *Klebsormidium* (Lokhorst 1996) have no stalk but may be attached with mucilage or some other adhesive. Some filaments of *Entransia* (but not *Hormidiella* or *Klebsormidium*) bear a spine at the end of the apical cell (Cook 2004b) (Fig. 1d). Fimbriate chloroplasts with multiple pyrenoids are characteristic of *Entransia* (Hughes 1948) (Fig. 1d), while chloroplasts of *Hormidiella attenuata* (Lokhorst et al. 2000) (Fig. 1e) and *Klebsormidium* (Lokhorst 1996) (Fig. 1c) have only a single pyrenoid and typically are not lobed, though some species of *Klebsormidium* may exhibit lobed chloroplasts (Lokhorst 1996), at least under certain conditions (Novis 2006; Škaloud 2006).

Coleochaetophyceae (Fig. 1f–i) are branched filaments. Whereas *Chaetosphaeridium* filaments exhibit an unusual sympodial mode of branching, often appearing to be unicellular (Thompson 1969) (Fig. 1f), *Coleochaete* (Pringsheim 1860) may be filamentous (Fig. 1g), pseudoparenchymatous (Fig. 1h), or parenchymatous (Fig. 1i) (Graham 1982). Parenchymatous species form more coherent thalli and more complex gametangia than filamentous species. *Chaetosphaeridium* and *Coleochaete* share distinctive sheathed hair cells (Fig. 1f–i) thought to function as antiherbivore defenses (Marchant and Pickett-Heaps 1977) or to increase absorptive surface area (Cimino and Delwiche 2002; Delwiche et al. 2002).

Cell Division

Ultrastructural studies of mitosis and cytokinesis have been conducted on *Chlorokybus atmophyticus* (Lokhorst et al. 1988), on *Hormidiella attenuata* (Lokhorst et al. 2000), and on several species of *Klebsormidium* (Floyd et al. 1972; Lokhorst and Star 1985; Pickett-Heaps 1972). An open spindle (nuclear membrane breaks down) widely separated telophase nuclei, and a cleavage furrow characterizes mitosis and cytokinesis in these organisms. In addition, cytokinesis in *Klebsormidium* includes interzonal vacuoles. The role of microtubules in cytokinesis was not clear. No microtubules were observed with TEM during cytokinesis in *Hormidiella attenuata* (Lokhorst et al. 2000), *K. flaccidum* (Floyd et al. 1972), or *K. subtilissimum* (Pickett-Heaps 1972), while there were microtubules parallel to the furrow in *K. mucosum* (Lokhorst and Star 1985) and in *Chlorokybus* (Lokhorst et al. 1988). Immunofluorescence microscopy demonstrated the presence of interzonal microtubules perpendicular to the division plane between the widely separated telophase nuclei in *Klebsormidium flaccidum* and *K. subtilissimum* (Katsaros et al. 2011). Hooplike cortical microtubules at interphase transitioned gradually to form a spindle during pre-prophase in these taxa. Microtubules and centrioles were closely associated with the single peroxisome during mitosis in *Klebsormidium flaccidum* (Honda and Hashimoto 2007).

Studies of living cells of *Chaetosphaeridium globosum* at the light microscope level and immunofluorescence localization of tubulin on fixed cells of this taxon have revealed the presence of a plantlike phragmoplast during cytokinesis (Doty et al. 2014). Marchant and Pickett-Heaps (1973) investigated the ultrastructure of mitosis and cytokinesis in *Coleochaete scutata.* They observed a phragmoplast similar to that found in *Chara* and land plants. A plantlike phragmoplast was also observed in *Coleochaete orbicularis* (Brown et al. 1994; Cook 2004a; Doty et al. 2014) (Fig. 2) and in *C. soluta* and *C. irregularis* (Doty et al. 2014). In the highly vacuolate cells of *Chaetosphaeridium* and *Coleochaete*, like those of the vascular plant *Arabidopsis* (Cutler and Ehrhardt 2002), the phragmoplast must in some cases negotiate a large vacuole (Cook 2004a; Doty et al. 2014). This process has been termed polar cytokinesis (Cutler and Ehrhardt 2002) because the cell plate forms first on one side of the cell and moves across to the other side of the cell, rather than moving out from the center as it would in cells without a single large vacuole.

Peroxisomes are located between the nucleus and the chloroplast in *Klebsormidium* (Floyd et al. 1972; Lokhorst and Star 1985), *Interfilum* (Mikhailyuk et al. 2008, 2014; Novis and Visnovsky 2011), *Hormidiella* (Lokhorst et al. 2000), *Chaetosphaeridium* (Moestrup 1974), and *Coleochaete* (Marchant and Pickett-Heaps 1973), while in *Chlorokybus* (Lokhorst et al. 1988; Rogers et al. 1980) and *Mesostigma* (Rogers et al. 1981), the peroxisome is associated with centrioles or flagellar basal bodies. Both associations facilitate distribution of the divided peroxisome into two daughter cells during cytokinesis and may represent an evolutionary transition from centriole-associated peroxisomes to the chloroplast-associated peroxisomes that occur in embryophytes (Graham and Kaneko 1991).

Life Cycle

Chlorokybus and members of the Klebsormidiophyceae and Coleochaetophyceae reproduce asexually by means of biflagellate zoospores. Each zoospore forms from the entire protoplast of one cell and is released by dissolution of the cell wall in *Chlorokybus* (Rogers et al. 1980) or through a pore in the cell wall (Fig. 3a) in members of the Klebsormidiophyceae (Cain et al. 1973; Cook 2004b; Lokhorst 1996; Lokhorst et al. 2000) and Coleochaetophyceae (Thompson 1969; Wesley 1928). Sexuality has not been documented for *Mesostigma*, *Chlorokybus,* or members of the Klebsormidiophyceae. The Coleochaetophyceae are oogamous (a large, nonmotile egg is fertilized by small, biflagellate sperm). So far as is known, sexually reproducing forms have a haplobiontic, haploid life cycle. The only diploid cell is the zygote, and as zygotes typically serve as resting cells, they are often called oospores.

The zoospores of *Chlorokybus atmophyticus* (Rogers et al. 1980), *Hormidiella attenuata* (Lokhorst et al. 2000), and *Klebsormidium flaccidum* (Marchant et al. 1973) have been studied ultrastructurally, as have zoospores of *Chaetosphaeridium* (Moestrup 1974) and zoospores, meiospores, and spermatozoids of *Coleochaete* (Graham and McBride 1979; Graham and Taylor 1986; Graham and Wedemayer 1984; Pickett-Heaps and Marchant 1972; Sluiman 1983). These motile cells are

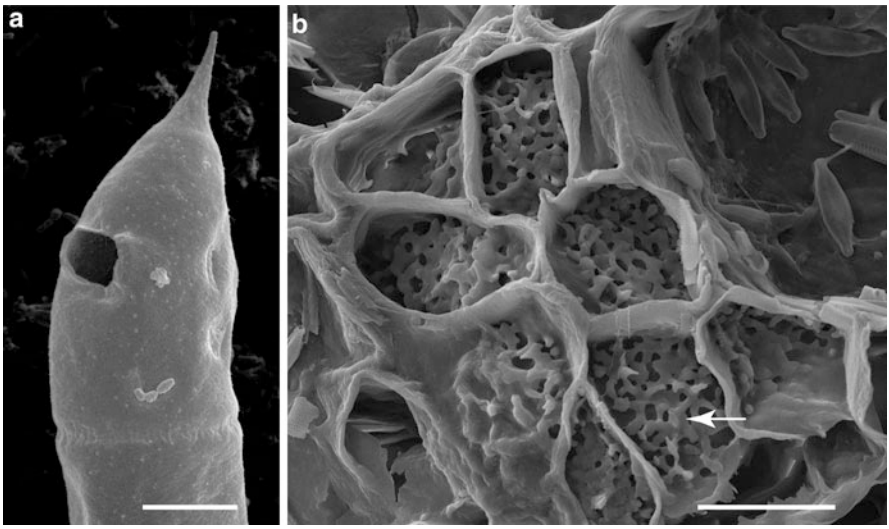

Fig. 3 Scanning electron micrographs of cells with evidence of asexual (**a**) and sexual (**b**) reproduction. (**a**) Empty cell with pore through which a zoospore escaped in filament of *Entransia fimbriata*. Scale bar = 5 μm. (**b**) A layer of elaborate cell wall ingrowths (*arrow*) covers the surface of protective cells adjacent to a zygote in a thallus of *Coleochaete orbicularis.* This thallus has overwintered, and the cell walls on the surface away from the zygote have decomposed, making it possible to see the wall ingrowths. Similar wall ingrowths occur in placental transfer cells at the interface of parent and offspring in land plants. Scale bar = 20 μm. Micrographs: (**a**) M.E. Cook; (**b**) M.E. Cook and L.W. Wilcox (From Graham et al. (2016) *Algae* 3rd edition, used with permission of LJLM Press)

characterized by flagella that emerge subapically and extend to the right when the cell is observed from the side down which the MLS microtubules extend. The MLS of these charophycean swarmers is considered to be homologous to one of the two MLSs of *Mesostigma* (Melkonian 1989; Rogers et al. 1981). The small diamond-shaped scales that occur on the zoospores of *Chlorokybus* and *Chaetosphaeridium* and on the swarmers of *Coleochaete* are similar to the maple-leaf-shaped scales of *Mesostigma* (Marin and Melkonian 1999). Unlike *Mesostigma*, none of the other streptophyte flagellate cells exhibits an eyespot.

Coleochaete is unique among charophycean algae, and similar to embryophytes, in retention of zygotes on parental thalli and in production of more than four meiospores per zygote. In *Coleochaete orbicularis*, there are zygote-associated cells that resemble the placental transfer cells of embryophytes (Graham and Wilcox 1983) (Fig. 3b). Wall ingrowths in these cells provide extensive surface area for efficient transfer of nutrients from the parent thallus to the developing zygotes. Nutritional support of the new diploid generation from the parent gametophyte generation, known as matrotrophy, is thought to be a critical step in the evolution of the plant life cycle (Bower 1908; Graham and Wilcox 2000).

Cell Coverings

Mesostigma is covered with three different layers of scales (Manton and Ettl 1965). The innermost layer is composed of small square scales like those on swarmers of other streptophyte taxa, while the middle layer is formed of larger flat oval scales, and finally the outermost layer consists of elaborate three-dimensional basket-shaped scales. All of these scales are produced in Golgi vesicles (Domozych et al. 1992; Manton and Ettl 1965). The basket scales have been found to include calcium, phosphate, and a sugar keto acid that is part of the pectic polysaccharide rhamnogalacturonan II found in cells walls of higher plants (Domozych et al. 1991). *Mesostigma* has no cell wall, only scales.

Members of the other charophycean lineages have cell walls made of cellulose and other components of plant cell walls. *Coleochaete scutata* exhibits rosette-type cellulose-synthesizing complexes that are similar to those of plants (Okuda and Brown 1992). These complexes are formed in Golgi vesicles and transported to the cell membrane where they produce cellulose microfibrils. Analyses based on rotational symmetry indicate that these complexes have eightfold symmetry in *C. scutata* (Okuda and Brown 1992), in contrast to the rosettes of six particles known from plants and members of the Zygnematophyceae (Tsekos 1999).

Biochemical analysis revealed that cell walls of *Coleochaete* are more like those of plants than are cell walls of *Chlorokybus* or *Klebsormidium.* For example, cell walls of *Chlorokybus* and *Klebsormidium* include less cellulose and more callose than those of *Coleochaete* (Sørensen et al. 2011), and they lack evidence for the pectic polysaccharide rhamnogalacturonan-I found in *Coleochaete* (O'Rourke et al. 2015). On the other hand, the pectic polysaccharide homogalacturonan was present in cell walls of *Chlorokybus* and *Coleochaete,* but not *Klebsormidium* (O'Rourke et al. 2015). In the cell walls of *Coleochaete*, small amounts of lignin-like compounds were identified (Sørensen et al. 2011). Hence, molecules prominent in plant cell walls were inherited from algal ancestors, and analysis of the cell wall components of streptophyte algae may lead to a greater understanding of the complex construction of plant cell walls.

Genomes

The genome of *Klebsormidium flaccidum* has been fully sequenced (Hori et al. 2014). This work revealed that plant genes important for survival on land were already present in *Klebsormidium*, including those associated with protection from high levels of light and with hormone signaling pathways. For example, a gene for transport of the hormone auxin in *Klebsormidium* appears to be intermediate between two forms of the gene present in the vascular plant *Arabidopsis* (Viaene et al. 2013; Hori et al. 2014).

Metagenomes

Long-read shotgun metagenomic analyses for *Coleochaete pulvinata* and *Chaetosphaeridium globosum* indicated that some microorganisms and genes characteristic of land plant microbiomes might have originated from algal ancestors (Knack et al. 2015). In addition to nitrogen-fixing cyanobacteria and rhizobialeans (e.g., *Rhizobium*), the *C. pulvinata* and *Ch. globosum* microbiomes included methanotrophs, as do those of early-diverging bryophytes (e.g., *Sphagnum* peat mosses, whose lineage extends back to at least the middle Ordovician (Laenen et al. 2014)). 16S rDNA amplicon analyses of *Nitella tenuissima* indicated diverse prokaryotic associations and greater similarity of microbiota to that of members of the Coleochaetophyceae than to a chlorophyte of similar size and ecology (Knack et al. 2015).

Sequence evidence for early-diverging fungi and *Nuclearia*, the protist sister to the Kingdom Fungi was also observed in metagenomes of the Coleochaetophyceae, suggesting the remarkable possibility that streptophyte-fungal associations originated prior to the origin of the plant and fungal kingdoms (Knack et al. 2015). Part of the pathway involved in signaling between plants and mycorrhizal fungi had already arisen in *Chlorokybus* (Delaux et al. 2015).

Metagenomic analysis of *C. pulvinata* and *Ch. globosum* (Knack et al. 2015) also allowed inference of presence of protein subunits serving as functional enzyme markers, e.g., diverse types of NifH indicating nitrogen fixation and particulate methane monooxygenases indicating methane oxidation, as well as all enzymes involved in aerobic and anaerobic biosynthetic pathways for vitamin B_{12}.

Maintenance and Cultivation

Mesostigma has been grown in nine parts Woods Hole Medium (Nichols 1973) supplemented with one part soil water extract (Domozych et al. 1991). Cultures of *Chlorokybus* and *Klebsormidium* can be maintained on agarized Bold's Basal Medium (BBM) (Nichols 1973). Liquid or agarized BBM with addition of vitamins and triple nitrate have also been used to grow *Klebsormidium* and *Interfilum* (Mikhailyuk et al. 2014; Rindi et al. 2011). *Hormidiella* can be cultured with Woods Hole Medium or liquid or agarized BBM and has sometimes been supplemented with 2% soil water extract (Lokhorst et al. 2000). *Entransia* prefers BBM with added B vitamins (Cook 2004b).

Coleochaete can also be maintained long term on BBM agar with the plate stored upside down. When actively growing cultures with normal morphology are required, specimens can be transferred to liquid SD11 medium (Hoffman and Graham 1984). Species of *Coleochaete* obtained from culture collections often exhibit abnormal morphology, and better results may be obtained using fresh isolates collected from nature by zoospore isolation (Graham et al. 1986). Cultures of *Chaetosphaeridium*

can also be obtained from nature by zoospore isolation techniques and may be grown in Woods Hole Medium (Delwiche et al. 2002) or in DYIII medium (Doty et al. 2014).

Most of the taxa discussed in this chapter can be maintained with a 16 h light: 8 h dark cycle at 15–20 °C. *Entransia* grows best with shade cloth to provide protection from high levels of light (Kitzing and Karsten 2015). Induction of zoosporogenesis via a dark treatment has been described for *Klebsormidium flaccidum* (Cain et al. 1974).

Evolutionary History

Overall Phylogenetic Position

The green algae are composed of two major clades: the Chlorophyta, including numerous lineages of scaly unicellular prasinophytes, and the Streptophyta (also known as Charophyta), which includes land plants (embryophytes) and their closest green algal relatives (Bremer 1985; Lewis and McCourt 2004; McCourt 1995; McCourt et al. 2004) (Fig. 4). These close algal relatives of plants are not a

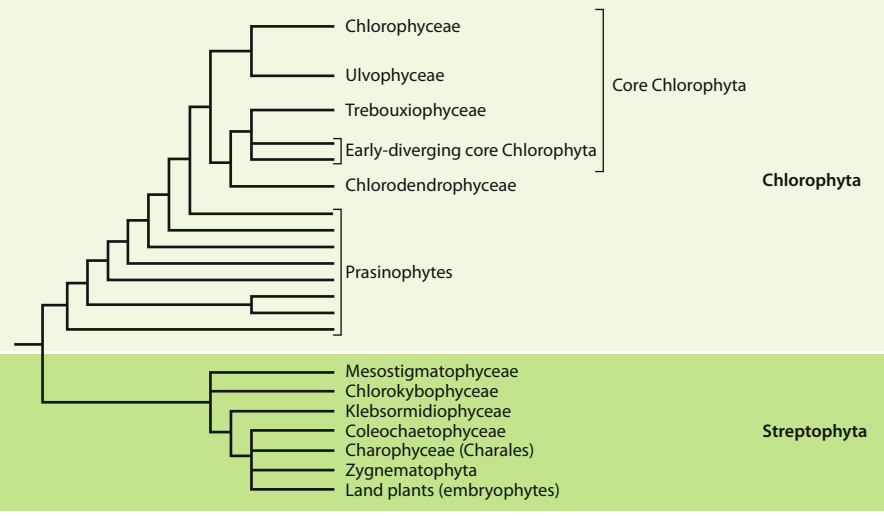

Fig. 4 Cladogram showing relationship of streptophyte algae to other green algae and land plants based on molecular analyses (Civáň et al. 2014; Karol et al. 2001; Leliaert et al. 2012; Timme et al. 2012; Turmel et al. 2013; Wickett et al. 2014). Molecular analyses support previous hypotheses of relationships among major green algal groups based on ultrastructure and biochemistry (Reviewed by Lewis and McCourt 2004)

monophyletic group without plants and have been referred to as charophycean green algae (Mattox and Stewart 1984), charophyte algae (Lewis and McCourt 2004), or streptophyte algae (Becker and Marin 2009).

While *Mesostigma* is a scaly flagellate, this genus is no longer classified with the prasinophytes and is therefore not a member of the Chlorophyta, though one recent molecular analysis found that there was insufficient data to resolve the position of *Mesostigma* (Grievink et al. 2013). Initial studies of organelle genomes (Lemieux et al. 2000; Turmel et al. 2002) placed *Mesostigma* at the base of the green algae, before Chlorophyta and Streptophyta diverged, but most evidence, including duplication of the gene for glyceraldehyde-3-phosphatase dehydrogenase (Petersen et al. 2006), a multilayered structure (MLS) in the flagellar apparatus like that of streptophyte zoospores and spermatozoids (Melkonian 1989; Rogers et al. 1981), the presence of the enzymes glycolate oxidase (Iwamoto and Ikawa 2000) and Cu/Zn superoxide dismutase (DeJesus et al. 1989), as well as data sets with molecules from all three genomes (Karol et al. 2001; Rodríguez-Ezpeleta et al. 2007), indicates that *Mesostigma* is a member of the Streptophyta.

Internal Relationships

While there is abundant evidence uniting *Mesostigma* and the other streptophyte algae with embryophytes, relationships within the streptophyte clade are less clear. Polytomies (Fig. 4) indicate this uncertainty at the base of the Streptophyta and at the top, where the sister group of embryophytes is much debated. At the base of the Streptophyta, some molecular studies identified a clade composed of *Mesostigma* and *Chlorokybus* (Lemieux et al. 2007; Turmel et al. 2013), while others found that *Mesostigma* diverged before *Chlorokybus* (Finet et al. 2010, 2012) or could not resolve the relationship of these two species (Civáň et al. 2014; Leliaert et al. 2011, 2012). Likewise, different molecular studies have identified the sister group of plants as the Charophyceae (Charales) (Karol et al. 2001; Qiu et al. 2007; Turmel et al. 2003), the Zygnematophyceae (Civáň et al. 2014; Timme et al. 2012; Turmel et al. 2006, 2007; Wickett et al. 2014), and a clade composed of the Zygnematophyceae plus Coleochaetophyceae (Finet et al. 2010, 2012; Laurin-Lemay et al. 2012). Other analyses could not resolve this position, finding that either the Zygnematophyceae or a clade composed of the Zygnematophyceae plus Coleochaetophyceae is the sister group of land plants (Leliaert et al. 2011, 2012; Turmel et al. 2013; Wodniok et al. 2011).

Because the extant lineages of charophycean algae have been evolving for hundreds of millions of years since they diverged from a common ancestor with plants, no single lineage is likely to hold the key to plant evolution. Even if the sister group of plants remains elusive, examination of the characters of all extant charophycean algae may lead to greater understanding of the evolutionary transition from simple aquatic algae to terrestrial plants.

Importance for Understanding the Evolution of Land Plants

While none of the recent analyses has identified the Coleochaetophyceae as the sister group to plants, it is likely that a loosely branched filament, perhaps like that of *Coleochaete pulvinata* (Delwiche and Cooper 2015), was the most recent common ancestor of the extant charophycean lineages and plants. The range of morphological form in *Coleochaete* has been used to illustrate possible evolutionary transitions involved in the origins of land plant tissues and complex, multicellular gametangia (Graham 1982, 1984). It has also been proposed that *Coleochaete* illustrates evolutionary steps occurring in the origins of the sporophyte generation and alternation of generations of land plants (Graham 1985, 1990; Graham and Wilcox 2000).

The freshwater habitat of all extant streptophyte algae indicates a freshwater origin for the ancestors of plants (Becker and Marin 2009; Delwiche and Cooper 2015; Graham 1993). Becker (2012) has hypothesized that adaptation to a drier glaciated earth may have lead to the divergence of the photorespiratory pathways that distinguish the Chlorophyta (glycolate dehydrogenase in mitochondria) from the Streptophyta (glycolate oxidase in peroxisomes) (Stabenau and Winkler 2005). Traits of modern streptophyte algae that have the ability to survive in a subaerial habitat, including *Chlorokybus* (Škaloud 2009), *Hormidiella, Interfilum*, and *Klebsormidium* in nature (Karsten and Holzinger 2014; Kitzing and Karsten 2015), as well as *Coleochaete* in laboratory experiments (Graham et al. 2012), may be useful for understanding characteristics of ancient green algae that made the transition to land. These algae may also provide clues to the future adaptation of plants and streptophyte algae in a warmer and drier world.

Bacillariophyta

7

David G. Mann, Richard M. Crawford, and Frank E. Round

Abstract

The diatoms (Bacillariophyta) are the most species-rich group of autotrophic algae, found in fresh, brackish, and marine waters worldwide, and also in damp terrestrial habitats. They are well represented in marine phytoplankton and may account for 20% of global photosynthetic carbon fixation. However, the vast majority of the estimated 100,000 species are benthic, living attached to surfaces or gliding over sediments using a unique organelle, the raphe system. Flagellate cells are absent, except in the sperm of some lineages. Diatoms possess a similar photosynthetic apparatus to that present in several other stramenopile lineages (with fucoxanthin and chlorophyll c as the principal accessory pigments) but are easily recognized by the unique construction and composition of their cell wall, which is usually strongly silicified and consists of two overlapping halves (thecae); these in turn consist of a larger end piece (valve) and a series of narrow strips (girdle bands). Expansion of the cell occurs by sliding apart of the thecae and addition of new bands to the inner, overlapped theca. At cell division, each daughter cell inherits one of the thecae of the parent and forms a new theca

internally. Hence, because the silicified wall is inelastic, average cell size usually declines during vegetative growth and has to be restored through expansion of a special cell, the auxospore, usually after sexual reproduction. A few diatoms have lost their plastids and are osmotrophic. Classification has traditionally relied on details of valve structure. There is a rich fossil record.

Introduction

General Characteristics

The Bacillariophyta, commonly known as ***diatoms***, are a group of unicellular (though sometimes colonial), diploid, golden or brown-pigmented algae, most of which occur in freshwater and marine habitats; just a few live on land. The aquatic species can be planktonic or benthic. The vast majority of diatoms are free-living phototrophs but some live as endosymbionts of other protists and a small number have lost photosynthetic capacity and have become obligate heterotrophs. Like related phototrophic stramenopiles (heterokonts), photosynthetic diatoms possess chloroplasts that are bounded by four membranes and contain thylakoids grouped into threes. The principal light-harvesting pigments are fucoxanthin, chlorophyll a, and various forms of chlorophyll c. The most characteristic feature of diatoms is their silicified cell wall, referred to as the ***frustule*** (see section "Cell Wall and Cell Division"), which is unlike anything found in other organisms. It is strong and sometimes massive but, crucially for these photosynthetic cells, transparent. It is composed of several interlocking and overlapping elements, comprising two ***valves***, one at each end of the cell, which are usually large and robust, and a variable number of more delicate ***girdle bands*** covering the space in between (Fig. 1a, b). The vegetative cells are always walled except in the few species that occur as endosymbionts; no free-living flagellated or amoeboid cells exist, except as gametes. In a very few cases (e.g., some stages of the highly unusual, polymorphic diatom *Phaeodactylum*), the cell wall is purely organic.

Diatoms have a simple diplontic life cycle, multiplying profusely by mitotic divisions during the diploid vegetative phase and producing haploid cells only as a result of gametogenesis. A characteristic and remarkable feature of most diatoms is that average cell size decreases during the vegetative phase and has to be restored through formation of a special cell – the ***auxospore*** (see section "Life Cycle"). Auxosporulation is usually preceded by sexual reproduction, the auxospore being a

[1] In the case that the eight informally named groups (leptocylindrids to proboscids) together comprise a monophyletic taxon (see "Taxonomy"), this is called the Coscinodiscophytina, containing a single class, Coscinodiscophyceae.

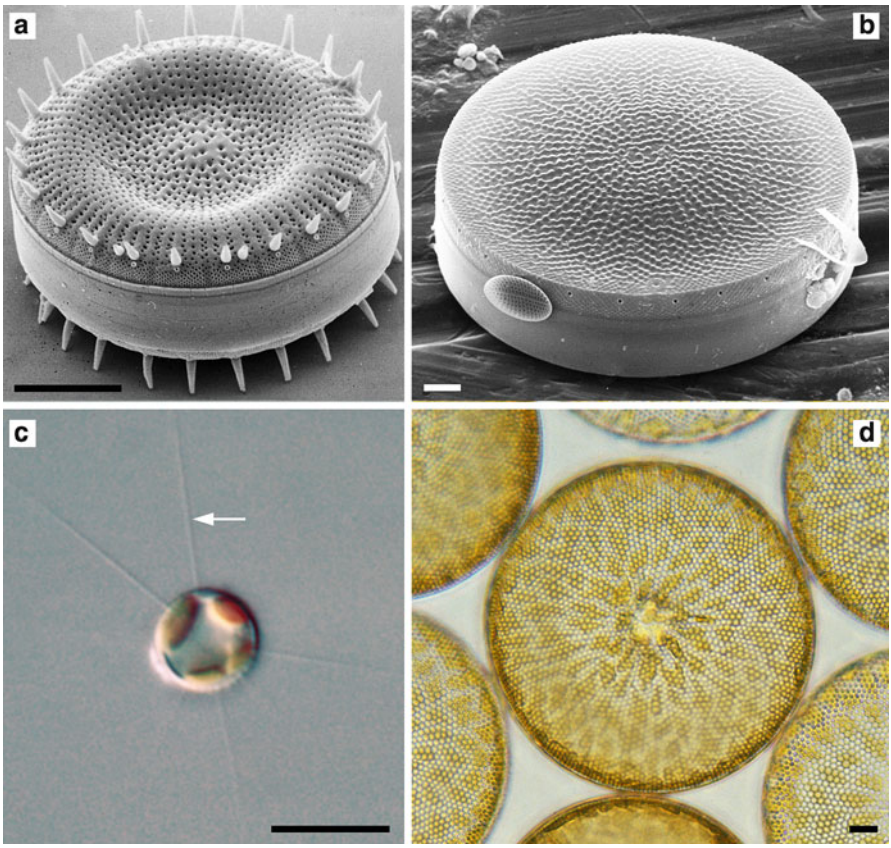

Fig. 1 Cells of planktonic centric diatoms. Scale bars = 10 μm. (**a**) Whole cell of *Stephanodiscus* with concentric undulations of the valve and a crown of spines. SEM. (**b**) Whole cell of *Actinocyclus,* SEM. (**c**) Living cell of *Cyclotella* with radiating fibrils of chitin (e.g., *arrow*) secreted through fultoportulae (Fig. 12c). (**d**) Living cells of *Coscinodiscus*; many small plastids are visible beneath the honeycomb-like pattern of markings on the valve

zygote formed through the fusion of motile or nonmotile gametes, but in some cases the auxospore is formed asexually. During auxosporulation, the cell walls of the old, small vegetative cells are discarded. In the "centric" lineages of diatoms, sexual reproduction is ***oogamous***: here the auxospore is formed by fertilization of a large ***nonmotile egg cell*** by a much smaller, ***anteriorly uniflagellate sperm***. However, in one late-evolving lineage (the pennate diatoms, comprising the majority of extant species), the gametes are relatively large and alike in size and appearance (though not necessarily in activity), and lack flagella. Auxospores (which are not dormant stages, contrary to what might be thought from the use of the word "spore") often possess special wall elements found at no other stage during the life cycle, which allow and control cell expansion and protect the newly enlarged vegetative cell while it forms its new frustule.

Some diatoms are nonmotile, drifting freely in the water column or lying loose on a substratum or growing attached to it. Others are motile, gliding actively over surfaces via a unique type of locomotion associated with a unique organelle, the ***raphe system***, which comprises slits through the cell wall (the ***raphe slits***) and associated elements of the cytoskeleton. Movement is generated by secretion of polysaccharide through the raphe slits, adhesion of the secreted material to the substratum, and active displacement of the secretions relative to the cell by interactions with the cytoskeleton, thus driving the cell forward (Edgar and Pickett-Heaps et al. 1984). Through their raphe secretions, stalks and pads, benthic diatoms often greatly modify their immediate environment, e.g., by gluing sediment particles together or by forming a thick biofilm that is colonized by other algae and microorganisms.

Several hundreds of genera of extant diatoms are recognized, and the number of named species and infraspecific taxa (including fossils) exceeds 60,000 (Kociolek and Williams 2015). Some of these taxa are synonyms, but many species have not yet been discovered or named, and it has been estimated that the final total of extant species will be between 100,000 and 200,000 (Mann and Vanormelingen 2013). Many small-celled diatoms have been poorly researched and some important, highly species-rich habitats have been largely neglected, e.g., the phytobenthos of sublittoral marine habitats. Furthermore, gene sequence data reveal that cryptic and pseudocryptic species are common. Hence the diatoms have a strong claim to be considered one of the most diverse and successful groups of protists. They also have a rich subfossil and fossil record, because their silica shells are resistant to decay. Many extinct fossil genera are known, and many modern genera are represented in the fossil record by extinct species.

Recently, diatoms have become the focus of intense research using genomic and transcriptomic approaches, because of their importance to the functioning of the biosphere and because of their unrivalled ability to metabolize silicon and produce patterned, silicified walls.

Occurrence and Sampling

Diatoms occur in almost all aquatic habitats, both freshwater and marine (Round 1981a), and probably account for about 20% of global net primary production (Mann 1999b). Virtually the whole ocean (70% of the earth's surface), down to depths to which photosynthetically available radiation (of wavelength 400–700 nm) penetrates, is colonized by diatoms, though they are numerically most abundant in regions of upwelling and other productive zones. However, the greatest diversity is probably in marine intertidal communities. For example, in two nearby samples from a North Carolina beach, Friedrich Hustedt (1955) recognized 369 species (of which 89 were new) belonging to 63 different genera. Diatoms occur on land too. Most soils capable of supporting plant growth bear diatoms, and they occur anywhere water drips, collects, or flows – even the moist regions between bryophyte leaves and on the surfaces of angiosperm leaves and lichens in wet tropical forests (Round 1981a).

Diatoms live as motile, attached, or suspended cells. Though the suspended (***planktonic***) species are those most often illustrated, and thus the most familiar to biologists (Figs. 1a–d and 2a–d), the range of form is greater in benthic habitats, and there are far more benthic species than planktonic ones (by a couple of orders of magnitude). Motile species occur in the surface film of soils and on dripping rock faces, and on the sediments of ponds, lakes, streams, rivers, coastal lagoons, and coastal seas. They often coat the surface of estuary muds with a dense brown layer of cells, which play an important ecological role in stabilizing sediments (Underwood and Paterson 2003). These ***epipelic*** diatoms (Fig. 3a) are motile and often migrate vertically upwards through the sediment in the morning and move back into the sediment later in the day, in a rhythm of movement under the control of a biological clock which, in tidal situations, is in synchrony with the tidal cycle (Palmer and Round 1967). Soil diatoms are of similar morphology to those occurring in aquatic epipelon, but they are generally smaller and less motile. Sand in both freshwater and

marine environments may be colonized not only by epipelon but also by extremely small diatoms attached to the surfaces of the sand grains themselves, comprising the ***epipsammon*** (Fig. 3d). Attached (***epilithic***) species coat rock surfaces, the hard surfaces of calcified algae, and the dead fragments of corals and calcareous algae. Filamentous algae in both freshwater and marine habitats are often so densely

covered by ***epiphytic*** diatoms (Figs. 3b, c, e, and 4a) that the host surface may be obscured (Fig. 4b), and animal hosts, from copepod hard parts and limpet shells to sea birds and cetaceans, sometimes have an external diatom microbiota (***epizoon***) involving species-specific forms. Vast areas of ***sea ice*** around Antarctica and the Arctic ice cap are coated on the undersurface with a dense layer of diatoms. Smaller forms are even found in the brine channels of the ice. Man-made objects placed in water soon acquire a covering of diatoms, and glass slides or ceramic tiles have sometimes been deployed for this reason in rivers, so that they can later be removed for assessment of water quality and ecological status (e.g., during biomonitoring under the European Union Water Framework Directive).

Collection of diatoms involves sampling of sediments, plants, or animals, or filtering (or sedimenting) quantities of lake or seawater. Sediments should be sampled by techniques that remove only the top few millimeters or so. If the sediment is then placed in a Petri dish or translucent plastic box, excess water removed, and cover glasses or lens cleaning tissue placed on the surface, motile diatoms will move upwards and attach to the new substratum and can be removed to

a microscope slide for examination or placed in culture media. Sand samples can be washed free of silt and organic matter by repeated agitation and settling and the sand grains then observed directly on a microscope slide. Communities on plant and animal surfaces can be observed directly if the plant or animal is microscopic, or the surface coating of diatoms may be removed from them or stones by scraping with a scalpel. Careful sampling will often show that an upper "canopy" is present. This is more easily detached than the initial colonizers, which grow appressed to the substratum. Planktonic diatoms can be sampled by drawing a net through the water either horizontally behind a drifting boat (or thrown in from the shore) or vertically by lowering a weighted net to a set distance below water level and then drawing it up. More complicated devices can be used if quantitative samples are required, including standard water bottle samplers that can capture known volumes of water from known depths.

Because of the nature of their cell walls, diatoms have left evidence of their evolution in the fossil record since the Cretaceous, often in the form of fairly pure deposits called ***diatomites***, produced by sedimentation of the plankton of fresh and marine waters. Diatomites may be powdery or more rocklike, the latter requiring treatment (grinding, disaggregation using chemicals, freeze–thaw cycles, or sonication) to reduce them to a finer state before examination. The material can often be mounted directly in water or high refractive index mountants but is often better if "cleaned" first (see below).

The fine detail of wall structure is usually critical for identification and has to be revealed by cleaning the cells with strong oxidizing agents (e.g., a mixture of concentrated sulfuric and nitric acids, or hydrogen peroxide; however, though widely used, the latter seems often to lead to erosion of fine detail) to remove organic material, leaving only the silica parts of the cell wall. If the sample contains much carbonate, this may have to be removed first (it can be dissolved with dilute hydrochloric or nitric acids and washing to remove the resulting salts), especially if sulfuric acid is to be used subsequently. After oxidation, samples must be thoroughly washed with deionized water by settling or centrifugation. Then the cleaned frustules (which often separate into their component pieces – valves and girdle bands) can be dried onto cover glasses and mounted in high refractive index media (e.g., Naphrax: Fleming 1954). Final identification of species can then be attempted. Care should always be taken to study the full range of forms present in a population because most diatoms undergo size reduction during the life cycle, and the shape and patterning of the valves can also change. It is not uncommon for the small and large cells in the life cycle to be mistaken for different species.

Because species are generally characterized and identified by the morphology of their silica valves, and because important details of valve structure cannot be seen easily in living cells, it is common for diatom communities to be studied only after cleaning, as described above. This has had the unfortunate side effect that many aspects of the structure and growth of living cells remain unknown, even in common species. Details of plastid form and position are often characteristic of the species or genus in benthic diatoms but must be examined in very fresh material (because gross changes often occur rapidly after sampling) or after fixation (with rapidly penetrating

fixatives such as glutaraldehyde or OsO_4-containing mixtures) and staining. It should also be remembered that the chloroplasts and other organelles often move around the cell in preparation for, or after, cell division (e.g., Mann 1996). Such changes need to be taken into account when interpreting and identifying live diatoms. Living diatoms can be studied for several hours or days in microscope slide preparations in which the coverslip is sealed to the slide using petroleum jelly. Alternatively, they can be examined using water immersion lenses dipped directly into Petri dish cultures, or through the base of the culture vessel using an inverted microscope. With the advent of molecular systematics, it is worth considering whether aliquots of samples should be preserved for subsequent genetic analysis, e.g., by freezing at −80 °C.

The gradual decrease of cell size that occurs in most diatom species during the life cycle has consequences for the maintenance of strains in culture. If conditions for sexual reproduction and auxosporulation are unfavorable in culture, or if the diatom is heterothallic, clonal strains will continue to get smaller and finally die (Chepurnov et al. 2004). Furthermore, even if clones are self-compatible and can complete the life cycle, their progeny may suffer from inbreeding depression and die out after a few sexual generations (Chepurnov et al. 2011). Consequently, most culture collections contain rather few diatom strains, many of which are atypical of the group (e.g., some avoid size reduction, whereas others auxosporulate automictically). Small numbers of diatom species are maintained in the major culture collections, e.g., at the National Center for Marine Algae and Microbiota (NCMA), Bigelow, Maine, USA (https://ncma.bigelow.org/); the Culture Collection of Algae (UTEX), Austin, Texas, USA (https://utex.org/); the Culture Collection of Algae and Protozoa (CCAP), Oban, Scotland, United Kingdom (http://www.ccap.ac.uk/); the Sammlung von Algenkulturen (SAG), Universität Göttingen, Germany (https://www.uni-goettingen.de/en/); the Roscoff Culture Collection, Roscoff, France (http://www.roscoff-culture-collection.org/); and the Microbial Culture Collection, National Institute for Environmental Studies, Tsukuba, Japan (http://mcc.nies.go.jp/). Pedigreed lineages of heterothallic diatom species, as well as homothallic and asexual lineages, are maintained by the specialized diatom culture collection at the Protistology and Aquatic Ecology Research Group, Ghent University, Belgium (http://bccm.belspo.be/about-us/bccm-dcg). Many individual workers also maintain small collections for research. Some progress has been made in cryopreservation of diatoms, but because of the complications caused by the life cycle, cryopreservation is not a permanent solution to culture maintenance, though it can considerably extend the availability of a strain. Not surprisingly, therefore, there is no system for designating “type strains” in diatoms; instead, proposals have been made for using DNA barcodes to help typify taxa (Evans and Mann 2009).

Once cleaned, diatom frustules can be preserved indefinitely either dry or suspended in alcohol; the use of aqueous preservatives (e.g., formalin, Lugol’s iodine) should be avoided because the frustules will slowly dissolve. Large collections of permanent slides of cleaned diatoms, including type specimens, are held by several institutions, notably the Academy of Natural Sciences,

Philadelphia; the Natural History Museum, London; and the Alfred-Wegener-Institut für Polar- und Meeresforschung, Bremerhaven; but many other museums and institutes also hold important collections (Fryxell 1975, lists some and De Wolf and Sterrenburg provide further information at http://home.planet.nl/~wolf0334/). Collections of slides with text catalogues were distributed by several diatomists in the late nineteenth and early twentieth centuries (e.g., Tempère and Peragallo 1915).

Literature

Most of the early literature on the structure, life cycle, and taxonomy of diatoms is in German and includes the following major works: Kützing (1844); Pfitzer (1871); Schmidt (1874–1959); Schütt (1896); Hustedt (1927–1966); Karsten (1928); and Geitler (1932). A widely used, more recent flora for identifying freshwater diatoms is the *Süsswasserflora von Mitteleuropa* by Krammer and Lange-Bertalot (1986–1991; see also the condensed and updated version by Hofmann et al. 2013). An excellent handbook to marine planktonic diatoms was produced in English by Hasle and Syvertsen (1996), though this is not comprehensive, focusing on the more commonly encountered species of temperate and polar regions. Online floras for freshwater diatoms are being assembled in the USA (http://westerndiatoms.colorado.edu) and the UK. There are no up-to-date, comprehensive accounts of marine and brackish benthic diatoms. For these, the French flora of Peragallo and Peragallo (1897–1908) is still indispensable, together with myriad papers scattered through many journals, which are often hard to access (however, digitization of the older literature means that many works can now be accessed at e.g., http://www.biodiversitylibrary.org/, http://gallica.bnf.fr/, https://archive.org/).

Several series of specialist diatom publications are active, including *Bibliotheca Diatomologica*, *Iconographia Diatomologica*, *Diatom Monographs*, and *Diatoms of Europe*. Most of the volumes in these series focus on taxonomy and biodiversity (e.g., Metzeltin and Lange-Bertalot 2007; Levkov 2009). The journal *Diatom Research* (1986–) is published on behalf of the International Society for Diatom Research, which also organizes the biennial International Diatom Symposium, and *Diatom* is published by the Japanese Society of Diatomology. There is an extensive Russian and Japanese literature on diatoms. The earlier Russian papers are catalogued in the Soviet bibliography of algal literature (reprinted in Koeltz 1976 and indexed by Gollerbakh and Krasavina 1971); see also the ongoing *Diatomovye vodorosli* flora of marine and freshwater diatoms (e.g., Glezer et al. 1974).

Of special interest is the collection of electron micrographs edited by Helmcke and Krieger (1953–1977), whereas listings of more recent micrographs have been compiled by Gaul et al. (1993) and Henderson and Reimer (2003). A remarkable catalogue of diatom names was compiled by VanLandingham (1967–1979), which laid the foundation for an online catalogue of diatom names (http://researcharchive.calacademy.org/research/diatoms/names/index.asp currently not updated past September 2011) compiled at the California Academy of Science by E. Fourtanier

and J.P. Kociolek. However, VanLandingham's catalogue contains extra information not present in the online catalogue, viz. key references illustrating the use of taxon names. Another useful resource for nomenclature and taxonomy, collating information from the literature, is the "Diatom New Taxon File" of the Academy of Natural Sciences, Philadelphia, at http://symbiont.ansp.org/dntf.

Ecological, biochemical, physiological, and genetic information on diatoms is widely scattered in a vast and rapidly growing literature. A review of genus-level biodiversity was produced by Round et al. (1990), who also provided an extended, referenced introduction to diatom structure and biology. The multiauthor volume edited by Smol and Stoermer (2010) gives many examples of applications of diatoms in ecological monitoring, paleoecology, and forensics. Eclectic collections of topics are reviewed in *The Diatom World* (edited by Seckbach and Kociolek 2011) and in the much earlier but still useful *Biology of Diatoms* (edited by Werner 1977). Much interesting information about diatoms and the early history of diatom research is summarized in a handbook by Taylor (1929), which also gives information about the derivations of diatom names. The terminology of cell wall structures and morphology is summarized by Ross et al. (1979) and Barber and Haworth (1981). The special terminology applied to sexual stages and auxospores has recently been codified by Kaczmarska et al. (2013).

History of Knowledge

The first diatom taxa were described at the end of the eighteenth century, but the earliest illustrations of a diatom (a *Tabellaria*) appeared much earlier (Anonymous 1703). The name "Diatomeae" was first used by C. A. Agardh in 1824, although the basic two-part nature of the diatom wall had been implicitly recognized by De Candolle in 1805, when he named the genus *Diatoma* (Lamarck and De Candolle 1805). During the first 50 years of the nineteenth century, a large number of species were described. In 1830–1832, Agardh published a *Conspectus Criticus Diatomacearum* containing c. 100 species; by 1844, Kützing could list c. 800 species. The great German scientist Christian Gottfried Ehrenberg studied both living and fossil material from all over the world and produced innumerable illustrations, excellent for their time, many of which appear in the volumes of the *Abhandlungen der Königlichen Akademie der Wissenschaften zu Berlin* (see references in VanLandingham 1967–1979). He noted diatoms attached to the under surface of ice, in soil, on animals, and on sediments, and speculated on many aspects of their biology. Ehrenberg (1854) wrote on the formation of geological strata by the growth and deposition of microorganisms, including diatoms.

The motility and organelles of some diatoms suggested to early workers, including Ehrenberg (1838), that diatoms were animals (the chloroplasts and reserve material being interpreted as organs of digestion), and it was not until the middle of the nineteenth century that they were shown to be autotrophs (Kützing 1844). Around this time there were also numerous arguments about the mechanism of motility and about whether diatoms could live in the dark ocean depths (they can

survive for some time but do not actually photosynthesize and propagate). There was at first little understanding of the diatom life cycle: auxospores were observed but thought to be sporangia (Smith 1856), involved primarily in multiplication and dispersal rather than in regeneration of large cells *per se*.

Throughout the first half of the nineteenth century, the principal focus of diatom research was the description of diatom genera and species. The second half of the century saw classic studies on cell structure by Pfitzer (1871), Lauterborn (1896), Müller (1886, 1889, 1901), and Schütt (1896). Some of their observations were truly remarkable for their detail and accuracy and could be confirmed only when electron microscopy became available (e.g., Pickett-Heaps et al. 1984). Meanwhile, compilations of descriptive data continued, such as in the *Atlas der Diatomaceen-Kunde*, begun by Adolf Schmidt in 1874 and continued by various other authors until 1959. Descriptions of genera and species were augmented from material during nineteenth-century expeditions, including the great oceanographic voyages of H.M.S. Challenger in 1873–1876. Fundamental studies on Arctic (Cleve and Grunow 1880) and Antarctic (Karsten 1905–1907; Heiden and Kolbe 1928) diatoms were also completed at an early date. Of course many more expeditions took place on land and none was more remarkable than that undertaken by Georgi as early as 1772, exploring the waters around Lake Baikal in Siberia. His material was included in the collection of Klaproth in Berlin.

Explanation of one of the unique features of the diatom life cycle – how average cell size decreases with each cell division – was presented formally and independently by MacDonald and Pfitzer (MacDonald 1869; Pfitzer 1869) and analyzed further by Geitler (1932), whose work detailing the shape and pattern changes that accompany size reduction should still be prescribed reading for all undertaking taxonomic studies of diatoms. Discovery of the size restoration stage – auxosporulation – had occurred earlier (Thwaites 1847), but its significance was not then fully understood. Meiosis was shown to be associated with gametogenesis in the pennate diatom *Surirella* by Karsten (1912), thus showing that pennate diatoms are diplonts, but it was not until 1950 that it was finally established that centric diatoms are also diplonts (von Stosch 1950), exhibiting oogamy. Knowledge of chloroplast morphology and division in diatoms, which is still far from complete, was given an excellent foundation by the eccentric Russian biologist C. Mereschkowsky (Sapp et al. 2002), better known for his championship of endosymbiosis, in a series of papers in the early 1900s (e.g., Mereschkowsky 1902–1903, 1904).

The first half of the twentieth century was notable for the massive contribution of Friedrich Hustedt who described nearly 2000 new taxa (most of them small-celled and freshwater) and also published numerous works on the structure, taxonomy, biogeography, and ecology of diatoms, including the seminal *Die Kieselalgen Deutschlands, Österreichs und der Schweiz* (1927–1966). The foundation for our current knowledge of diatom life cycles and sexual reproduction was laid principally by just three workers: L. Geitler (see Schmid 1991), H.A. von Stosch (see Anonymous 1987), and A.M. Roshchin (e.g., 1994, and see Chepurnov et al. 2004).

From the 1960s onwards, the *Deep-Sea Drilling Project* and its successors (currently the *International Ocean Discovery Program*) have provided long cores from all the oceans and stimulated work on the geological record of diatoms. Many new species have been described and evolutionary events documented. Cores have also been made for paleoecological analyses in countless lakes worldwide (though rarely from earlier than the Quaternary) and have documented both natural and anthropogenic environmental changes (e.g., Smol and Stoermer 2010).

The development of transmission electron microscopy (which allowed the study of organelle structure, mitosis, cell division mechanisms, and wall formation) and, since c. 1967, scanning electron microscopy has transformed our knowledge and interpretation of diatom structure and also stimulated a resurgence in systematics. Little physiological or biochemical work on diatoms was undertaken until the 1950s, and there is no comprehensive review of the many recent developments.

The advent of cheap sequencing technologies has provided new insights into diatom systematics and has also allowed the first microsatellite-based investigations of the genetic structure of marine (e.g., Rynearson and Armbrust 2004; Godhe et al. 2013) and freshwater diatom populations (e.g., Evans et al. 2009; Vanormelingen et al. 2015); the only previous studies of population structure were based on isozymes (e.g., Gallagher 1982).

A diatom, *Thalassiosira pseudonana*, was the first eukaryotic microalga to have its genome wholly sequenced (Armbrust et al. 2004), inaugurating a new phase of research into the developmental genetics and metabolism of the group. The genome of another diatom, the highly unusual polymorphic pennate *Phaeodactylum tricornutum*, has also been sequenced (Bowler et al. 2008) and other species have followed (e.g., *Pseudo-nitzschia multiseries*, *Fragilariopsis cylindrus*). Several unexpected features of diatoms have been discovered as a result of genomic studies, such as that they possess a urea cycle, which is thought to help diatoms make particularly effective use of C and N following periods of N limitation (Allen et al. 2011). Diatoms have also been discovered to have unusual actin and microfilament-related components (Aumeier et al. 2015), and many examples of horizontal gene transfer from bacteria have been found (e.g., Bowler et al. 2008; Raymond and Kim 2012). Transcriptome studies are being used to dissect the process of sexual reproduction in raphid diatoms (e.g., Patil et al. 2015; Moeys et al. 2016). The advent of high-throughput sequencing has also provided new insights into the diversity and distribution of marine planktonic diatoms (Nanjappa et al. 2014; Malviya et al. 2016) and the mechanisms that maintain this diversity (Alexander et al. 2015), and has the potential to revolutionize the use of diatoms in biomonitoring (e.g., Kermarrec et al. 2014).

Practical Importance

The importance of diatoms in planktonic communities has long been recognized, and the control of their populations by silica limitation was shown in detail for several freshwater species by Lund (1949 and subsequent publications). The total contribution by diatoms to the algal biomass within many communities is still not clear

because they do not usually grow alone but in assemblages containing other algal groups. Nevertheless, their overall biomass and contribution to carbon fixation are certainly enormous (Mann 1999b estimated that they may account for c. 20% of total global C-fixation), and they are clearly very important in the food chains of aquatic habitats and have been significant players during the evolution of the biosphere (e.g., Falkowski and Knoll 2007; Berger 2007; Renaudie 2016).

Diatoms can be used as indicators of water quality and ecological status, and systems have been devised to utilize diatom populations growing on natural substrata in running waters and in lakes for biomonitoring (e.g., Kelly et al. 2008). Because their frustules are preserved well in many lake and ocean sediments, diatoms are very important for detecting long-term changes (over tens to millions of years) in aquatic environments (Smol and Stoermer 2010). Diatoms are valuable in water supply reservoirs because they oxygenate the water and remove excess nutrients; however, with excessive growth, they can become a nuisance, blocking the filtration devices in water treatment plants. Other undesirable effects include the production of the neurotoxin domoic acid (a noncanonical amino acid) by marine species of the genera *Nitzschia* and *Pseudo-nitzschia* (and apparently by *Amphora coffeaeformis*), causing potentially lethal "amnesic shellfish poisoning" (Trainer et al. 2012).

The sediments left in freshwater and marine basins that have been drained or raised above sea level often yield diatomite because of the fact that, under favorable conditions, planktonic diatoms settle to the bottom and their silica, being relatively insoluble, builds up to form deposits several hundreds of feet thick in places, e.g., Lompoc in California. This material can be processed by relatively simple means to remove organic or calcareous matter and then used in many industries, e.g., as fine abrasives and filtration material (Smol and Stoermer 2010). Fossil diatoms are also important as stratigraphical markers, e.g., for oil exploration (Krebs et al. 2010).

The unique ability of diatoms to fashion intricate cell walls of amorphous silica has stimulated particular interest among cytologists (Pickett-Heaps et al. 1990) and also biochemists and engineers (e.g., Kröger 2007; Wee et al. 2005), because of the potential to develop new methods for synthesizing silica in ambient conditions and new biomimetic materials, and to provide inspiration for architecture (Kooistra and Pohl 2015).

Habitats and Ecology

A division of diatom habitats can be made along freshwater/marine lines and indeed the vast majority of diatom genera (even whole families and orders) occupy either one or the other habitat. However, some genera occur in both and some others, especially among lineages of motile diatoms, are predominantly found in one but "spill" a few species into the other (Mann 1999a; Alverson et al. 2007). It is quite common to find similar life forms in similar habitats, whether marine or freshwater, as a result of convergent evolution (e.g., between *Tabellaria* or *Diatoma* and *Grammatophora*, which all produce zig-zag colonies: Figs. 2a, and 5b, d). Almost

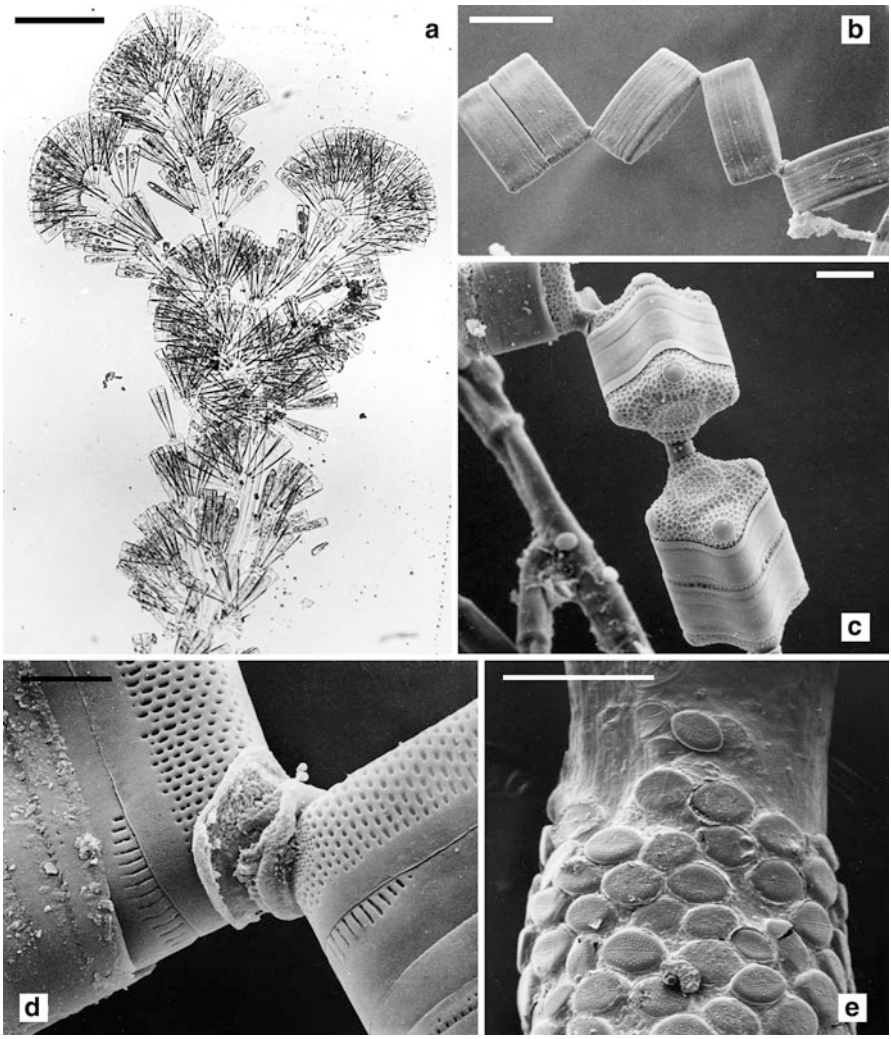

Fig. 5 Colony formation through the formation of mucilage (polysaccharide) pads and stalks. (**a**) *Licmophora* colony. Scale bar = 100 μm. (**b**) Chain of four cells of *Diatoma* linked by pads secreted from the ends of the valves. SEM. Scale bar = 20 μm. (**c**) Chain of *Amphitetras* cells linked by pads secreted through areas of small, unoccluded pores at the corners of the valves. SEM. Scale bar = 20 μm. (**d**) Detail of two *Grammatophora* cells united by a pad of mucilage at their apices. SEM. Scale bar = 3 μm. (**e**) *Cocconeis* on a marine hydroid. SEM. Scale = 100 μm

all diatoms are free-living autotrophs and out of the more than 10,000 described living species, fewer than 10 are colorless heterotrophs (Kamikawa et al. 2015), though this may in part reflect limited sampling of suitable habitat. A similar number of diatoms have been discovered living symbiotically, mainly in Foraminifera (Lee 2011), and a few dinoflagellates (so-called dinotoms) have incorporated diatoms as

permanent endosymbionts, with which they coevolve (Tamura et al. 2005; Pienaar et al. 2007; Saburova et al. 2009). The colorless forms, mostly species of *Nitzschia* (Lewin and Lewin 1967; Li and Volcani 1987; Kamikawa et al. 2015), have secondarily lost the ability to photosynthesize but retain a nonpigmented plastid (leucoplast: Schnepf 1969; Kamikawa et al. 2015).

Free-living diatoms occur in two major types of communities: (i) plankton, occurring in open water masses, and (ii) benthos, which are the communities associated with underwater surfaces and by extension also the subaerial habitats on soil, plants, etc. These gross habitat boundaries disguise a number of sub-habitats and countless niches (Round 1981a).

Plankton

The open waters of oceans and lakes are potentially available for diatom growth, down to the depth to which photosynthetically available light penetrates: populations in tropical oceans have been recorded down to 120–140 meters. However, it is unusual to find living diatoms circulating from the surface to such depths. Instead, the surface waters are extremely barren in parts of the tropical oceans and a deep-lying population occurs in the region of the thermocline in a zone of relatively high nutrient availability derived from the ample store of nutrients in the deep water, although the diatoms may be close to the point of light limitation. In temperate to cold oceans, populations tend to congregate in the surface 30–40 meters.

No diatom cells have a motility mechanism that can move them actively through water, except for the sperm of centric diatoms. Indeed, many planktonic diatoms tend to sink because the specific gravity of silica is significantly greater than that of water; maintenance of such cells in the water column is mainly because of wind- or current-induced turbulence, as can be readily seen when a lake freezes and the water column becomes isolated from wind and wave action – in this case, the diatom population sinks (Lund 1954). A characteristic of many marine planktonic diatoms is the possession of a very large vacuole, accommodated by a wide girdle containing many girdle bands. Some marine diatoms are consequently able to offset the excess weight of the silica wall by incorporating low-density solutes or adjusting ion concentrations in the cell vacuole (Boyd and Gradmann 2002). However, this is feasible only in larger-celled species (Raven and Waite 2004). A further consequence of the large vacuole is that it enables the plastids to spread out over a large surface area in conditions of low light or to clump the plastids round the nucleus (karyostrophy: see Mann 1996), supposedly for protection of the latter against high irradiation in bright sunlight.

There is an enormous range in cell size and form among planktonic genera. Small-celled, pill-box-shaped species of *Stephanodiscus* (Fig. 1a), *Cyclotella*, *Minidiscus*, and *Thalassiosira* may be only 3–5 μm in diameter, whereas the common marine *Coscinodiscus* and *Actinocyclus* (Fig. 1b) species vary between 30 and 600 μm. The largest cells of the centric genus *Ethmodiscus* can reach 2 mm in diameter. Needlelike species are also common among planktonic diatoms, ranging

from small Cymatosirales a few μm long (Hasle et al. 1983), through *Thalassionema* (10–100 μm in length) to *Thalassiothrix*, which can attain lengths of more than 5 mm. Some planktonic diatoms are solitary (e.g., *Stephanodiscus*, *Coscinodiscus*: Fig. 1a, d), but in many others the cells remain attached to each other after division to form colonies, which may be long filaments or stepped chains, e.g., in *Rhizosolenia*, *Chaetoceros*, *Skeletonema* (Fig. 2d), and *Pseudo-nitzschia*; ribbons, e.g., in *Fragilaria* (Fig. 2c) and *Fragilariopsis*; starlike (stellate), e.g., *Tabellaria*, *Asterionella* (Fig. 2a), and *Asterionellopsis*; or zigzags, e.g., *Thalassionema* and *Diatoma* (Fig. 5b). In some diatoms, the ability to form chains is facultative (e.g., *Mediopyxis*: Fig. 2b). In still others, the cells have long extensions or produce long chitin fibrils (Fig. 1c) that slow the rate of sinking, e.g., Walsby and Xypolyta (1977). Colonial morphology, such as in *Asterionella* and *Fragilaria*, can also be argued on physical grounds to be adaptations that slow sedimentation (Reynolds 2006). However, other diatom species growing in the same water may have no apparent mechanism to reduce sinking rate and indeed, sinking is arguably advantageous in some circumstances, e.g., to remove diseased cells from populations or to alleviate diminishing nutrient availability (Raven and Waite 2004). Sinking is enhanced by aggregation in the form of "marine snow" and live cells and empty frustules may be rapidly exported in this way (Smetacek 1985), facilitating deposit of diatom frustules on the ocean floor (rather than dissolution during sedimentation).

Growth in the plankton is dependent upon a supply of silica (generally in good supply in cold temperate oceans and after the winter input in lakes), and the rate of recycling of this element may be critical for the maintenance of populations. Other nutrients (especially N, P, and Fe), light intensity, and temperature are also controlling factors, in combination with the genetically determined physiological capacities and nutrient uptake systems of the cells. Equally important for population dynamics, however, are the "loss processes," which include sinking, outwash (in lakes at certain times of the year), physical or biochemical damage, parasitism, and grazing (Reynolds 2006). Only when the rate of cell growth overcomes these loss factors will the population increase and a diatom "bloom" occur, which can sometimes color the water brown, especially in spring. If a bloom continues for a long time, the available silica may be used up and the majority of cells may die. Small residual populations remain and grow again when conditions are favorable. Some marine planktonic species form thick-walled cells, which seem to help ensure short- or long-term survival of adverse conditions (McQuoid and Hobson 1996). These may be modified vegetative cells or specialized "resting spores" with a morphology quite unlike that of the vegetative cells (Round et al. 1990). A few freshwater diatoms, such as *Aulacoseira italica*, have been shown to sediment to the lake bottom and remain there in a viable vegetative state until the next growing period; in this case, in winter when the turbulence stirs the cells from the lake bottom into the water column (Lund 1954). This is impossible over most of the ocean surface, where the bottom is beyond the action of turbulence sufficient to resuspend the cells, but it may happen in inshore waters. A further ecological attribute of some marine planktonic species is the fixation of atmospheric nitrogen via endobiotic cyanobacteria (e.g., *Richelia intracellularis* in species of several diatom genera: Carpenter et al. 1999).

Benthos

The situation here is much more complex than that of the plankton because of the range of habitats in which either motile or nonmotile attached species occur. Nutrient concentrations are usually higher in benthic habitats than in the water column above. Nevertheless, the growth of benthic diatoms can also be limited by nutrient availability, and it has recently been shown that benthic diatoms perceive gradients of nutrient concentrations, e.g., of silicate (Bondoc et al. 2016), and exhibit directional movements in relation to them.

Epipelon and Soils. The surfaces of sediments of all kinds support a motile microbiota of diatoms. Whereas they can be found at some depth in the deposits and may exist there for some time, they only grow actively in the top few millimeters of the sediment. There are many records of soil diatoms at greater depths, but these are probably species that have been washed down or carried there by animals. In many lakes the epipelic microbiota only colonize sediments down to 5–10 meters below the water surface, depending upon the transmission of light through the water; in the sea, epipelon may extend to much greater depths. The vast majority of diatoms in this habitat are motile biraphid species (having raphe slits on both valves: Fig. 3a) because, after disturbance or burial by inwashed sediment, phototactic movement up to the surface is essential. These species often undergo circadian movements in and out of the surface sediment (Palmer and Round 1967; Round 1981a). A few filamentous species also "float" on the surface sediments in flocs where they seem to maintain themselves and avoid burial. Many epipelic diatoms are grazed by other protists, such as ciliates, and small animals, such as mollusks, and in some marine habitats by fish. Whereas the latter are probably nonselective, grazing by protists (Hamels et al. 2004) and parasitism by chytrids and oomycetes (Canter and Jaworski 1983, Mann 1999b) probably play a major role in controlling the diversity of epipelic and other diatom communities.

Epipsammon. Sand grains are often the site of attachment of small diatoms, and in some habitats every grain is covered by up to a hundred or more diatoms. Some grow adnate (closely appressed) to the surface of the grain, often forming short chains, whereas others perch on small mucilage pads and stand out from the grains, e.g., *Martyana* (Fig. 3d). The subtidal marine sand community (comprising both epipsammic and epipelic species) is probably the least explored in diatom ecology, due to its inaccessibility.

Epiphyton. All photoautotrophic groups, including algae and a few diatoms, are hosts to diatom species. A brown coating of diatoms on angiosperms and on green and red algae along coasts is often obvious to the naked eye. As with the sand-associated microbiota, some species are "glued" onto the plant surfaces (*Epithemia*, *Cocconeis*; Fig. 3c), whereas others are on short pads or stalks, projecting into the water (*Ulnaria*, *Achnanthes*; Figs. 3b and 4a). Yet others occur on long branching stalks (*Gomphonema*, *Licmophora*; Figs. 3e and 5b). Many attach by a corner pad of mucilage and then form zig-zag colonies when the cells remain attached to each other after cell division (*Diatoma*, Fig. 5b; *Amphitetras*, Fig. 5c; *Grammatophora*, Fig. 5d). All these features probably function (here and in other attached

communities) to project cells into positions where they will intercept more nutrients, capture more light, and compete less with adjacent organisms, with the counterbalancing risk of becoming more susceptible to grazers and parasites.

Epilithon. Rock surfaces support a microbiota of attached species. In protected regions, e.g., rock pools, filamentous species may develop upward into the water and some species grow inside mucilage tubes up to several centimeters long, e.g., *Berkeleya* (Fig. 4c) and *Parlibellus*. Recent evidence suggests that the diatoms inside a single tube may not be genetically identical (Hamsher and Saunders 2014): the tube may therefore be a cooperatively assembled structure, produced by several or many pioneer cells.

The relationship between the epilithic and epiphytic floras is not clear. Some genera and even species certainly live in both habitats, but whether any species are actually confined to one or the other requires further study. Both epiphytic and epilithic habitats may be stable for long periods of time (relative to the generation time of individual cells) and allow the establishment of "climax communities."

Metaphyton. Nonattached diatoms occur in the colorless mass of mucilage produced by some algae growing epibiotically (probably also epilithically) and remaining as a gel around the substratum. This community was first studied by Behre (1956) but few have investigated it in detail since then. Medlin (1983) showed that the metaphytic and epiphytic communities were distinct entities and that the epiphyton showed host specificity but the metaphyton did not. The diatoms within the mucilage are weakly motile. This community is very similar to the one developing in some acid streams and bog pools, consisting of masses of mucilage-forming sheets in which diatoms coexist with many other algae. These mucilage-based associations tend to be confined to waters of low pH.

Epizoon. This community is very little studied. Habitats include the feathers of diving sea birds (Holmes and Croll 1984) and the perisarc of hydroids, which often forms a rich substratum for *Cocconeis* (Fig. 5e) and *Grammatophora*. Small crustaceans can have species of *Synedra* (in fresh water) and *Pseudohimantidium* (in the sea) on their appendages; these diatoms seem to be specific to the animals. Shells of mollusks also support attached diatoms and all hard parts of dead animals become coated with diatoms. The skin of cetaceans is the substratum for species of *Bennettella* and *Epipellis* (Holmes 1985; Denys and De Smet 2010), whereas marine turtles bear diverse epizoic communities (Majewska et al. 2015) and may be important natural dispersal vectors for benthic species.

Symbiosis. The first endosymbiotic diatom recorded was *Licmophora* in *Convoluta* (Ax and Apelt 1965) and since then diatoms have been discovered to be endosymbionts of foraminifera (Lee et al. 1979; Lee 2011) and dinoflagellates (e.g., Pienaar et al. 2007; Chesnick et al. 1997; Imanian and Keeling 2014). The *Convoluta* and foraminiferan endosymbionts do not form siliceous wall elements within their hosts but can produce them again when extracted and cultured. Foraminifera also ingest free-living diatoms, and free-living species of diatoms may attach to the outside of the carbonate skeleton. As far as is known, the endosymbionts of dinoflagellates have totally lost the capacity to grow independently. A symbiotic relationship between the Antarctic ice diatom *Amphiprora kufferathii*

and its epiphytic bacteria has been demonstrated by Hünken et al. (2008). The diatom benefits with enhanced antioxidative defenses, and the bacteria utilize hydrogen peroxide produced by the diatom's photosynthesis.

Ice Diatoms. The microbiota of sea ice is a rather mixed one with diatoms being the dominant group (Thomas and Dieckmann 2003). When sea ice forms, the surface plankton is incorporated into the ice where it occupies brine pockets and channels which arise during freezing. The water in the brine pockets can attain salinities up to 4 times that of seawater as temperatures in the sea ice drop to below −10 °C. Some species do not survive, but many can withstand the hypersaline conditions and low temperatures, proliferating to form dense brown layers on the periphery and underside of the ice. Some of the species have narrow temperature requirements with optima around 2 °C and ceasing growth at 5 °C. *Melosira arctica* attaches to the lower surface of multiyear ice in the Arctic and produces long pendant columns.

The Siliceous Wall as Protection

The diatom protoplast of vegetative cells is never exposed, even during cell division, and its robust nature has led to suggestions, reviewed by Hamm et al. (2003), that the silica cell wall functions as a defense against predators. Whatever the truth of this, broken fragments of diatoms are common in fecal pellets and provide ample evidence of grazing in the marine water column, and there are also records of parasitism both in freshwater and the sea (Raven and Waite 2004). Canter showed evidence of infection of diatoms leading to accelerated decline of populations and demonstrated specificity in choice of closely related hosts (Canter and Jaworski 1983; Crawford et al. 1985; Mann 1999b). Penetration by parasites is sometimes achieved between the girdle bands or via apparent "weak points," such as the rimoportulae or raphe, but may also be through the valves (Kühn et al. 1996). The use of silica as a wall material has been suggested by Raven (1983) to reflect its lower energetic cost, relative to carbon.

Tolerance of Ecological Factors

Each individual species has a genetically determined range for existence and for optimal growth, which is then restricted further by competition and grazing. The ranges for very few species have been worked out in detail, but together, the diatoms occupy a remarkably wide span of environments. One important determinant of distribution is salinity. Some diatoms are stenohaline, being restricted to a narrow range of salinity (usually either freshwater or fully marine), but others are less fussy. Some marine diatoms extend down the salinity scale almost to fresh water and many grow optimally at salinities below the average 33–35‰ of seawater. Equally, some tolerate hypersaline conditions but as salinity increases, e.g., in tropical lagoons or salt works, the number of species decreases until at 120‰ only one or two survive

(Ehrlich 1975). However, no species have yet been confirmed as confined to salinities above that of normal seawater.

Extremes of temperature are also tolerated by a few species. For example, some diatoms are able to withstand extremely high temperatures in thermal springs: *Denticula elegans* was found living at 60–62 °C by Cassie and Cooper (1989) at Rotorua, New Zealand, and Cassie (1989) reported *Fragilaria construens* surviving 77 °C. However, most diatoms have much lower tolerance limits, and Hustedt (1959) considered 45 °C to be the upper limit for most species.

Fresh waters are chemically much more diverse than seawater and here there are clear species preferences, e.g., for acid, alkaline, or sulfate-rich waters. Some *Pinnularia* species can tolerate a pH of less than 2 (Sabater et al. 2003). In most cases, the physiological basis of these preferences has not been established. For example, in the case of pH, it is usually unclear whether it is pH itself that is selective or whether it is some other factor, such as the availability of carbon dioxide or bicarbonate, or of silicate or other nutrients, that is causal. The abundance of a few species is clearly correlated with water flow, e.g., *Meridion*. Whatever the physiological mechanisms, however, the combination of adequate taxonomy, identifiable preferences, and the long-term preservation of diatoms in lake and ocean sediments makes diatoms unrivalled for reconstruction of environmental change in aquatic habitats over periods of tens to millions of years (reviewed in Smol and Stoermer 2010).

Just as conditions may become suitable to sustain massive growths of planktonic diatoms, so too may benthic species be favored. This occurs spectacularly and disastrously in rivers in many parts of the world as a consequence of blanket growths of *Didymosphenia geminata* (e.g., Bothwell et al. 2014). This species severely compromises the ecosystem of affected rivers and causes expensive problems for water management.

Characterization and Recognition

Cell

The Bacillariophyta are all unicellular or colonial. Their vegetative cells are diploid and characterized above all by their complex siliceous walls. In many species the ornate pores, thickenings, and spines of the siliceous wall components are clearly visible under high magnifications in the light microscope, but further significant detail is always detectable by electron microscopy. It is possible to identify some species in live material, but traditionally the cells have been treated to separate the wall components and it is above all the morphology of the valves that forms the basis for classification and identification.

Inside diatom cells are the organelles typical of heterokont (stramenopile) algae. The plastids are conspicuous and vary in color from yellowish or greenish hues to a deep brown, and they are therefore sometimes called chromoplasts or chromatophores, rather than chloroplasts. They may be small discoid or lobed structures (Figs. 1d and 2b), or platelike (Fig. 6e), or ribbonlike (Fig. 7d), or highly dissected

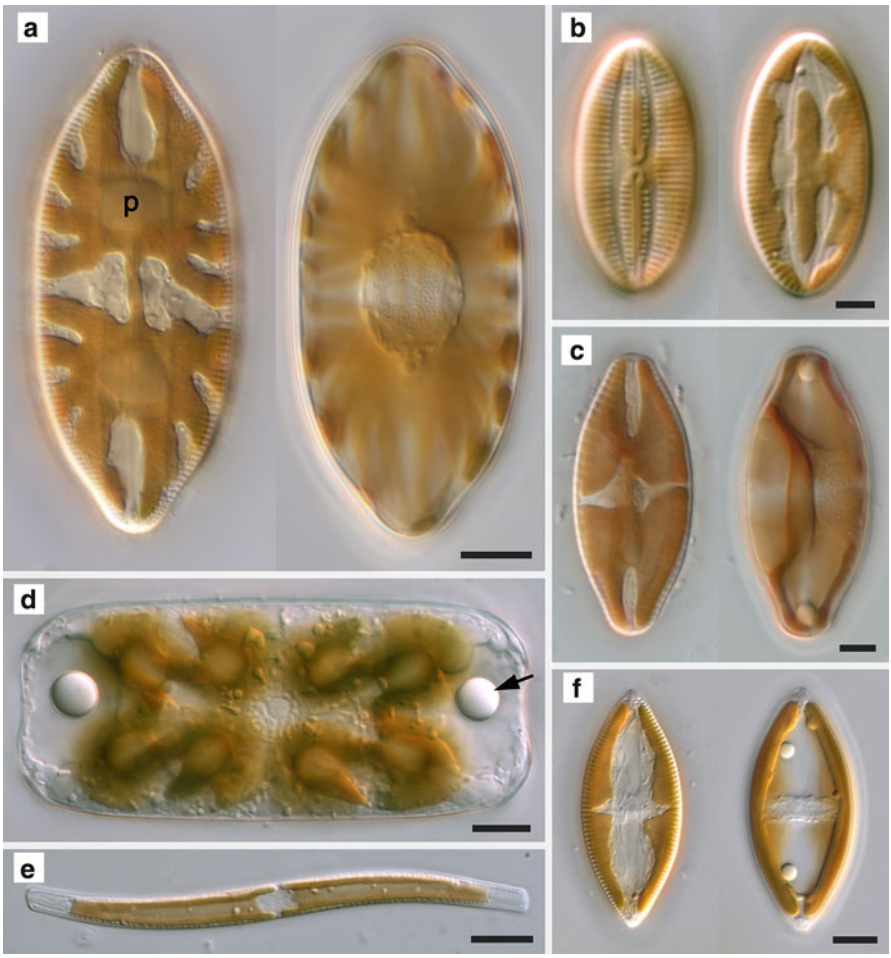

Fig. 6 Living cells of raphid pennate diatoms, all seen in valve view except (**d**, **e**). All scale bars = 10 μm, except (**c**). (**a**) Peripheral and central focuses of *Lyrella* cell. Note the strongly lobed chloroplast, which contains two roundish pyrenoids (e.g., p), and the central nucleus containing a prominent nucleolus and surrounded by a shell of cytoplasm containing Golgi bodies (appearing as short *curved bars*). (**b**) Valve and peripheral focuses of *Fallacia*. The lobes of the chloroplast are clearly related to the pattern of markings on the valves, avoiding the lyre-shaped clear area. (**c**) Peripheral and central focuses of *Placoneis*. Scale bar = 5 μm. (**d**) Amphoroid diatom in girdle view, with a highly convoluted chloroplast and two 'volutin' granules (e.g., *arrow*). (**e**) Sigmoid *Nitzschia* species containing two chloroplasts arranged end to end. (**f**) Peripheral and central focuses of *Navicula* cf. *palpebralis*; there are two chloroplasts, one on each side of the cell. Note also the central, transversely elongate nucleus and two volutin granules

and complex in shape (Figs. 6a–d, f, and 7a). In raphid diatoms, chloroplast morphology and position are usually highly constant within genera and can be used to help identify living diatoms. There is often a clear relationship between the position and shape of the chloroplasts and cell wall structures and other organelles (Fig. 6b).

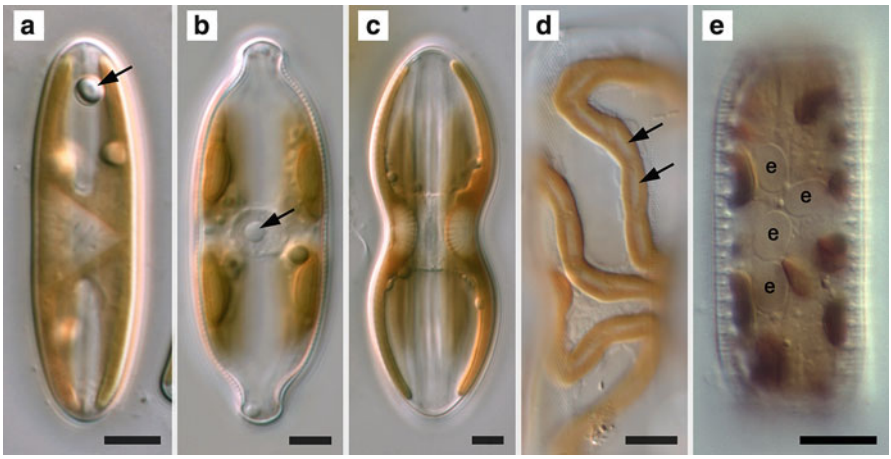

Fig. 7 Detail of chloroplasts and cells of raphid pennate diatoms. (**a**) *Sellaphora bacillum*. Note the H-shaped chloroplasts, the eccentrically placed triangular profile of the pyrenoid (with invaginations) and volutin granule (*arrow*). Scale bar = 5 μm. (**b**) *Neidium* cell with four chloroplasts and a central nucleus surrounded by Golgi bodies (appearing as *curved bars*) and containing a prominent nucleolus (*arrow*). Scale bar = 5 μm. (**c**) *Diploneis* cell with two chloroplasts, one on either side of the cell, each with a prominent invaginated pyrenoid at the center. Scale bar = 5 μm. (**d**) Part of a *Donkinia* cell with ribbon-like chloroplasts. Note the bar-like pyrenoids along the axis of the chloroplast (arrows). Scale bar = 10 μm. (**e**) *Epithemia* cell, containing four endosymbionts (e). Scale bar = 10 μm

The chloroplasts contain chlorophylls a and c, fucoxanthin, and various other carotenoid pigments, e.g., diatoxanthin and diadinoxanthin (Jeffrey et al. 2011; Egeland 2016). One or more pyrenoids are usually present in each chloroplast and are often conspicuous (Figs. 6a and 7a–d). The number of pyrenoids per chloroplast and their structure and positions vary among genera; some have angular shapes (Fig. 7a), probably reflecting a semicrystalline substructure. In a few genera the pyrenoids are penetrated by fingerlike extensions of the cytoplasm (Fig. 7a, c). The chloroplasts are bounded by four membranes, reflecting their ultimate origin through secondary endosymbiosis of a red alga (van den Hoek et al. 1995). Chloroplast (cp-) DNA is usually contained in a peripheral "ring nucleoid," running around the margin of the organelle (Kuroiwa et al. 1981; Coleman 1985), but in large-celled diatoms the arrangement can differ: in *Nitzschia sigmoidea* cp-DNA lines the sides of the linear pyrenoids (Mayama et al. 2004) and in *Pinnularia nobilis* it occurs as scattered granules (Mayama and Shihira-Ishikawa 1994).

The mitochondria have tubular invaginations of their inner membranes (Fig. 12f). Prominent shells of Golgi bodies occur around the nucleus in many pennate and most bipolar centric diatoms (Figs. 6a and 7b), whereas elsewhere among the centrics there are sometimes special associations of a Golgi body, endoplasmic reticulum, and a mitochondrion (e.g., Pickett-Heaps et al. 1990), or of a Golgi body and either a mitochondrion or a chloroplast (Idei et al. 2012). The principal

carbon storage products are oil globules and glistening whitish deposits of chrysolaminarin (a β–1,3 glucose polymer). Polyphosphates are also produced (Kuhl 1962), forming conspicuous "volutin" granules in some species (Figs. 6d, f, and 7a), and it seems likely that diatoms play an important role in transferring phosphorus from the water column to the sediments in the world's oceans (Diaz et al. 2008).

Some diatoms contain endosymbionts. Heterotrophic bacteria have been found in the raphid diatom *Pinnularia* (Schmid 2003a, b), and cyanobacteria are present in the vacuoles of some planktonic diatoms, such as *Hemiaulus* and *Rhizosolenia* (e.g., Janson et al. 1995), and in the cytoplasm of *Epithemia* (Fig. 7e) and *Rhopalodia* (Geitler 1977; Nakayama et al. 2011). These cyanobacteria contribute to the symbiosis principally through nitrogen fixation (e.g., Foster et al. 2011; Kemp and Villareal 2013). The endosymbionts of *Epithemia* and *Rhopalodia* are incapable of independent existence and indeed of photosynthesis (Nakayama et al. 2014). How these cyanobacteria entered diatom cells, despite the presence of the frustule, is a mystery; the only naked cells known in *Epithemia* and *Rhopalodia* are the amoeboid gametes.

Cell Wall and Cell Division

The diatom cell wall (***frustule***) is often likened to a Petri dish (cf. Fig. 1a, b) because it consists of two overlapping halves (***thecae***). However, this is a little misleading, because each theca is itself composite, consisting of a series of hoops (the ***girdle bands***) attached to the edge of a large endpiece (the ***valve***). One theca (the ***hypotheca***) is generally slightly smaller than the other (the ***epitheca***: Fig. 8a–d) and is always younger, being formed after the latest mitosis. During the cell cycle, the hypotheca slides out from beneath the older, overlapping epitheca and new bands are added to its edge; in this way, the cell increases in volume. The volume cannot be increased in any other direction because the siliceous valves and girdle bands, like glass, are essentially inelastic, although they can flex (e.g., in the living cells of the raphid diatom *Craticula*, the valves bow outwards as a result of the turgor of the cell, despite being well-silicified and robust: Mann 1994).

Once the cell has grown sufficiently and the hypotheca has attained more or less the same length and structure (with the same number of girdle bands) as the epitheca, mitosis is initiated. As the division of the nucleus is completed, cytokinesis takes place and two new valves (usually with at least some of their accompanying girdle bands) are formed within the frustule of the parent cell, before the old thecae separate. Then the two daughter cells separate, each inheriting one of the valves of the parent cell and one of the newly formed valves. This highly characteristic, semiconservative mode of cell division, is known only from this phylum and has fundamental consequences for much of diatom biology, e.g., causing average cell size to decrease during the vegetative phase (see below).

In many diatoms, the daughter cells separate fully once the new valves are complete, but in some the valves remain connected by organic material or

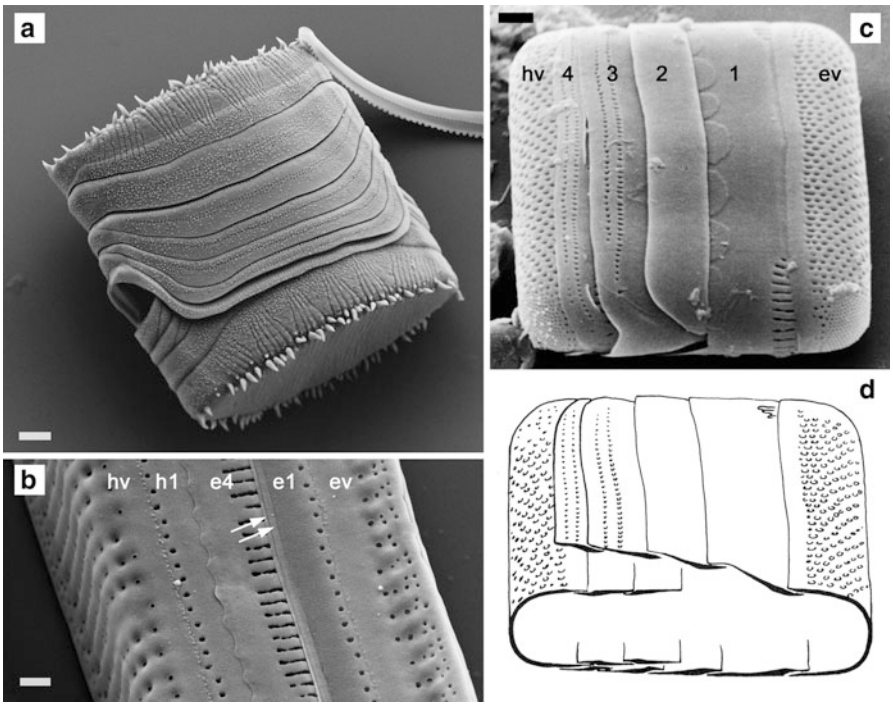

Fig. 8 Frustule and girdle structure. SEM. (**a**) *Diatoma* frustule: the epitheca is at the top, overlapping the hypotheca. Scale bar = 2 μm. (**b**) Detail of a *Nitzschia* frustule. The epitheca comprises the epivalve (*ev*) and four girdle bands, two wide (e1, e4) and two very narrow ones (*arrows*) in between. The epitheca partially overlaps the hypotheca, of which the hypovalve (*hv*) and one band (h1) are visible. Scale bar = 500 nm. (**c**, **d**) Photograph and drawing of a *Grammatophora* frustule. The epivalve to the *right* (ev) is linked to four girdle bands (1–4), which partly obscure the hypovalve to the *left* (hv). Note the variation of markings in the girdle-bands. The schematic cut-away drawing of a *Grammatophora* frustule (**d**) illustrates the spatial relationships of the frustule components in **c**. The two girdle-bands of the incompletely formed hypocingulum (*left*) are assumed. Scale bar = 10 μm

interlocking or fused silica projections (Figs. 2d and 12d, e). In this way, chains can be formed, which, with some important exceptions (these include colonies of cells on branched stalks, thalloid mucilaginous colonies in *Dickieia* and mucilaginous tubes in various raphid diatoms, e.g., *Berkeleya* [Fig. 4c]), are the only means of colony formation. In a few diatoms, the new valves are not smaller than the valves of the parent cell because of an unusual flexibility of the girdle. Consequently, these species can grow in culture indefinitely, without any reduction in the average size of the cells in the population (Chepurnov et al. 2004).

The valves are perforated by numerous small pores, arranged in species-specific patterns. Traditionally, two main types of valve pattern have been recognized (Schütt 1896). In the "***centric***" type of organization, the pores are arranged in radiating rows (striae: Figs. 1a, b, d), subtended at the pattern center (which is not always at the

center of the valve) by a small ring (***annulus***), within which pores are less regularly arranged or absent. Centric diatoms can be circular (Fig. 1a–d), oval, triradiate or triangular, quadrate (Fig. 5c), or many angled; less often they are elongate. Molecular phylogenetic studies have shown that the centric diatoms are not a monophyletic grouping but, depending on the criteria selected for the analysis (see Medlin 2014), fall either into a grade of separate lineages or into two monophyletic classes, comprising the radial and bipolar centrics, respectively (see section "Summary Classification"). In the "***pennate***" type of organization (Fig. 9a–g), the pattern is feather-like (Latin *pinna* or *penna* = feather), the striae lying in two rows either side of a longitudinal bar or rib (the ***sternum***). Pennate diatoms are almost invariably elongate but may be isopolar (Figs. 9b, g) or heteropolar (Figs. 9a, c), bilaterally symmetrical (Figs. 9b) or dorsiventral (Fig. 9d, i). The down-turned side of the valve is known as the ***valve mantle*** and the markings on this may differ from those on the top of the valve (the valve face). Unlike the centrics, the pennate diatoms are always recovered as monophyletic in molecular phylogenies (e.g., Sims et al. 2006; Theriot et al. 2010), but sternum-like structures have evolved independently in some centric lineages, perhaps through elongation of the annulus (e.g., Kooistra et al. 2003a).

The majority of pennate species have two complex slits along or near the midline of the valves – these are known as ***raphe slits***, and it is through them that the organism achieves locomotion (Fig. 9b–i). A model to explain raphe function was proposed by Edgar and Pickett-Heaps (1984) and no major revision of this seems yet to be needed. Mucilage fibrils are secreted into and through the raphe slits, apparently from Golgi-derived vesicles, but remain connected to the protoplast via transmembrane components. In turn, the transmembrane components interact with actin microfilaments lying immediately beneath the raphe and are constrained to stream along the raphe slits (Round et al. 1990). Hence, if the mucilage fibrils become attached distally to a firm substratum, the effect of the streaming will be to generate motion of the whole cell, which occurs at speeds of up to 20 μm or more per second. Mucilage is left behind as a trail when it reaches the ends of the slits, forming part of the "extracellular polymeric substances" released by diatom cells and performing various functions including adhesion and providing structure (Daniel et al. 1987; Underwood and Paterson 2003).

Some genera have raphe slits on both valves (***biraphid***), while others (the ***monoraphid*** diatoms, which are polyphyletic) have slits on one valve only. In the latter, motility is limited and slow and the cells are attached to the substratum for most of the time by mucilage, e.g., *Cocconeis* (Fig. 3c) and *Achnanthes* (Fig. 3b). For accounts of the various diatom polysaccharides, see Hoagland et al. 1993; Underwood and Paterson 2003; Gügi et al. 2015. The raphe slits can run along the midline of the valve (Figs. 9b, c, f) or may be displaced to one side (Fig. 9g, i) or even circumferential (Fig. 9e). The raphe normally consists of a pair of slits running from either side of a clear central area to the apex, where the external fissure often bends and continues as a blind surface groove (Fig. 5c). In several genera, e.g., *Nitzschia* and *Hantzschia* (Fig. 6d), the slits are bridged internally by short bars (fibulae), which appear to function as ties, preventing the valve from splitting along the raphe. In the genus *Eunotia* and its allies, which seem to be an early offshoot of

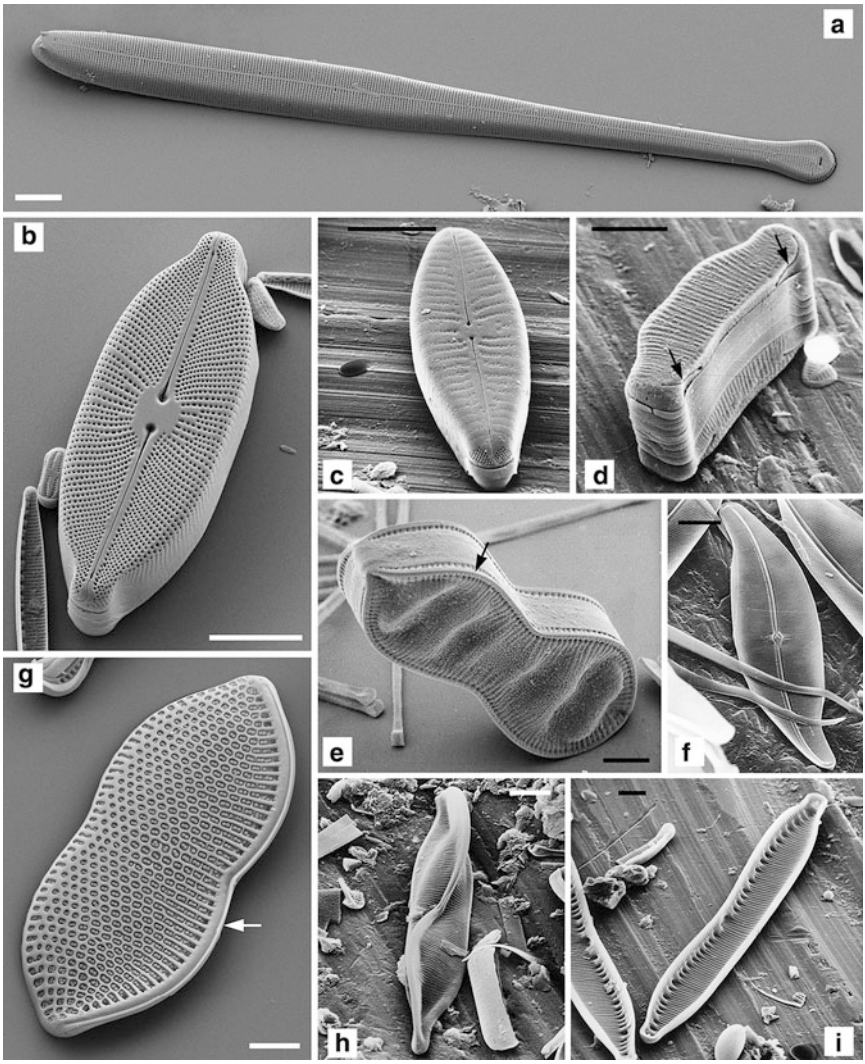

Fig. 9 Pennate diatoms. SEM. All except *Licmophora* (**a**) are raphid diatoms. (**a**) *Licmophora* valve; a stalk (like those shown in Figs. 3e and 5a) is secreted through special pores at the narrower end. Note the sternum running along the center of the valve and bearing transverse ribs on either side. Scale bar = 5 μm. (**b**) *Cosmioneis* frustule. Note the two axial raphe slits and slightly radiating striae. Scale bar = 10 μm. (**c**) *Gomphonema*, with heteropolar symmetry. Scale bar = 10 μm. (**d**) Frustule of *Eunotia*, which has short raphe slits (*arrows*) that run from the valve face over onto the mantle. They are found on the same side in the two valves of each frustule. Scale bar = 10 μm. (**e**) *Cymatopleura* frustule. The valve face is undulate and the raphe (*arrow*) runs round the rim of the valve with a discontinuity at either end. SEM. Scale bar = 10 μm. (**f**) Sigmoid symmetry of *Gyrosigma*. Scale = 10 μm. (**g**) *Psammodictyon* valve. The raphe (*arrow*) is borne on a raised keel at the margin of the valve. Scale bar = 2 μm. (**h**) *Entomoneis* valve: the raphe is elevated on a ridge, which takes a sigmoid curve along the valve. Scale bar = 10 μm. (**i**) The raphe of *Hantzschia* lies to one side of the valve (shown here from the inside) and is subtended on the inside by a number of small bridges (fibulae). Scale bar = 5 μm

the raphid diatom lineage (Theriot et al. 2010), the raphe slits are very short and lateral to the sternum instead of integrated into it (Fig. 9d), but the cells are nevertheless motile. As in the centric series (Figs. 1b and 5c), there is all manner of variation in valve outline and topography in pennate diatoms, including sigmoid (Fig. 9f, h) and keeled (Fig. 9h) forms.

The siliceous girdle bands are frequently split rings, with the splits in adjacent bands lying at 180° to each other. Opposite the split in one band there is a tonguelike extension (ligula) of the adjacent girdle band to fill the gap (Figs. 8a, c, and 10a). In a few genera some of the bands are complete hoops, e.g., in *Grammatophora*, where the bands also bear well-developed septa extending part way into the cell lumen (Fig. 10b). Still other diatoms have a girdle composed of individual segments (Fig. 10c), appearing like diamond-shaped scales.

The pores of the valves and girdle bands, termed ***areolae***, allow transfer of water, nutrients, gases, cellular products, etc. between environment and cell. Only rarely,

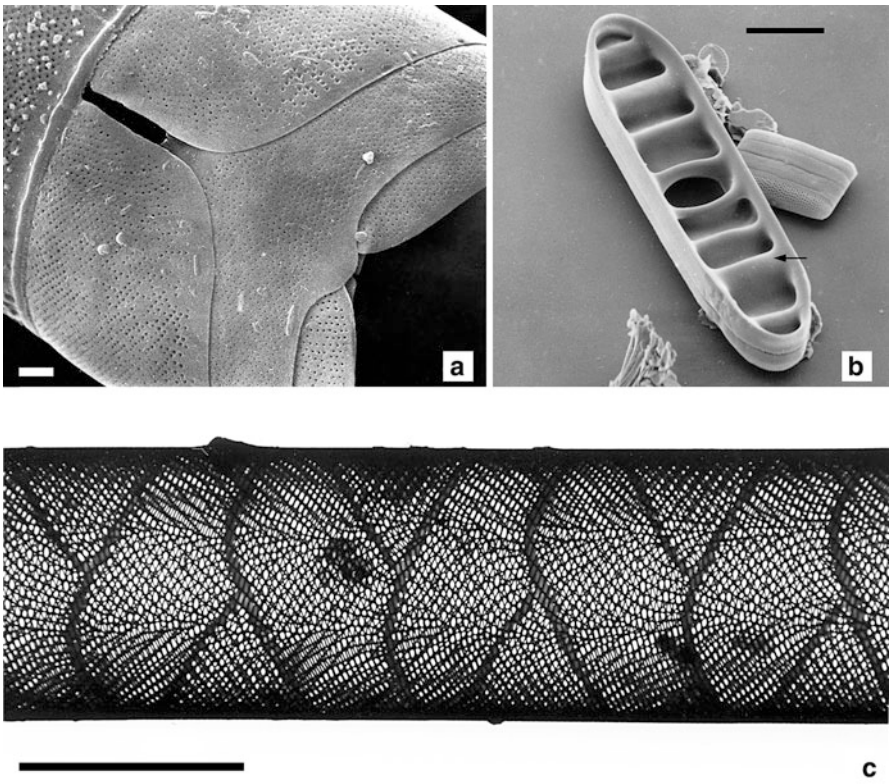

Fig. 10 Girdle bands. (**a**) *Pleurosira:* the gaps left by the split ends of the first and third bands are partially or completely closed by an enlargement of the second band. SEM. Scale bar = 10 μm. (**b**) Girdle band of *Grammatophora* with its characteristic undulate septum (*arrow*). SEM. Scale bar = 10 μm. (**c**) The scale-like girdle bands of *Rhizosolenia*. Transmission electron micrograph (*TEM*). Scale bar = 1 μm

however, are they simple channels through the silica. In most cases, a fine plate of silica, itself perforated by tinier holes, stretches across the pores. These plates are known as ***vela*** or ***pore plates*** and take many different forms, each to some extent characteristic of genera or groups of genera; the position of the velum, towards the inner or outer ends of the areolae, is also of systematic importance. Some of the variation to be found among vela can be seen in Fig. 11a–d. The areolae of the girdle bands are usually similar to those on the valves but much smaller. The last-formed bands (furthest from the valves) are often plain. In some cases, all the girdle bands lack pores.

The valves tend to be more complex than the girdle bands and may have special types of apertures in addition to the areolae. The most common type of special aperture, found in most centric and a few pennate diatoms, is developed internally as a slit between a pair of lips and externally either as a simple opening or a tube and is termed a ***rimoportula*** (Fig. 12a, b) or ***labiate process***. The functions of rimoportulae

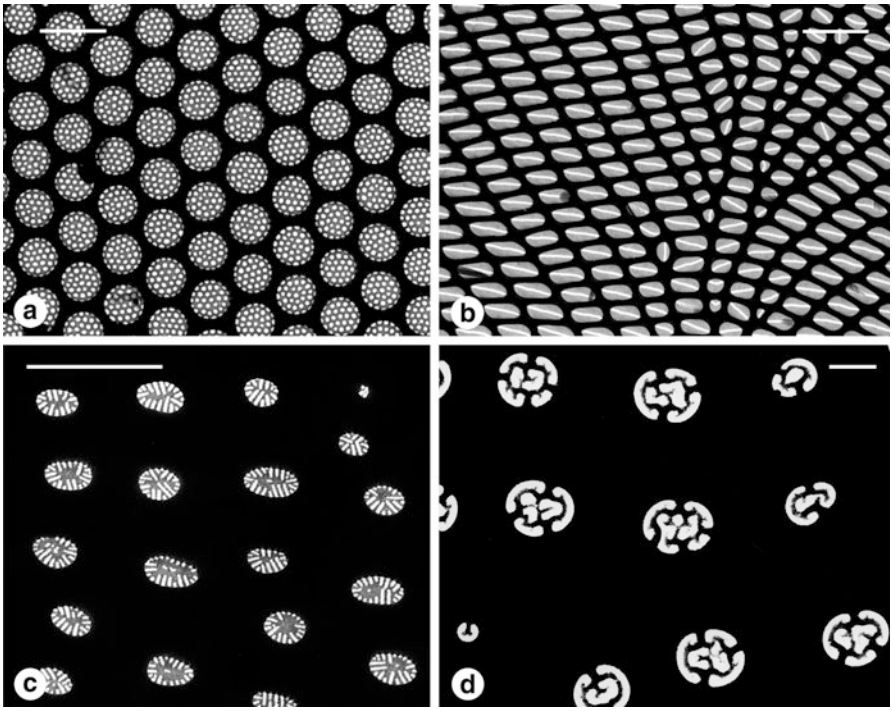

Fig. 11 Details of areola structure. TEM. Scale bars = 1 μm. (**a**) *Roperia*: each areola has many small pores in a thin siliceous velum. (**b**) Each velum of *Rhizosolenia* has just one narrow slit. (**c**) The areolae of *Cocconeis* are variable in size and shape and so is the pattern of slits in the velum**.** (**d**) The vela of *Rhaphoneis* are branching, interconnected projections from the side of the areolae

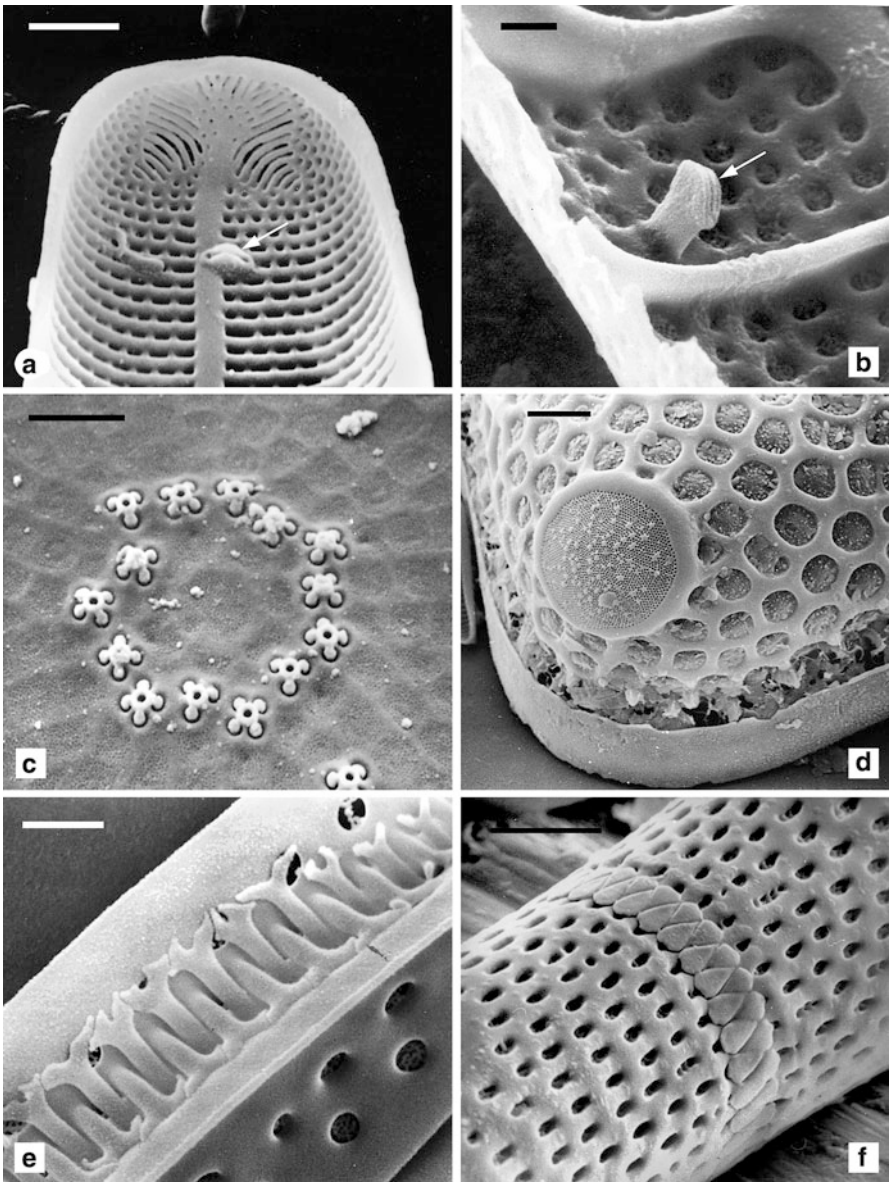

Fig. 12 Special wall structures. SEM. Scale bars = 1 μm. (**a**) Rimoportula of *Cyclophora* (*arrow*). (**b**) Stalked rimoportula of *Triceratium* (*arrow*). (**f**) Linking spines connecting two valves of *Aulacoseira*

remain unclear in most cases, although in a few cases they have been shown to be involved in secretion for motility (Medlin et al. 1986; Pickett-Heaps et al. 1990) or endocytosis (Kühn and Brownlee 2005). The other well-known type of process is confined to the centric order Thalassiosirales and is called the ***fultoportula*** or ***strutted process***. This consists externally of a simple tube or opening and internally of a tube surrounded by a number of basal satellite pores separated by buttresses (Fig. 12c), or with the satellite pores developed as tubes. Its function is the secretion of chitin fibers (Fig. 1c) that connect cells together or control sedimentation (Walsby and Xypolyta 1977). Additionally, in many epiphytic, epilithic, and epipsammic diatoms there are areas of simple pores near the periphery or ends of the valves (Figs. 5d, 8c, 9c, and 12a, d), from which stalks or pads of mucilage are secreted to link the cells to the substratum or to one another.

Spines, tubercles, etc. are common on the outer surfaces of the valves but never on the girdle bands, nor on the inner surface of the valves. Some spines (Fig. 12e, f) act to connect cells together in chains and in a few genera the exit tubes of the rimoportulae or fultoportulae act as interlocking devices.

Diatom mitosis and particularly the structure and functioning of spindle and associated structures have been the focus of considerable detailed research, which has contributed significantly to a general understanding of the mechanism of mitosis (Pickett-Heaps 1991). In some species a small dense body of granular material is associated with microtubules and lies near the nucleus during interphase. This ***microtubule organizing center*** (***MTOC*** or ***centrosome***) breaks down at prophase and at the same time a complex and highly ordered spindle develops nearby. Cytokinesis occurs through ***cleavage*** (Round et al. 1990). Mitosis and cytokinesis are followed by the formation of new valves (indeed, this sequence is generally obligatory). The MTOC reforms and migrates to a position between the nucleus and the ***silica deposition vesicle*** (***SDV***), which is a flattened sac beneath the cell membrane in which the new valves are formed. The nucleus and the MTOC usually remain intimately associated with the developing valve, and systems of microtubules (subtended by the MTOC) and microfilaments are present, which may play a role in the expansion of the SDV and the morphogenesis of the valve (Pickett-Heaps et al. 1990). In some diatoms, treatment with microtubule inhibitors results in the formation of distorted valves, although the basic rib–stria system appears to be little affected. A special structure, the ***raphe fiber***, has been found immediately below the forming raphe slits in recently divided cells of raphid diatoms and may be involved in generating the complex shape of the raphe (Pickett-Heaps et al. 1990). A somewhat similar fibrous structure – ***the labiate process apparatus*** – is present while the rimoportulae are formed.

Since 2000, there have been major advances in our understanding of how silicate is acquired by cells and converted into the amorphous hydrated silica of the valves and girdle bands (Hildebrand 2008; Hildebrand & Lerch 2015; Finkel 2016), stimulated by the realization that diatoms achieve feats of chemical engineering in ambient conditions that materials chemists achieve only by using high temperatures

and pressures. Building on earlier studies by Volcani and coworkers (e.g., chapters in Simpson and Volcani 1981) and using modern molecular and genomic approaches, it has been possible to characterize components of the silicon transport system (Hildebrand 2008) and to show that silica deposition in the SDV is catalyzed and mediated by at least two classes of proteins: (1) ***silaffins***, which are peptides rich in serine and lysine that have been extensively modified after translation by methylation, phosphorylation, and covalent linkage with polyamines and silacidins; and (2) ***silacidins***, which contain mostly phosphorylated serine and aspartic and glutamic acids (Sumper and Brunner 2008). It appears that interactions between silaffins, silacidins, the polyamines, and polysaccharides, e.g., chitin, control the detail of silica deposition (e.g., Richthammer et al. 2011). Recently, transcriptomics approaches have added considerably to knowledge of which genes are involved in silicification (reviewed by Finkel 2016).

However, although the biochemical and electrostatic properties of silaffins and silacidins probably take us a long way towards understanding the finer detail of cell wall development, it is not yet clear that they are relevant to larger-scale morphogenesis in diatoms: the creation of the beautifully ordered patterns of ribs and pores of diatom valves still mostly eludes explanation. Pickett-Heaps et al. (1979) proposed that an organic template is formed, onto which silica is deposited from both sides. This may be true for pennate diatoms whose wall is a simple laminate structure but the structure of more complex walls, such as are found in many centric diatoms, suggests the formation of one layer first, onto which a chambered or ***loculate*** system is later superimposed (Crawford 1974a; Schmid and Volcani 1983; Round and Crawford 1984). Lenoci and Camp (2008) have been able to generate patterns very similar to those of many diatoms possessing chambered or folded valves, using a model based on phase separation on a planar surface, and Pickett-Heaps et al. (1990) argue that the cytoskeleton and cell organelles are probably also involved in mesoscale patterning in diatoms; this is supported also by more recent studies using fluorescence labeling (Tesson and Hildebrand 2010).

The initial development of the valve almost always involves sequential formation of a tightly controlled rib–stria pattern, and the way that the pattern varies in relation to disturbances (e.g., Mann 2006) and natural variation in valve size indicates that the rib–stria system and any template controlling its appearance must form as the SDV expands outwards from the initial pattern center (e.g., Schmid and Volcani 1983; Pickett-Heaps et al. 1990), which is usually either the annulus (in centric diatoms) or the sternum (in pennate diatoms). Explanation of the control of rib spacing during the production of the initial layer (which must be very precise, since otherwise the species taxonomy of diatoms would not work as well as it does) is probably the main remaining challenge in understanding diatom morphogenesis.

At the gross level, cell shape in diatoms is created largely during the expansion of the auxospore (see below) and then gradually modified by differential flexing of the girdle during the subsequent phase of slow decline in size during the vegetative phase (Mann 1994), except in species with circular valves where no modification occurs except in teratologies.

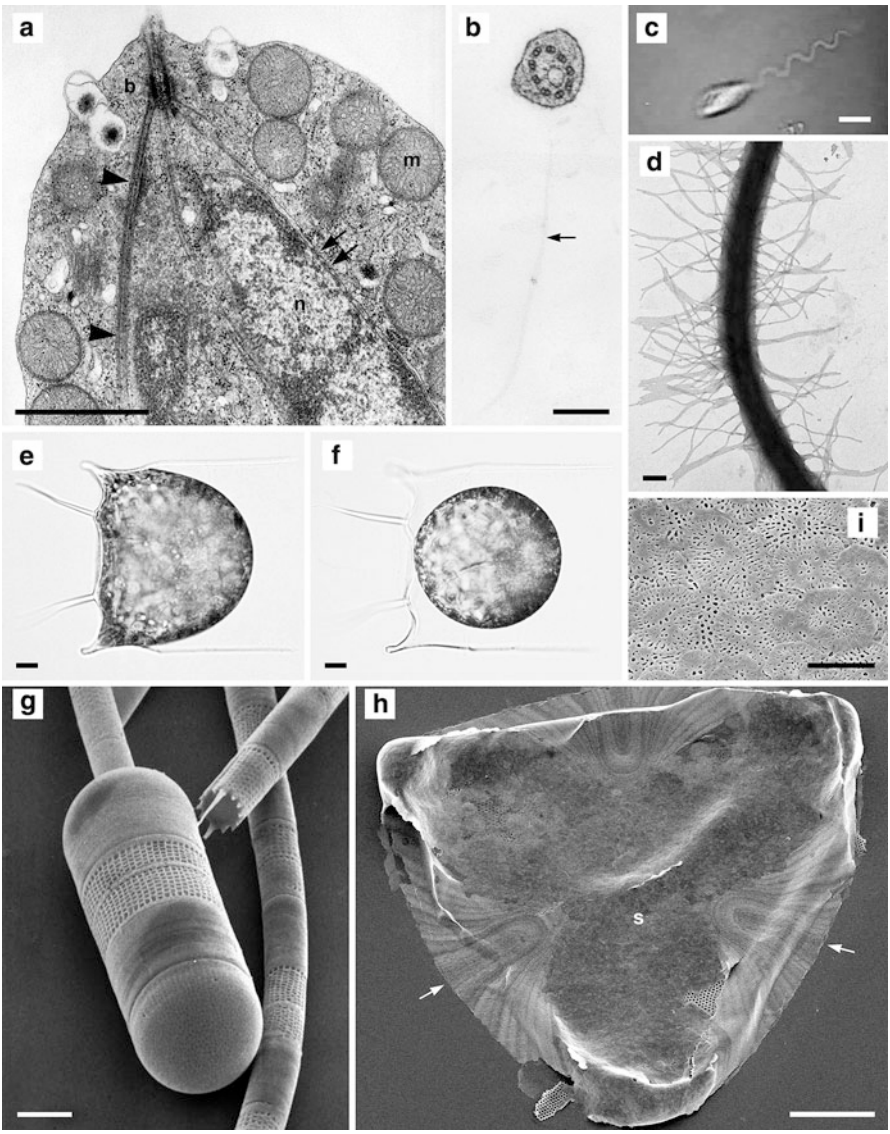

Fig. 13 Sexual reproduction in centric diatoms. Micrographs (**a**–**d**, **h**, **i**) were very kindly provided by Professor Masahiko Idei (Bunkyo University, Japan) and are reproduced here by permission (**a**) Apex of a *Thalassiosira* sperm in longitudinal thin section, showing the flagellar basal body (*b*) subtending a cone of microtubular bundles (e.g., *arrowheads*) that extend over the surface of the nucleus (*n*). Many nuclear pores are evident (*arrows*). Note also abundant rounded mitochondria (*m*) containing tubular invaginations of the inner membrane. TEM. Scale bar = 1 μm. (**b**) Transverse thin section through the flagellum of *Melosira moniliformis* var. *octogona*. The axoneme lacks central microtubules (9+0 configuration) but frequently contains vesicles, as here. Long mastigonemes are attached to either side of the flagellum (e.g., *arrow*). (**c**) Swimming sperm of *Thalassiosira*. High-speed video still, showing quasi-sinusoidal beat. Scale bar = 5 μm.

Life Cycle

As noted above, in some species the girdle bands are sufficiently flexible to allow the new valves to be as large as the old valves, even though they are formed within the parent cell's frustule. However, in most diatoms one of the new valves is smaller than the smaller of the two parent valves by double the thickness of the girdle bands (Crawford 1981). Consequently, a succession of mitotic cell divisions generally results in a diminution of the average valve dimensions. Ultimately, death of the population will result unless the maximum dimensions of the cells are restored. This usually occurs via an auxospore formed following sexual reproduction. Sexual reproduction is morphologically isogamous in most pennate genera, but oogamous, with motile sperm and larger nonmotile egg cells, in the various lineages of centric diatoms (although information is absent for many genera).

Though regarded until recently as almost universally homothallic, diatoms do in fact exhibit a variety of mating systems (Chepurnov et al. 2004; Sato et al. 2011; Davidovich et al. 2012). Some pennate diatoms (probably the majority) are heterothallic, whereas others (and also most centric diatoms) are facultatively or habitually homothallic. Reduced sexuality (via auto- or apomixis) has evolved independently in several lineages (e.g., Mann et al. 2013; Poulíčková et al. 2015).

In oogamous diatoms, ***sperm*** (Fig. 13c) are produced following a series of divisions within a modified cell (***spermatogonium***); they are then released and swim to find the ***egg cell*** (produced within an ***oogonium***: Fig. 13e), presumably guided by chemotaxis. Pennate diatoms lack flagellate stages and here the gametes (Fig. 14b) are usually all alike (morphologically isogamous) and show very limited autonomous movement; in raphid pennate diatoms, it is the sexualized vegetative cells that move, using their raphe systems to find each other and pair actively before meiosis is initiated (Fig. 14a). The cells then often surround themselves with a capsule of mucilage (Fig. 14d), in which gametogenesis and fertilization take place. Araphid pennate diatoms are not generally able to move very effectively and in some genera (e.g., *Tabularia*, *Pseudostaurosira*), the gametes are differentiated into small nonmotile female gametes and ± equally small male gametes that possess curious threadlike appendages that generate spinning and unidirectional movements, which help the gametes find each other (Sato et al. 2011; Davidovich et al. 2012),

Fig. 13 (continued) (**d**) Mastigonemes in two rows on the flagellum of *Hydrosera*. Whole mount, TEM. Scale bar = 200 nm. (**e**) Theca of living *Odontella* oogonium containing partly naked egg cell. Scale bar = 10 μm. (**f**) Egg of *Odontella* with polarized cell contents. Scale bar = 10 μm. (**g**) Pre- and postauxospore cells of *Aulacoseira*. The large hemispherical valves either end of the wider filament are initial valves, i.e. the first valves formed within the spherical auxospore. SEM. Scale bar = 10 μm. (**h**) Ventral side of the auxospore wall (incunabula and perizonium) of *Triceratium*. The center is covered by a mass of small scales (detail in **i**). The triangular shape is created as a result of differential wall hardening through deposition of a complex set of perizonial strips, beginning with a triradiate element with its center on the dorsal side, whose three arms curve back (*arrows*) onto the ventral side. Other bands are then added adjacent to the primary band (cf. Round et al. 1990, fig. 65). (**i**) Incunabular scales of *Triceratium*. SEM. Scale bar = 5 μm

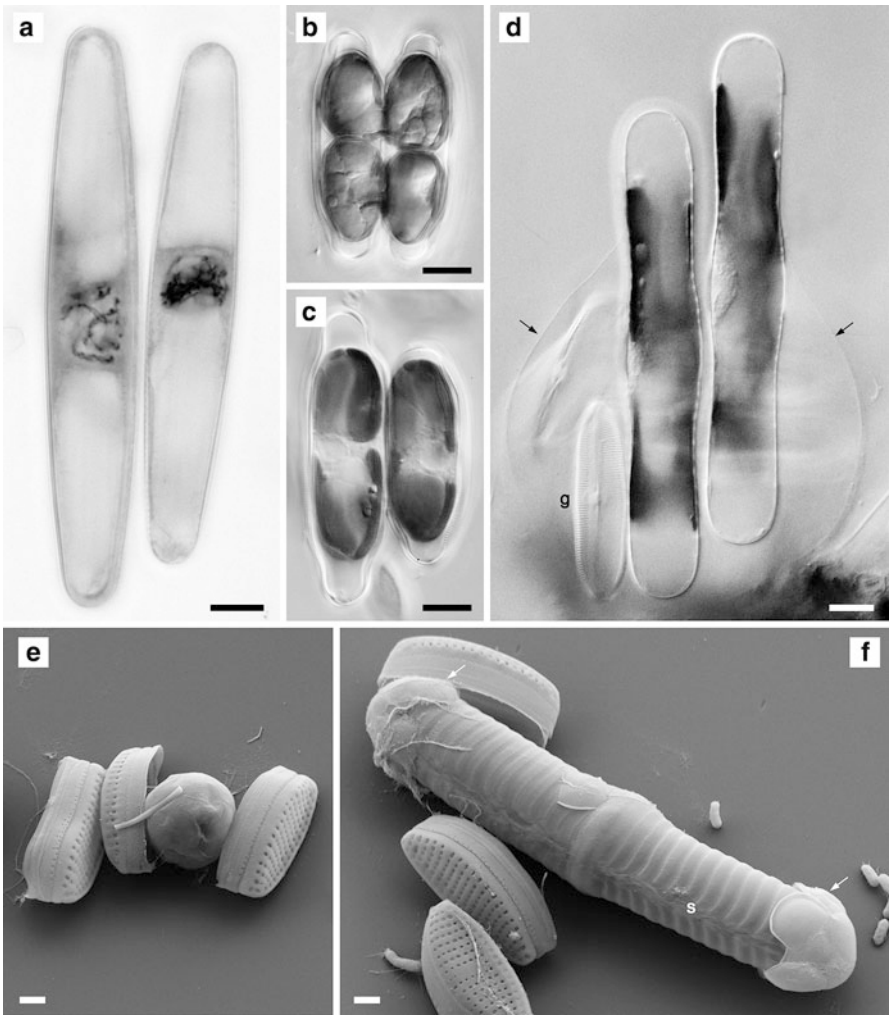

Fig. 14 Sexual reproduction in pennate diatoms**.** The images in (**e**) and (**f**) were very kindly provided by Drs Shinya Sato and Laia Rovira. (**a**) Paired cells of the raphe-bearing pennate diatom *Navicula oblonga* in meiotic prophase (diplotene at *left*, zygotene at *right*). Haematoxylin-stained preparation. Scale bar = 10 μm. (**b**) Paired cells of *Neidium*, each containing two large non-flagellate gametes. The gametes are beginning to move (clockwise) into the adjoining cell. Scale bar = 10 μm. (**c**) Paired cells of *Neidium* following fusion of the gametes and movement of one gamete from each gametangium into the other cell. Each parental frustule therefore now contains a single zygote. Scale bar = 10 μm. (**d**) Expanded auxospores of *Caloneis*, flanked by a valve of one gametangium (*g*). Gametogenesis and fertilization occurs here within a large ellipsoidal mass of mucilage (*arrow*). Scale bar = 10 μm. (**e**) Spherical zygote of *Nitzschia inconspicua* flanked by the thecae of the gametangial frustule. The zygote is covered by incunabula of silica scales. Scale bar = 1 μm. (**f**) Expanded auxospore of *Nitzschia inconspicua*. The scale-case of the zygote has been split into two scaly caps (*arrows*) by the growth of the auxospore, which develops a cylindrical shape through sequential hardening of its wall, outwards from the center, by perizonial strips; these are open on one side, forming a 'suture' (*s*). Scale bar = 1 μm

though only over very short distances. ***Pheromones*** have recently been demonstrated to be involved in the sexualization and chemotaxis of pennate diatoms (Sato et al. 2011; Gillard et al. 2013; Moeys et al. 2016), and the genetic basis of sex determination is now being explored for the first time (Vanstechelman et al. 2013).

Meiosis occurs during gametogenesis (Fig. 14a). The isogametes of pennate diatoms (Fig. 14b) and the egg cells of oogamous diatoms (Fig. 13e, f) all possess plastids, as do some sperm, although it is unclear whether sperm plastids ever survive in the zygote after fertilization of the egg cell. The gametes mostly lack their own siliceous walls, although they are often protected by mucilage capsules or (in centric eggs and many pennate diatoms) by remaining partly enclosed within the frustule of the mother cell (e.g., Idei et al. 2012). Diatom sperm possess two opposite rows of tripartite mastigonemes (Fig. 13b, d) and perform quasi-sinusoidal movements (Fig. 13c) in the plane of the mastigonemes, like the flagellate cells of other heterokont protists, but they differ from them in the structure of the flagellar axoneme, which lacks central microtubules (i.e., the axoneme has a ***9+0 configuration***: Fig. 13b and Idei et al. 2013b). The flagellar apparatus is also unusual in lacking the usual systems of microtubular and fibrous roots, though it sometimes possesses instead a cone of microtubules extending down over the surface of the nucleus (Fig. 13a). No transitional helix is present, and there is no trace of a second flagellum or basal body in the few sperm that have been studied in detail.

Fertilization is followed by development of the zygote into an auxospore, so-called because it is this cell that is able to grow and restore the maximum size characteristic of the species. The zygote produces an organic wall as it differentiates into an auxospore and, as the auxospore expands, silica elements are often inserted into the wall, creating regions that afford some rigidity and probably control expansion. Consequently, an initially spherical (Fig. 14e) or ellipsoidal zygote (Fig. 14c) can be transformed into more complex shapes – elongate cigars with or without a swollen central portion (Fig. 14d, f), bananas, spindles, triradiate forms, or stars (Mann 1994). The special silica elements added to the auxospore wall to stiffen it are sometimes many and intricate (e.g., Poulíčková et al. 2007) and can be divided into (1) the ***incunabula*** – i.e., those elements formed by the zygote before expansion (Trobajo et al. 2006), which can include circular or elliptical scales (Figs. 13i and 14e) or narrow strips of plain silica – and (2) the ***perizonium*** (Figs. 13h and 14f), which comprises several or many bands (often differentiated into transverse and longitudinal series) that are formed sequentially by the auxospore as it expands (Idei et al. 2013a). The development of the auxospore often involves a considerable increase in dimensions (to twice or several times the length of the gametangia in some pennate diatoms: Figs. 14d, e, f). Once expansion is complete, a new cell – the ***initial cell*** – is formed within the auxospore (Fig. 13g). This involves two successive mitoses, each preceding the deposition of a new large valve. The initial valves are usually unlike the valves produced during the vegetative phase because they are formed within and molded by the auxospore, not by another frustule. In addition, the initial valves of chain-forming diatoms differ from those produced subsequently by virtue of the fact that they lack interlocking spines, etc., and come to lie at the ends of the filaments to which they give rise after subsequent cell divisions. Sometimes

modifications of cell shape occur during formation of the initial valves, after auxospore expansion is complete, as a result of contractions of the auxospore away from parts of its wall. The divisions of the initial cell and its immediate descendants are followed by the formation of valves that correspond ever more closely to those typical of the species.

The chloroplasts can be inherited uniparentally or biparentally in diatoms (Mann 1996), and it has recently be shown that recombination can occur between chloroplast genomes located in different plastids within the same cell (D'Alelio and Ruggiero (2015).

The sexual process – and hence restoration of the maximum size – is initiated only when the cells are within a certain size range (Geitler 1932; Chepurnov et al. 2004). Until a ***critical size threshold*** is passed, cells can only reproduce vegetatively. Particular environmental conditions are probably also required for sexualization in many cases, although in culture there seems to be little difference between the conditions required for active vegetative growth and those that permit auxosporulation. Auxospore formation occurs infrequently in nature, because the length of the sexual phase is much shorter than the period of vegetative multiplication during which cell size diminishes (a few days or weeks as opposed to months or years: Mann 1988). Hence it is not surprising that there are rather few records of auxosporulation in natural populations (but see references in Mann 1988 and, e.g., D'Alelio et al. 2010, Jewson & Granin 2015). In temperate planktonic communities, records of auxospores tend to be restricted to the beginning or end of the growing period, i.e., in spring and late summer (e.g., Jewson 1992). Thinning of the population by entering the sexual phase with a large commitment of cells to gamete formation, as in *Corethron pennatum* (Crawford 1995, as *C. criophilum*), could have advantages for survival of the assemblage through periods of low nutrients brought about by a bloom (Crawford et al. 1998) and sidestep the interruption of synthesis that is one costly consequence of the sexual phase (Lewis 1983). In natural populations of single species, small cells generally outnumber large cells; this seems also to reflect the costs of sexual reproduction, in lost synthesis and aborted or unfit gametes and zygotes (Mann 2011).

Taxonomy

Karsten's (1928) system is a convenient starting point for tracing the development of modern diatom classifications. Karsten placed the diatoms in a division (or phylum), the Bacillariophyta, as have many modern workers (see Round 1981b). Within this, he recognized two orders, the Centrales (***centric diatoms***) and the Pennales (***pennate diatoms***), based on the organization of the pattern on the valves – which is radially or concentrically ordered (rarely irregular) in the Centrales, and feather-like in Pennales. This subdivision is also echoed in the features of the sexual reproduction of the two groups – oogamous in centrics but usually isogamous and always lacking flagellate sperm in pennates. Silva (1962) elevated the centrics and pennates to classes (Centrobacillariophyceae and Pennatibacillariophyceae) and created or

amended a number of orders within them, which brought the classification of diatoms into line with that of other major algal groups.

Scanning electron microscopy revealed further groupings beyond those recognized by Karsten and Silva. Round et al. (1990) therefore suggested many changes and new taxa, from classes to genera, in an attempt to summarize likely relationships, based not only on cell wall detail but also on cytological and other information. Analyses of molecular sequence data (especially from 18S rDNA) have subsequently shown that neither the traditional classification nor the revised system by Round et al. can be upheld, although some aspects of each gain support. Unfortunately, there is as yet no agreement about what should replace the older classifications, nor about whether it is sensible to make any changes at all until a clearer picture of diatom evolution emerges.

In the Round et al. (1990) classification, the diatoms (Bacillariophyta) were split into three classes: Coscinodiscophyceae, Fragilariophyceae, and Bacillariophyceae. These three are readily identifiable. The Coscinodiscophyceae equated more or less to the Centrales (Centrobacillariophyceae) and comprised all those diatoms with radial organization of the primary valve pattern, centered upon a small ring (annulus). The Fragilariophyceae and Bacillariophyceae together comprised the Pennales (Pennatibacillariophyceae) of earlier classifications, all having feather-like organization (transverse ribs and rows of pores, subtended by a longitudinal sternum). The two classes were separated by the absence (Fragilariophyceae) or presence (Bacillariophyceae) of a raphe system. The three classes of Round et al. (1990) seem mostly to avoid the charge of polyphyly. However, it is now clear that they do not capture the essential features of diatom evolution, since two of the three classes (Coscinodiscophyceae and Fragilariophyceae), as defined by Round et al. (1990), are almost certainly paraphyletic. Medlin and Kaczmarska (2004) therefore suggested a new system, in which the diatoms are split into two subdivisions, Coscinodiscophytina and Bacillariophytina. The Coscinodiscophytina comprised only centric diatoms (i.e., having a centric organization of the valve pattern); the Bacillariophytina, on the other hand, contained both centric diatoms, classified by Medlin and Kaczmarska into the Mediophyceae, and pennate forms, classified in the Bacillariophyceae. However, in some subsequent analyses the Coscinodiscophytina and the Mediophyceae have both been paraphyletic (e.g., Sorhannus 2007; Theriot et al. 2011), or the Mediophyceae have been monophyletic but not the Coscinodiscophytina (e.g., Ashworth et al. 2012; Nakov et al. 2015). If either of these later reconstructions accurately reflects evolution, the Medlin–Kaczmarska scheme will not satisfy most systematists, who require monophyly of taxa. Medlin (2014) notes, on the other hand, that if certain criteria are met in the molecular analysis, the Coscinodiscophytina and Mediophyceae **are** recovered as monophyletic clades and it has also been suggested (e.g., Medlin 2015, 2016a) that some reproductive and morphological features are consistent with the Medlin–Kaczmarska classification. In summary, there is as yet no consensus on the phylogeny and classification of centric diatoms. However, even if the Coscinodiscophytina and Mediophyceae are not monophyletic, Medlin and Kaczmarska's revision made two significant advances on the previous system

proposed by Round et al. (1990): (1) it recognized that the primary evolutionary radiation took place among diatoms with a centric organization and oogamous reproduction, and (2) it restored unitary status for the pennates, which are monophyletic in most molecular phylogenies and are characterized morphologically by the possession of a single sternum as the pattern center.

At the ordinal to family level, some of the groupings recognized by Round et al. (1990) and earlier authors appear monophyletic in molecular phylogenies and formal analyses of morphological characteristics. Examples are the Cymatosirales, Thalassiosirales, Bacillariales, Sellaphorineae, and Naviculaceae (e.g., Theriot et al. 2010, Ruck and Theriot 2011). However, many do not. Thus, *Proboscia* and *Urosolenia* are not closely related to *Rhizosolenia* (Round et al. placed them together in the same family, Rhizosoleniaceae), and *Achnanthes* and *Achnanthidium* are not related, despite their similarly monoraphid frustules (Round et al. placed them together in the Achnanthales) (e.g., Medlin and Kaczmarska 2004; Sorhannus 2007; Theriot et al. 2010). In contrast, at the genus level, many of the revisions suggested or incorporated by Round et al. (1990) have been supported by later analyses, such as the removal of *Ardissonea* and *Toxarium* from *Synedra* (Medlin et al. 2008), or the separation of *Lyrella*, *Petroneis*, *Fallacia*, *Sellaphora*, and *Placoneis* from *Navicula* (Jones et al. 2005; Bruder and Medlin 2007; Evans et al. 2008). At present, however, there are few or no molecular data for many genera and even where molecular data are available, the phylogenetic trees they yield often contain few nodes that (from bootstrap support values or posterior probabilities, or congruence with morphological or other data sets) can be regarded as reliable. Furthermore, different approaches to alignment and phylogeny reconstruction are adopted by different researchers, with significant effects on the phylogenies obtained (e.g., contrast Medlin & Kaczmarska 2004 with Theriot et al. 2015). Hence it is not surprising that there is no consensus yet about what should replace the Round et al. classification. The completion of current initiatives to develop multigene phylogenies of diatoms (e.g., Ashworth et al. 2013) will hopefully lead to a more satisfactory system. This will probably involve many major changes in how particular groups of species or genera are classified: a good example, showing the difficulties of reconciling existing taxonomy with new understanding, based on molecular and refined morphological analysis, is given by Ruck et al. (2016) in a study of the Rhopalodiales and Surirellales.

Given current uncertainty (except that previous classifications are wrong in many respects), we depart significantly from the previous edition of this book and present a greatly simplified classification (Table 1) modified from Adl et al. (2005). It is based on a comparison of recent published phylogenies and classifications (e.g., Theriot et al. 2010, 2011; Nanjappa et al. 2013; Nakov et al. 2015; Li et al. 2015; Medlin 2016a, b), taking into account the persistent lack of support for many basal nodes in molecular analyses (e.g., Theriot et al. 2015, fig. 1) and the frequent lack of a clear pattern in the distribution of morphological and cytological characters. Decisions about which clades should be recognized among the "radial centrics," ("Coscinodiscophytina") is especially problematic. In order to get an idea of the diversity that Table 1 represents, but ignoring the classification imposed upon it in

Table 1 Major clades and paraphyletic taxa of diatoms. The examples of genera listed include the genera illustrated in this chapter

Division	*Bacillariophyta*	Descriptions and subgroups	Examples of taxa
Subdivision Subdivision Coscinodiscophytina: monophyletic in Medlin and Kaczmarska (200$) (and then comprising the single class Coscinodiscophyceae), paraphyletic in Theriot et al. (2015). Contains several clades of radial centric diatoms whose interrelationships are unclear. Valves generally circular; pattern-center an annulus; sexual reproduction via oogamy; auxospores with scales only	leptocylindrids	Chain-forming, delicate; valves circular, striae radiating from a central circular annulus; unique simple process present near the annulus; girdle bands segmental; auxospore forming a dormant resting stage (not present in other centric clades)	*Leptocylindrus*, *Tenuicylindrus*
	corethrids	Solitary; valves circular; radially symmetrical; articulating spines secreted from around the valve margin; rimoportulae absent; girdle bands segmental	*Corethron*
	melosirids	Usually chain-forming, sometimes forming special "separation valves"; valves circular, radially symmetrical; rimoportulae small, scattered on the valve face or marginal; girdle bands hooplike or segmental	*Aulacoseira*, *Melosira*, *Podosira*, *Stephanopyxis*
	ellerbeckiids	= "paralids" of Mann in Adl et al. (2005): Chain-forming, heavily silicified; valves circular, radially symmetrical; small tube processes present, restricted to the mantle; girdle bands hooplike	*Ellerbeckia*
	arachnoidiscids	Solitary, heterovalvar; valves circular, radially symmetrical; one valve with its center surrounded by radial slits (apparently modified rimoportulae); girdle bands hooplike	*Arachnoidiscus*
	coscinodiscids	Solitary, isovalvar; valves usually circular, striae radiating from a central, subcentral, or submarginal circular annulus; rimoportulae central, scattered on the valve face or marginal; girdle bands hooplike	*Actinocyclus*, *Actinoptychus*, *Coscinodiscus*, *Stellarima*, and many others
	rhizosolenids	Chain-forming, with a long perivalvar axis, rarely solitary; valves circular, almost radially symmetrical or with the pattern-center displaced towards one side; rimoportula single, associated closely with the annulus, sometimes developed into a spine; girdle bands segmental	*Guinardia*, *Rhizosolenia*
	proboscids	Usually solitary, with a long pervalvar axis; valves circular, extended into an eccentric beak (proboscis); rimoportulae and other processes absent; girdle bands segmental	*Proboscia*

(*continued*)

Table 1 (continued)

Division	*Bacillariophyta*	Descriptions and subgroups			Examples of taxa
	Subdivision Bacillariophytina	Valves usually elongate or structurally bipolar or multipolar, as a result of anisometric expansion of the auxospore, constrained by a perizonium (not present and likely secondarily lost in Thalassiosirales)			
		Class Mediophyceae (possibly paraphyletic with respect to the Bacillariophyceae)	Pattern-center an annulus (which is sometimes elongate rather than circular); valve outline and structure highly varied, mostly bi- or multipolar; sexual reproduction via oogamy		Thalassiosirales, Cymatosirales, Lithodesmiales, Chaetocerotales, Biddulphiales, *Attheya* and others; includes *Amphitetras*, *Cyclotella*, *Cymatosira*, *Hydrosera*, *Mediopyxis*, *Odontella*, *Pleurosira*, *Skeletonema*, *Stephanodiscus*, *Thalassiosira*, *Triceratium*
		Class Bacillariophyceae (pennate diatoms)	Pattern-center a sternum; sexual reproduction via morphological isogamy, rarely anisogamy		
			Subclass Urneidophycidae	Nonmolecular characters as for Bacillariophyceae	*Asterionellopsis*, *Delphineis*, *Plagiogramma*, *Rhaphoneis*, *Talaroneis*
			Subclass Fragilariophycidae (core araphids)	Nonmolecular characters as for Bacillariophyceae	*Asterionella*, *Diatoma*, *Fragilaria*, *Grammatophora*, *Martyana*, *Rhabdonema*, *Tabellaria*
			Subclass Bacillariophycidae (raphids)	Possession of a raphe system	*Achnanthes*, *Berkeleya*, *Caloneis*, *Cocconeis*, *Cymatopleura*, *Diploneis*, *Donkinia*, *Entomoneis*, *Epithemia*, *Eunotia*, *Fallacia*, *Gomphonema*, *Gyrosigma* *Hantzschia*, *Hippodonta*, *Lyrella*, *Navicula*, *Neidium*, *Nitzschia*, *Placoneis*, *Psammodictyon*, *Sellaphora*, and many others

1990, readers should refer to the atlas of genera by Round et al. (1990), although many further genera have been described since that book was written.

A complementary approach, in which molecular phylogenies are used to test explicit hypotheses concerning the evolution of specified traits, has recently been applied and has provided insights into variation and changes in salinity preference (Alverson et al. 2007), cell size (Nakov et al. 2014), growth form (Nakov et al. 2015), and reproductive behavior (Mann et al. 2013; Poulíčková et al. 2015).

At the species level, studies of reproductive isolation and fast-evolving genes indicate that the diatoms are even more speciose than was already known. Common freshwater and marine diatoms have proved to be complexes of several or many species that are difficult or impossible to identify reliably using the light microscope (e.g., Sarno et al. 2005; Amato et al. 2007; Evans et al. 2008; Souffreau et al. 2013; Vanormelingen et al. 2013). It is likely that many other "species" are likewise composite, with potentially adverse consequences for ecological studies, biomonitoring, biogeography, and other sciences dependent on consistent and accurate identification. To help obviate difficulties, DNA barcoding is being developed (e.g., Mann et al. 2010; Zimmermann et al. 2011).

Maintenance and Cultivation

Enrichment and Isolation from Nature

Diatoms are relatively easy to culture in mixed populations simply by enriching natural water with nutrient solutions or transferring subsamples to artificial media (see below). It is convenient to do this in Petri dishes, which can then be observed directly at low magnification with a stereo-microscope or inverted microscope to check for growth. It should always be remembered that diatoms require dissolved silicate for growth and this is usually added to media, although it is sometimes assumed that supply will be adequate if soft-glass dishes are used. Light may be natural or artificial and alternating light/dark cycles or silicon-starvation can be used to achieve a degree of synchrony (e.g., Darley and Volcani 1971). Temperature should be adjusted by experimentation; most diatoms grow over a wide range but some, e.g., ice diatoms, can have a very narrow range.

To isolate clones, individual cells or colonies can be picked out from mixed cultures or natural samples with a micropipette, washed in sterile medium, and transferred to new sterile media. Alternatively, natural samples can be spread on agar plates, using normal microbiological technique. If the plates have been previously dried for a short time in an oven at 30 °C or in a flow hood, the liquid of the sample will quickly be absorbed and the individual cells will be trapped on the agar surface, where they can either be picked off immediately using a micropipette or allowed to grow into colonies. If the latter approach is taken, discrete colonies can be removed after a few days or weeks by cutting out agar blocks, each with a colony originating from a single cell, or subsampled using a micropipette and transferred to clean agar or liquid media. Clones may survive for months or years (especially if the growth rate is reduced by use of low

light and temperature), but as previously noted, many cannot be kept indefinitely because of size reduction and a mating system that enforces outbreeding. Thus clonal cultures may not always be ideal for maintaining diatoms in culture and unialgal cultures may be more suitable for long-term survival. It should be remembered in any case that meiosis and recombination are likely to occur in clones of homothallic and automictic diatoms maintained for months or years in culture and that consequently cells should be reisolated before critical experimental work is undertaken.

Axenic Cultures

The usual mixtures of antibiotics (e.g., of streptomycin, ampicillin, or penicillin) can be added to cultures to suppress bacteria and, through repeated transfer, produce axenic cultures (Andersen 2005).

Culture Media

Growth media suitable for freshwater and marine diatoms and other algae are given in the handbook edited by Andersen (2005). Relatively high quantities of silicate are of importance for culturing diatoms, but otherwise no special requirements are necessary for routine culture. Apart from vitamins, no organic additives to media are generally needed, except of course for the few obligate heterotrophs. However, some diatoms have so far remained recalcitrant ("unculturable"), particularly large-celled species from marine intertidal sandflats (e.g., Droop et al., 2000).

For freshwater diatoms, we frequently use WC medium, which was developed originally by Guillard and Lorenzen (1972). This contains:

36.76 mg	$CaCl_2.2H_2O$
8.71 mg	K_2HPO_4
36.9 mg	$MgSO_4.\ 7H_2O$
28.42 mg	$Na_2SiO_3.\ 9H_2O$
12.6 mg	$NaHCO_3$
85.01 mg	$NaNO_3$

Micronutrients:

3.15 mg	$FeCl_3.\ 6H_2O$
0.18 mg	$MnCl_2.4H_2O$
0.01 mg	$CuSO_4.5H_2O$
0.022 mg	$ZnSO_4.7H_2O$
0.01 mg	$CoCl_2.6H_2O$
0.006 mg	$Na_2MoO4.2H_2O$
1.0 mg	HBO_3
4.36 mg	Na EDTA

Vitamins:

0.1 mg	Thiamine.HCl
0.5 µg	Biotin
0.5 µg	Vitamin B12

Make up to 1 l with deionized water. Alternatively, stock solutions can be made at 1000× concentration and added at 1 mL L^{-1}. The vitamins should be added after autoclaving. WC is a fairly nutrient-rich medium, usually adjusted to around pH 7 (with drops of HCl). Diatoms from acid oligotrophic waters may be better grown in a modified GG medium (von Stosch and Fecher 1979).

For marine diatoms, we have found Roshchin medium (Roshchin 1994) to be effective: dissolve 202 mg KNO_3, 17.9 mg $Na_2HPO_4.12H_2O$, 1.2 mg $Na_2S_2O_3.5H_2O$, and 10 mg Na_2SiO_3. $9H_2O$ in 1 L filtered seawater; trace elements and vitamins can be added as for WC medium. Again, stock solutions can be made at 1000× strength. The medium is sterilized by pasteurization or filtration, since autoclaving leads to precipitation of some components. Alternatively the well-known series of "f" media can be used, in particular f/2 medium (Andersen 2005). If fully defined marine media are required, an artificial seawater mix can be used instead of natural seawater.

Evolutionary History and Biogeography

Fossil Record

The fossil record of diatoms has been briefly summarized by Sims et al. (2006) and Harwood et al. (2007). The earliest generally accepted records of diatoms are of "*Pyxidicula*" species, from the late Early Jurassic of Germany (Toarcian; c. 190 Mya) (Rothpletz 1900). However, the original source of the material is unknown. Rothpletz boiled a fossil sponge in HCl (hence the original specimen was destroyed), and the resultant siliceous residue (diatoms) was mounted and sectioned (Medlin 2015, 2016a). The earliest diverse, well-preserved diatom assemblages studied in modern times are from the Early Cretaceous, especially a deposit from the Weddell Sea (Gersonde and Harwood 1990; Harwood and Gersonde 1990). Paleozoic records have been reported but are now discounted as contamination. The absence of diatoms from Paleozoic or PreCambrian deposits has sometimes been ascribed (e.g., Round 1981b) to conversion of the diatomaceous silica to porcelanite and later to chert (a process described by Calvert 1977). However, although many diatom deposits have undoubtedly been lost through diagenesis, the order of appearance of major diatom groups in the fossil record agrees reasonably well with molecular phylogenies (Sims et al. 2006; Kooistra et al. 2007) and tentative dating of molecular trees suggests that the fossil record, though imperfect, does not hugely underestimate the origin of the diatoms: a Mesozoic or latest Paleozoic (late Permian) origin is the most likely (Kooistra

and Medlin 1996; Sorhannus 2007; Medlin 2011, 2015, 2016a). The date of origin of the pennates, however, is particularly controversial (Medlin and Desdevises 2016). In the Tertiary, an extensive fossil record has been preserved and is used for stratigraphic correlation and for calibrating the molecular clock in phylogenetic studies.

Nevertheless, although the fossil record is more reliable than some have thought, dissolution and fragmentation of the more delicate species certainly does occur and results in a modified picture of the natural assemblages that originally existed. For example, biochemical markers indicate that the microfossil record of *Rhizosolenia* and related genera (whose frustules are composed largely of girdle bands) underestimates their age (Sinninghe Damsté et al. 2004), and the blanket bogs of boreal regions often contain a rich diatom flora of strongly silicified acidophilic species whereas a few centimeters down in the peat there are often no diatom remains, presumably because of dissolution. Further sources of serious bias for evolutionary studies is the greater likelihood that planktonic species will become fossilized, because of their much greater initial abundance and distribution, relative to benthic species, and the lack of suitable depositional environments for marine littoral species. The Eocene diatomites at Oamaru in New Zealand are an important exception, preserving a highly diverse assemblage of well-preserved near-shore marine diatoms (Edwards 1991). On land, the short life of most lakes and destruction of deposits by glacial and other erosion lead to a surprisingly poor fossil record for freshwater diatoms, though there are some remarkable exceptions (e.g., the Eocene Giraffe Pipe deposits in NW Canada: Siver et al. 2010). Preservation of internal structure is extremely rare, but diatoms with cell content have been discovered in late Cretaceous cherts in Mexico (Beraldi et al. 2015).

Freshwater and terrestrial diatoms are usually considered to occur somewhat later in the geological sequence than marine ones, but some recently discovered Early Cretaceous deposits in Korea may be of terrestrial origin (Harwood et al. 2007). Multiple invasions into freshwaters have been documented using molecular phylogenies (Sims et al. 2006), and some have been demonstrated to occur in the reverse direction (Alverson et al. 2007). Molecular clock methods have been used to date invasion times in the Thalassiosirales (Alverson 2014). Recently, diatoms have been found preserved in amber (Girard et al. 2009).

The fossil record is still underused as a source of information for phylogenetic reconstruction and systematics at the generic and species level. Increasingly, however, the fossil record is being used in conjunction with neontological analysis and molecular phylogenies to estimate the tempo of evolution in particular diatom genera or families (e.g., Souffreau et al. 2011). In a few cases, it has been possible to use fossil material to detect anagenetic changes within what appears to be a single lineage, such as the evolution of *Stephanodiscus yellowstonensis* from *S. niagarae*-like ancestors in Yellowstone Lake, Wyoming (Theriot et al. 2006). For some marine planktonic groups impressive fossil records are available,

documenting morphological evolution over many millions of years (e.g., Yanagisawa and Akiba 1990).

Biogeography

During most of the twentieth-century species, species concepts and delimitation in diatoms – and consequently data on species distributions – were based almost entirely on the morphology of the valve as seen with the light microscope. Latterly, details observable with EM have gained importance and this, coupled with insights from mating experiments and (still more recently) molecular sequence data, has been accompanied by an explosion in the descriptions of new species. There has certainly also been a trend towards narrower species definitions – a coarse-grained taxonomy has been replaced by a much finer one (Mann 1999b). Furthermore, whereas it was always accepted (e.g., Hustedt 1942) that some diatoms appeared to be restricted to particular regions because of dispersal constraints, as opposed to ecological restrictions, a much greater proportion of new species are now being claimed to be endemic to particular small regions or lakes.

It is doubtful whether many of the claims of endemism are justified, given the difficulties and inconsistencies in identifying diatoms (partly because there are so few critical revisions of any diatom genera [Kociolek and Williams 2015] and partly because of problems in accessing all the relevant literature), the rather limited sampling of many parts of the world (especially in Africa, S America, and SE Asia, and more generally in the tropical zone both in the sea and on land), and the very real problem of how to detect microeukaryote species when they are rare (i.e., occurring at frequencies of less than, say, 1 in 10^6). Likewise, claims that particular species have been introduced (e.g., Coste and Ector 2000) also need to be treated with caution (e.g., Gómez and Souissi 2010). Some diatoms do seem to be restricted to particular regions by geographical barriers, rather than the availability of suitable habitats: examples are discussed by Vanormelingen et al. (2008) and include the unmistakable genus *Eunophora*, apparently restricted now to temperate Australasia. There is also clear evidence for isolation by distance between populations of some heterothallic species, even on scales of a few tens or hundreds of kilometers (Vanormelingen et al. 2015). On the other hand, there are also examples, confirmed by barcode and/or mating data, of species and haplotypes with extremely wide distributions (e.g., Evans et al. 2009; Rimet et al. 2014), and geographical pattern disappears very quickly as one ascends the taxonomic hierarchy from species to genera, implying rather rapid spread of diatom lineages, relative to higher plants and vertebrates. On the other hand, there is also evidence of range contractions. For example, the genus *Arachnoidiscus* was formerly present in Europe (e.g., in the Miocene: Hajós 1986), but is now extinct there, the nearest populations being in the Indian Ocean.

Origin of the Diatoms

There is still a huge gap in our understanding of how and when diatoms acquired their unique morphology and life-cycle characteristics. Originally, the diatoms were kept as a quite separate group, allied to various algal/animal groups. Pascher (1914, 1921) seems to have been the first to suggest that the diatoms have features in common with the Chrysophyceae and Xanthophyceae. To reflect this, he placed all three groups together in the phylum Chrysophyta. Ultrastructural and molecular sequence data have confirmed the general thrust of Pascher's idea, placing the diatoms unambiguously among the heterokont protists ("stramenopiles") within the chromalveolates (e.g., Andersen 2004; this position is recognized in the overall classification of protists by Adl et al. 2005). However, a close relationship to silica scale-producing algae, such as the Chrysophyceae, is not likely according to molecular and ultrastructural evidence (e.g., Derelle et al. 2016). At present, molecular phylogenies indicate that the closest known relatives of the diatoms are the Bolidophyceae and Parmales, which are small groups of marine autotrophic picoplankton with the same kind of four-membrane-bound plastids as diatoms and other autotrophic heterokonts (Guillou et al. 1999; Ichinomiya et al. 2011). The relationship with the Parmales was earlier predicted by Mann and Marchant (1989), because Parmales produce silica scales that, in their pattern and apparently space-filling ontogeny, resemble diatom valves and girdle bands. In particular, the round plates produced by Parmales often possess ring structures (annuli) at their centers (Booth and Marchant 1987), like centric diatom valves (Round and Crawford 1981). However, although Parmales scales seem to develop centrifugally from an annulus, as in diatoms, the two groups differ significantly in their morphogenesis, because Parmales plates develop within the cell (Yamada et al. 2016), whereas diatom valves and girdle bands are always formed peripherally in association with the cell membrane; and also in the control of silicification, because cell growth and division are not prevented by silicon depletion in Parmales (Yamada et al. 2014), whereas in diatoms they are.

There is therefore some support for the suggestions of Round and Crawford (1981, 1984) and Mann and Marchant (1989) that the diatom frustule originated as a ***scale-case***. Both sets of authors postulate that diatoms evolved from cells bearing uniform scales, via an early stage where scales were differentiated into larger valve-like scales and narrower ones resembling the segmental girdle bands of modern rhizosolenids (cf. the differentiation of round shield plates and triradiate girdle and dorsal plates in Parmales), and a later stage when the proto-girdle bands became thinner and stretched to form hoops encircling the cell. This assumes that valves and girdle bands have a common origin and indeed their fine structure is often so similar that this is a reasonable assumption, and it seems that girdle bands are also formed centrifugally, like valves (e.g., Sato 2010). Furthermore, cells covered evenly with scales are known in diatoms, in the auxospores of some centric species, e.g., of *Melosira* and *Ellerbeckia* (Crawford 1974b; Schmid and Crawford 2001) and in several pennates (e.g., Mann et al. 2013). The Round–Crawford and Mann–Marchant schemes differ principally in the assumptions made about the nature of the scales and scaly cell in the early ("Ur") diatoms. In the Mann–Marchant scheme, the scales

of the ancestral diatom are abutting space-filling components of a cyst wall, whereas Round and Crawford envisaged the scales as discrete imbricating elements covering growing vegetative cells, as in modern synurophytes. In a series of opinion papers, Medlin (e.g., 2007) has suggested that that silica may originally have had the property in diatoms of inducing a temporary resting state, which is consistent with the "Ur" diatom being a cyst.

No precursors of diatoms are known from the fossil record. Though it now seems clear that the Bolidophyceae–Parmales are their nearest relatives, the diatoms are an extremely well-characterized, distinctive, and monophyletic group, and it is nomenclaturally convenient to regard them as a separate phylum, which allows maintenance and gradual refinement of the lower-level classification of diatoms developed during the twentieth century.

Acknowledgments The authors are most grateful to Prof. Linda Medlin for comments on the manuscript, Prof. Masahiko Idei for micrographs of sexual stages and auxospores, and Drs. Shinya Sato and Laia Rovira for SEM images of auxospores.

Abstract

Brown algae (Phaeophyceae) are benthic macroalgae constituting a primary element of coastal ecosystems in temperate and cold water seas and are also economically important. Currently ca. 2,000 species in ca. 300 genera are recognized. They are mostly marine and only a few genera are known in freshwater habitats. They are photosynthetic organisms, sharing chloroplasts originated from secondary endosymbiotic events with photosynthetic heterokonts (chromists, stramenopiles) and surrounded by four layers of membranes. Major photosynthetic pigments are chlorophylls *a* and *c* and fucoxanthin and produce laminaran as the storage polysaccharide. All known species are multicellular, with cell walls composed of alginates, fucoidan (fucan), and cellulose, and traversed by plasmodesmata. Basal taxa generally show isomorphic life history and apical growth. Derived taxa have evolved heteromorphic life histories and modified life history patterns, some with only a diploid generation (thallus), as well as diverse growth patterns such as diffuse and intercalary growth. They commonly reproduce by asexual heterokont zoospores, or zygotes formed by fusion of motile or nonmotile female gametes with heterokont male gametes.

Keywords

Algal bed • Alginate • Brown algae • *Ectocarpus* • Fucoidan • Fucoxanthin • Heterokont • Heterokonta • Kelp • Life history • Multicellular alga • Ochrophyta • Phaeophyceae • Secondary endosymbiosis • Stramenopile • Tripartite tubular mastigoneme

Introduction

General Characteristics

Brown algae (Phaeophyceae, Heterokonta/Ochrophyta) are multicellular organisms that vary in size from microscopic branched filaments less than a millimeter in diameter to large macroscopic fleshy thalli that may attain lengths in excess of 50 m (Bold and Wynne 1985; van Den Hoek et al. 1995; Graham and Wilcox 2000). They are essential elements of coastal ecosystems, often forming dense algal beds comparable to the forests in terrestrial ecosystems (Dayton 1985). They commonly reproduce by asexual heterokont zoospores, or zygotes formed by fusion of motile or nonmotile female gametes with heterokont male gametes. They are photosynthetic organisms, with chloroplasts originated from a secondary endosymbiotic event in a common ancestor shared with photosynthetic heterokonts and surrounded by four membranes (Fig. 1). All known species are multicellular, with cell walls composed of alginates, fucoidan (fucan) and cellulose, and traversed by plasmodesmata (cytoplasmic continuity retained through cell division) (Figs. 2 and 3) (Terauchi et al. 2012, 2015).

Brown algae comprise approximately 2,000 species in around 300 genera (AlgaeBASE: http://www.algaebase.org/). Genera such as *Cystoseira, Dictyota, Ectocarpus, Sargassum*, and *Sphacelaria* include large numbers of species, which present considerable taxonomic difficulty and are in need of critical review (Stache-Crain et al. 1997; Peters et al. 2010; Ni-Ni-Win et al. 2010; 2011a, b;

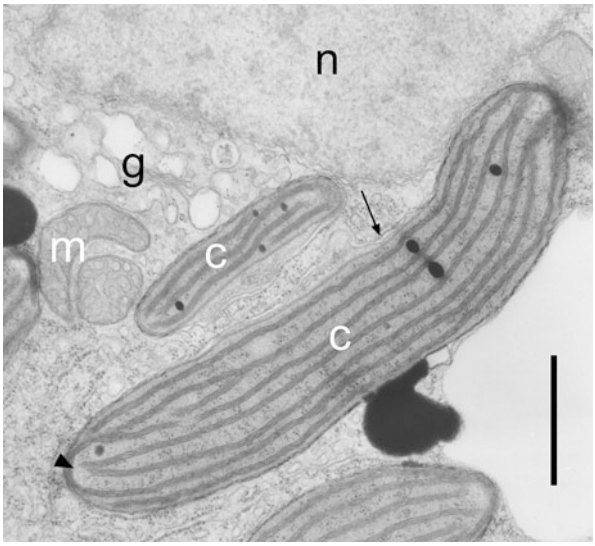

Fig. 1 Brown algal chloroplasts (*c*) of *Saccharina* sp. with four surrounding membranes. The outermost chloroplast membrane with attached ribosomes is shown by an *arrow*. The chloroplast has girdle lamella, and ring-shaped DNA within the girdle lamella (*arrowhead*). *g* Golgi body, *m* mitochondrion, *n* nucleus. Scale bar, 1 μm (TEM micrograph courtesy of Taizo Motomura)

Tronholm et al. 2010; Silberfeld et al. 2014a). Furthermore, a number of cryptic species have been discovered in the course of taxonomic re-examinations employing molecular phylogenetic analyses. The life histories of brown algae are varied. Most involve meiosis and fertilization, with an alternation of haploid and diploid phases. The haploid gametophyte generation often exhibits varying degrees of morphological reduction. In some taxa, the reduced generation has become cryptic so that they superficially lack alternation of generations.

Morphology varies greatly among brown algae. Some of the smaller species form inconspicuous filamentous tufts and cushions or grow as crusts in close contact with the substrate. Larger forms include a variety of simple and branched thalli with differentiation into foliose blade, stem-like stipe, and basal holdfast. Some thalli are exceedingly mucilaginous. The larger fleshy species include the intertidal and upper subtidal seaweeds known as wracks and kelps.

Occurrence

Brown algae are almost exclusively marine organisms that inhabit the intertidal and subtidal zones of coastal regions throughout the world. They grow to varying depths depending on the availability of light and substrates. Only a few species grow in estuarine and freshwater habitats. Most of the freshwater taxa are considered to be relatively recent descendants of marine taxa and are scattered among diverse phylogenetic groups, although the taxonomic positions of some taxa need reexamination (McCauley and Wehr 2007).

Freeze substitution TEM micrograph (Courtesy of Chikako Nagasato). (**b**, **c**) TEM micrograph by chemical fixation showing the early stages of cell wall formation and plasmodesmata (arrows) in *Chorda* meristematic cells

Most brown algae grow attached to a great variety of surfaces including rock, concrete, metal, and wood structures, as well as the surfaces of other organisms such as other macroalgae or shells. A few species that grow on macroalgae and sea-grasses penetrate the tissues of their living hosts (Kawai and Tokuyama 1995; Burkhardt and Peters 1998; Garbary et al. 1999), sometimes exhibiting a semiparasitic habit (Peters 1989). Some brown algae grow free-floating in sheltered habitats such as bays and estuaries. In the Sargasso Sea in the middle North Atlantic Ocean, a large biomass of floating *Sargassum* species propagates only vegetatively.

Many brown algae are easily collected from their natural habitats and can be grown and maintained in culture. Some taxa (e.g., *Cladosiphon, Laminaria, Saccharina, Sargassum, Undaria*) are grown on a large scale in the field (mariculture) and used for food and industrial materials. Numerous culture strains available for research purposes are deposited in several culture collections: KU-MACC (Kobe University Research Center for Inland Seas, Japan), NCMA (National Center for Marine Algae and Microbiota, USA), SAG (Sammlung von Algenkulturen der Universiät Göttingen, Germany), and UTEX (The Culture Collection of Algae,

University of Texas at Austin, USA). Most of the available strains are unialgal, and some are axenic. Some strains are cryopreserved in the culture collections (Heesch et al. 2012).

Literature and History of Knowledge

Papers concerning brown algae appear in a range of botanical and marine biological journals, including the specialist algal journals *Phycologia, Journal of Phycology*, *European Journal of Phycology*, *Phycological Research*, *Algae, Cryptogamie Algologie*, *Journal of Applied Phycology*, and *Botanica Marina.* Pioneering studies on the morphology and development of a wide range of brown algae were described in the publications of Kylin (1933), Kuckuck (1929, 1964), and Sauvageau (1929, 1931, 1933); Fritsch (1945) comprehensively reviewed the literature before 1945. Brown algae are also discussed in comprehensive phycology textbooks in English (Wynne 1981; Bold and Wynne 1985; South and Whittick 1987; van den Hoek et al. 1995; Graham and Wilcox 2000; Lee 2008; Reviers et al. 2015). Life histories of the brown algae have been reviewed by Wynne and Loiseaux (1976), Pedersen (1981), Peters (1987), and Hori (1993). Ecological and physiological studies of brown algae were reviewed by Lobban and Harrison (1994). Entire genome sequences of brown algae were first reported in the model species *Ectocarpus siliculosus* (Cock et al. 2010), followed by the kelp species *Saccharina japonica* (Ye et al. 2015), and diverse information on their genomes has become available.

Traditionally the classification schemes devised by Kylin (1933), Papenfuss (1955), and Wynne and Loiseaux (1976) have been widely accepted, but the basic concept of the fundamental importance of life history patterns and thallus constructions has been challenged by recent biological studies (e.g., life histories, sexual pheromones), and have been considerably revised based on molecular analyses, mostly using ribosomal DNA and RuBisCO gene sequences (Tan and Druehl 1996; Siemer et al. 1998; Reviers and Rousseau 1999; Draisma et al. 2001; Sasaki et al. 2001; Cho et al. 2004; Kawai et al. 2007; Lim et al. 2007; Draisma et al. 2010). More recently, molecular phylogenetic studies using multiple gene data sets have elucidated the general phylogenetic relationships among orders (Phillips et al. 2008; Silberfeld et al. 2010, 2011, 2014b; Kawai et al. 2015a). Information on taxonomic names is available at AlgaeBASE (http://www.algaebase.org/) and Index Nominum Algarum (http://ucjeps.berkeley.edu/INA.html).

Brown marine algae were recognized by European phycologists as a distinct group of organisms in the early nineteenth century. Detailed studies of their structure and reproduction, along with the first attempt at cultivation, began to appear in the latter half of the century. Some of the more notable works include that of Thuret, who made the first microscopical observations of fertilization in algae using the eggs and flagellated sperm of *Fucus* (Thuret 1854). Improved microscopical and histochemical techniques have made possible critical investigations of brown algal anatomy (Gantt 1980). Alternation between macroscopic sporophyte and microscopic gametophytes in the life histories of kelps was first reported by Sauvageau (1915), who

also made the first culture studies of many other brown algae. The culturing of brown algae was greatly advanced by development of growth media by Shreiber (1927) and Provasoli (Tatewaki 1966; Provasoli 1968; Starr 1978). Culturing techniques of brown algae are reviewed in Kawai et al. (2005b; for details see below).

Practical Importance

Species of Laminariales with foliose thalli (3–4 families) and Fucales (*Ascophyllum* and *Durvillaea*) are utilized commercially as sources of alginates, the salts of alginic acid, a major component of brown algal cell walls. Alginates, polysaccharide compounds composed of mannuronic and guluronic acid subunits, can form highly viscous solutions and readily form gels (Percival and McDowell 1967). Alginates are used widely in the manufacture of products including foods, cattle and poultry feeds, adhesives, dyes, and explosives (Chapman and Chapman 1980). Species harvested for alginate extraction include *Ascophyllum nodosum, Durvillaea potatorum, Eisenia bicyclis, Ecklonia cava, Macrocystis pyrifera, Laminaria* spp., and *Saccharina* spp.

Brown algae are a particularly valuable natural source of vitamins and minerals, notably iodine (Critchley and Ohno 1998). The larger species of brown algae are utilized as fertilizers and growth promoters by coastal agricultural communities. Extracts of some, for example, *Ascophyllum nodosum,* are manufactured and sold widely for use in agriculture and horticulture (Chapman and Chapman 1980). Fucoidan (one of the sulfated polysaccharides in brown algae) extracted from some taxa (*Cladosiphon, Laminaria*, *Undaria*) are used as a functional food. A number of species, primarily belonging to Laminariales (*Ecklonia*, *Laminaria, Saccarhina, Undaria,* etc.), are widely cultivated and used as food in Japan, Korea, and China.

Habitats and Ecology

Geographical Distribution

Studies of the biogeography of benthic marine algae (e.g., van den Hoek 1975; Lawson 1978; South 1975; Santelices 1980; Womersley 1981; Lüning 1990) include information on the distribution of brown algal species. Brown algae dominate many benthic marine biotas. The characteristics of the marine biotas of four types of region – polar, cold temperate, warm temperate, and subtropical/tropical – have been outlined by Womersley (1981). The polar regions, which possess more limited algal biotas, include some distinctive taxa, for example, the Antarctic *Himantothallus* in the Demarestiales, *Ascoseira,* and the Arctic species of *Laminaria*, *Saccharina*, *Saccorhiza* and *Chorda*. A high species diversity is found among the marine algal biotas of cold temperate regions. Fucales (e.g., *Ascophyllum*, *Fucus* spp., *Hormosira banksii*) dominate the intertidal zone of rocky shores and the kelps

form dense communities in the subtidal and lower intertidal zones. The coastal regions of the world with the greatest numbers of species and genera of brown algae include Japan, Pacific North America, Southern Australia, and Britain, all regions of temperate climate with a significant cold temperate component. Large kelps are absent on tropical coasts and are not conspicuous in warm temperate regions. The Dictyotales and *Sargassum* spp. (Fucales) are the common brown algae of tropical and subtropical regions (Womersley 1981; Silva et al. 1996; Silberfeld et al. 2014a).

Temperature and salinity strongly affect horizontal distributions of species of benthic marine algae (Druehl 1981). Experimentally determined lethal or growth- and reproduction-limiting temperatures correlate with phytogeographic boundaries of several species of marine benthic algae, including some phaeophycean taxa (van den Hoek 1982).

Measuring Seaweed Vegetation

Methods have been developed for describing and analyzing the composition, distribution, and structure of local communities of benthic marine algae (Russell and Fielding 1981). Protocols for long-term monitoring of seaweed communities are described by Kautsky and Maarel (1990), Kautsky (1993), Shirayama et al. (2002), and Kawai and Henry (2007).

Environmental gradients and the physiological tolerance limits of species have been studied with the goal of understanding zonation, the vertical banding of seaweed communities. Biotic interactions between different algal species and intertidal animals are significant in determining the vertical limits of seaweed distribution (Chapman 1974; Russell and Fielding 1981).

Kelp Ecosystems

Large brown algae called kelps are either Ascoseirales (*Ascoseira*), Desmarestiales (*Himantothallus*), Fucales (*Durvillaea*), Laminariales (*Alaria*, *Chorda*, *Ecklonia, Eualaria*, *Macrocystis, Laminaria, Nereocystis, Saccharina*), or Tilopteridales (*Sacchorhiza, Phyllariopsis*) and dominate the kelp communities of the world. *Chorda* is dominant on sheltered coasts in Arctic regions. Kelp communities dominated by *Alaria*, *Laminaria,* and *Saccharina* occur in the northern Atlantic and on the coasts of China and Japan, whereas *Macrocystis*-dominated communities are found along the Pacific coast of North America and the temperate Atlantic and Pacific coasts of South America and New Zealand (Lüning and tom Dieck 1990; Santelices et al. 1980). *Ecklonia*-dominated kelp communities are found in Australasia and South Africa (Mann 1982). *Durvillaea* and *Lessonia* kelp beds occur in the circumpolar cold temperate regions of Australasia, South America, and around the

subantarctic islands (Hay 1979). *Ascoseira* and *Himantothallus* are primary elements of Antarctic regions.

Kelp species have very high levels of productivity, on the order of 1,000 g of carbon per square meter annually (Mann 1982). Growth in many species is seasonal (*Macrocystis pyrifera* is an exception) with the highest rates in winter and early spring (Chapman 1974; Kain 1979). Several methods have been used to describe and measure the growth and productivity of kelp species (Kain 1979, 1982), including measurements of standing crop, morphological parameters (including the use of punched holes), chemical components such as alginic acid (cell walls), fucoidan, laminaran, and mannitol (food reserves) (Hellebust and Craigie 1978), and in situ measurements of the rate of photosynthesis (Kremer 1978). In *Laminaria* spp., reserves are built up during the summer when levels of radiant energy are high and are used up during the winter growth phase (Chapman 1974). Many so-called kelps growing seasonally from holdfasts are perennials. Some, like *Laminaria saccharina,* have life spans of less than 3 years (Kain 1979), whereas others (*Durvillaea*) may live for 7 or more years. Thalli of *Laminaria hyperborea* up to 15 years old have been recorded (Kain 1979). Sea urchins are often the most important herbivores in kelp communities. In many localities, they feed on detritus, drifting kelp, and ephemeral algae and cause little disturbance to the attached kelps. Along the northern Pacific coasts, the increase in sea urchin (*Strongylocentrotus* spp.) populations related to the decrease in populations of their major predator, the sea otter (Mann 1982), has led to considerable damage to the kelp beds.

Fucoid Communities

Fucales species are dominant in the rocky intertidal zone in many temperate regions of the world, whereas in the tropics they more commonly form subtidal communities. *Fucus* spp. and *Ascophyllum* abound on temperate shores in the northern hemisphere. In the southern hemisphere, subtidal fucoid communities are often better developed than the intertidal ones, e.g., in Australasia extensive dense stands of *Sargassum* and species in the Cystoseiraceae and Seirococcaceae. *Durvillaea* belongs to Fucales, but is treated as kelp in this chapter (see above).

Fucoids are highly productive, but stresses in the intertidal environment may cause them to exude a considerable amount of soluble organic matter that is rapidly taken up by bacteria (Mann 1982) so that in contrast to kelps, a significant proportion of fucoid productivity is not realized as algal biomass. Intertidal northern hemisphere fucoids grow predominantly during the summer and to a limited extent accumulate storage carbohydrates that permit survival during the winter, when levels of radiant energy and the rate of photosynthesis are very low (Chapman 1974). Sea urchins, starfish, limpets, chitons, littorinid snails, and fish influence the structure of intertidal fucoid communities by grazing, affecting the species composition and biomass (Mann 1982).

Effects of Environmental Factors on Growth and Reproduction

Brown algae are notorious for their morphological plasticity in response to the environment. Thallus form changes in response to variation in such factors as irradiance, water movement, temperature, and salinity. The more dramatic effects occur in the larger species. Kelp species growing on high wave-energy coasts tend to have highly digitate fronds, whereas in calmer water the laminae are more likely to be entire. Unattached fucoids (e.g., *Ascophyllum, Fucus,* and *Hormosira*) in extremely sheltered localities tend to develop a number of distinctive characteristics. Holdfasts are lacking, branching is more profuse, reproduction is often by means of fragmentation, and sexual reproduction is inhibited (Norton et al. 1981).

Changes from the asexual to sexual modes of reproduction are environmentally elicited. Seasonal changes in light quality, irradiance, and temperature have been shown to regulate the fertility of kelp gametophytes. In many species, low temperatures (e.g., 5 °C) and a certain quantum dose of blue light are required to induce gametogenesis, which in nature occurs in winter and spring (Lüning 1981). In *Scytosiphon,* a member of the Scytosiphonaceae, a photoperiodic response controls the transition between the two phases (blades and crusts) of the heteromorphic life history. Blades in laboratory culture develop in response to short days; in nature, blades develop in winter and spring, crusts in summer. Temperature affects reproduction in many species of brown algae. In *Ectocarpus siliculosus*, the development of unilocular (meiotic) sporangia on the sporophyte occurs only below 13 °C so that the gametophyte generation is initiated at lower temperatures. At higher temperatures, only asexual plurilocular sporangia are formed (Müller 1964). Species of brown algae from different orders (Ectocarpales, Sphacelariales, and Fucales) produce their gametes in winter or spring in temperate regions when seawater temperatures are low. Relatively little is known of the factors initiating the developmental sequence leading to gametogenesis in the gametophytes of most brown algae.

Trans-ocean Introductions: Some brown algal species have been introduced across the oceans by human activities intentionally (e.g., fisheries) or accidentally (e.g., associated with ship transportation) and have spread widely and become a considerable threat to local ecosystems. *Sargassum muticum* and *Undaria pinnatifida* were introduced from Asia to North America and Europe attached to young oysters, or as ship hull communities (Critchley and Dijkema 1984; Uwai et al. 2006; Russell et al. 2008). Another Asian-origin *Sargassum* species, *S. filicinum,* has recently spread on the North American Pacific coast (Miller et al. 2007).

Collection of Brown Algae: Brown algae are best collected in buckets and bags from the intertidal zone of the seashore when the tide is low, preferably during spring tides. They may be collected from subtidal habitats by snorkeling and SCUBA diving. Specimens from deep water may occasionally be found in storm drift, caught in fishing nets, or by dredging. Brown algae in the temperate and cold water regions should be kept moist and cool and processed as soon as possible after collection. Only the more tolerant intertidal species survive more than 2 or 3 days of temporary storage in a cold room or refrigerator (see below*).* Tropical and subtropical species are generally better kept at room temperature.

Specimens for herbaria must be prepared from healthy and, if possible, entire thalli. Most species can be preserved as dried herbarium specimens. Individual specimens are spread in a shallow dish of seawater, cleaned of sand, any epibionts, and, if very bushy, carefully pruned of some fronds so that the form can be seen clearly. The specimen is then floated and arranged over a sheet of mounting paper in a tray of clean water, and the paper is slowly tilted and removed from the tray, allowing the water to drain off and the seaweed to remain spread over the paper. Covered with a piece of cheesecloth or plastic nonwoven fabric and pressed between several sheets of newspaper, specimens are stacked and placed in a press. Newspaper must be changed frequently during the first day or two and then daily until the specimens are quite dry. Instead of changing newspapers for removing moisture of the specimens, the pressed specimens on mounting paper and covered with cheese cloth may be put between corrugated cardboard sheets, and the stack placed in a continuous air flow from a fan, so that the moisture is removed through the channels of the corrugated cardboard. Steady firm pressure is essential to obtain flat, unwarped sheets. Delicate soft algae adhere very firmly to the mounting paper and less firmly to the cheesecloth, which can be peeled off when drying is complete. Coarse, thick, or wiry algae do not adhere satisfactorily but can be attached to paper with glue or strips of gummed paper after they are dry. The collector's name, date, and site of collection, code number, and other data are recorded in pencil on each herbarium specimen before mounting. A permanent label is affixed later. Dried specimens, stored flat and away from light, will keep indefinitely and not lose their color.

To preserve specimens, the larger brown algae may be soaked in 50% glycerol, to which some phenol has been added to discourage the growth of microorganisms. The thalli will remain soft and flexible. Brown algae are commonly preserved in seawater-formalin at a concentration of 2–5%. For critical light and electron microscope studies, great care should be taken to select a suitable schedule for the fixation and preparation of the tissue. For this purpose, recent studies on related species should be consulted (see also references in Gantt 1980). For DNA extraction for molecular analyses, fresh specimens should be quickly dried in silica gel and kept desiccated, or frozen.

Some species (e.g., *Desmarestia* spp., *Dictyopteris* spp., *Spatoglossum* spp.) are remarkably delicate and apt to die and turn green when exposed to air or fresh water, revealing the strong acidity within their cell vacuoles when so damaged (Sasaki et al. 1999, 2004).

Characterization and Recognition

Definition of the Class

Brown algae are heterokont, multicellular algae with varying life cycles involving an alternation of haploid and diploid nuclear phases. In a large portion of the taxon, there is a corresponding alternation of independent haploid gametophyte and diploid sporophyte generations. Some orders tend toward an increase in size and morphological complexity of the sporophyte generation and reduction of the gametophyte

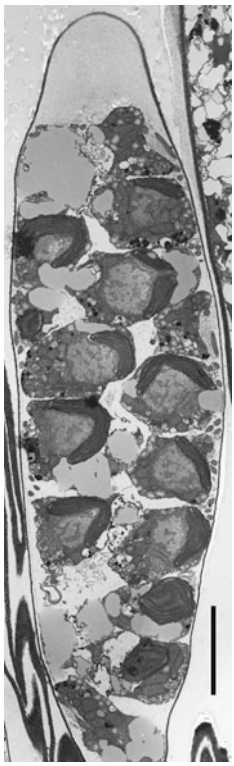

Fig. 4 Unilocular sporangia of *Saccharina japonica* in longitudinal section (TEM micrograph courtesy of Taizo Motomura). Scale bar, 5 μm

generation. Meiosis occurs in cells known as unilocular zoidangia (meiosporangia, Fig. 4) borne on sporophytic thalli, resulting in the formation of haploid spores (meiospores). These are, in most taxa, motile cells (zoospores) having two unequal flagella; they settle, germinate, and give rise to the gametophyte generation. The gametes are generally produced in plurilocular gametangia (Fig. 5) borne on gametophyte thalli. Fertilization varies from isogamous (gametes of different sex are the same size) to oogamous (gametes are nonmotile eggs and motile spermatozoids).

Sexual attractants (pheromones) are known to be involved in the sexual reproduction in brown algae. Attractants, mostly volatile hydrocarbons of low molecular weight (Müller 1981a; Maier and Müller 1986), which are secreted by female gametes to attract male gametes, have been isolated from several species and characterized chemically. In Laminariales, the sexual attractant also induces the release of sperm from the spermatangia (antheridia) (Maier 1995). The diploid zygote develops into the sporophyte generation. In many species, asexual reproduction involving the production of zoospores (motile cells) in multichambered plurilocular sporangia borne on either the gametophyte or sporophyte generation is very common. Brown algae produce heterokont reproductive zoids and sperm with characteristic ultrastructure: two unequal flagella inserted laterally, the anterior bearing mastigonemes and the posterior one lacking them (Figs. 6 and 7). The

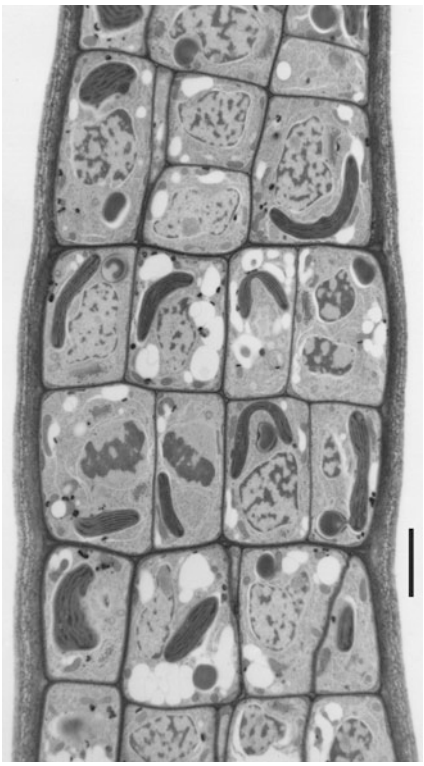

Fig. 5 Immature plurilocular sporangia of *Ectocarpus* sp. Freeze substitution (TEM micrograph courtesy of Taizo Motomora). Scale bar, 2 μm

genes of the proteins constituting mastigonemes have been identified in a unicellular heterokont (*Ochromonas*, Yamagishi et al. 2007) and shown to be comparable to the corresponding genes of the proteins in brown algae.

Most brown algal zoids show photo-orientation responses (phototaxis). In the posterior flagellum, a green autofluorescent substance and a basal swelling, appressed to an eyespot of carotenoid globules in the adjacent chloroplast (Fig. 8), is involved in the photoreception of blue light (Kawai et al. 1990; Kawai 1992a; Kawai and Kreimer 2000). In contrast, zoids of Laminariales and sperm that lack phototaxis in some other orders lack these structures.

Structural characteristics of brown algal chloroplasts (plastids) include the arrangement of thylakoids in groups of three, the presence of a lamella lying just inside the plastid membrane (called the girdle lamella), and the plastid endoplasmic reticulum, which is continuous with the nuclear envelope. The chloroplast DNA is arranged in a peripheral ring (Coleman 1985). The characteristic brown accessory pigment fucoxanthin is active in photosystem II of photosynthesis (Braun and Braun 1974); carotenes, violaxanthin, and chlorophylls *a, c* and c_1 are also present. Pyrenoids, appendages of chloroplasts, are observed in species of the orders Ectocarpales *s.l.* and Scytothamnales (Kawai 1992b) (Fig. 8). Pyrenoids are lacking or not obvious in other orders including basal taxa, and those in Ectocarpales (Nagasato et al. 2003) and

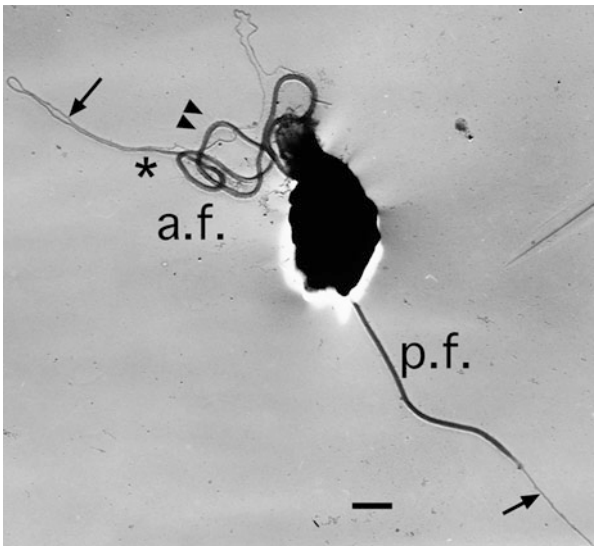

Fig. 6 Sperm of *Stschapovia flagellaris* with hairy anterior flagellum having very long acronema at the tip, and posterior flagellum with shorter acronema. Whole mount TEM micrograph. Scale bar, 2 μm

Scytothamnales (Tanaka et al. 2007) have distinctive morphological features; therefore, pyrenoids are considered to have evolved (or became elaborated) multiple times in brown algae (Silberfeld et al. 2011). The carbon storage material commonly found in the phaeophytes is laminaran, a β-(1, 3) glucan containing mannitol.

Brown algal cell walls are composed chiefly of three kinds of polymer: cellulose, alginic acid, and the heterogeneous fucose-containing sulfated polysaccharides (fucan, fucoidan). The microfibrillar organization of cellulose contributes to the skeletal role of the walls (Kloareg et al. 1986). The cellulose-synthesizing terminal complexes (TCs) associated with the tips of microfibril impressions in the plasmatic fracture face of the plasma membrane (observed by freeze-fracture techniques) consist of subunits arranged in a single linear row (Peng and Jaffe 1976; Tamura et al. 1996). Alginic acid, a polymer of mannuronic and guluronic acids, and other sulfated polysaccharides such as fucoidan (McCandless and Craigie 1979), even though they are chemically more complex than cellulose, do not form structural wall components. Alginic acid was long considered to be a defining characteristic in the Phaeophyta (Phaeophyceae) among the Chromista, but has now also been shown to be present in members of Schizocladiophyceae, Xanthophyceae, and Chrysomeridales (Chi et al. 1999; Kawai et al. 2003). Whatever skeletal functions alginates possess are thought to derive from their property of forming gels and viscous solutions. Fucans apparently have a role in the desiccation resistance of intertidal brown algae by virtue of their strong affinity for highly hydrated magnesium ions (Percival 1979).

Physodes, vacuole-like refractive bodies containing osmiophilic material of phenolic nature, are common in brown algae cells. Chemical analysis (Ragan 1976) has shown physodes to contain primarily phloroglucinol derivatives along with tannins and terpenes. The phenolic compounds in brown algal cells are thought to act as herbivore deterrents in a similar way as the tannins in higher plants (Targett and

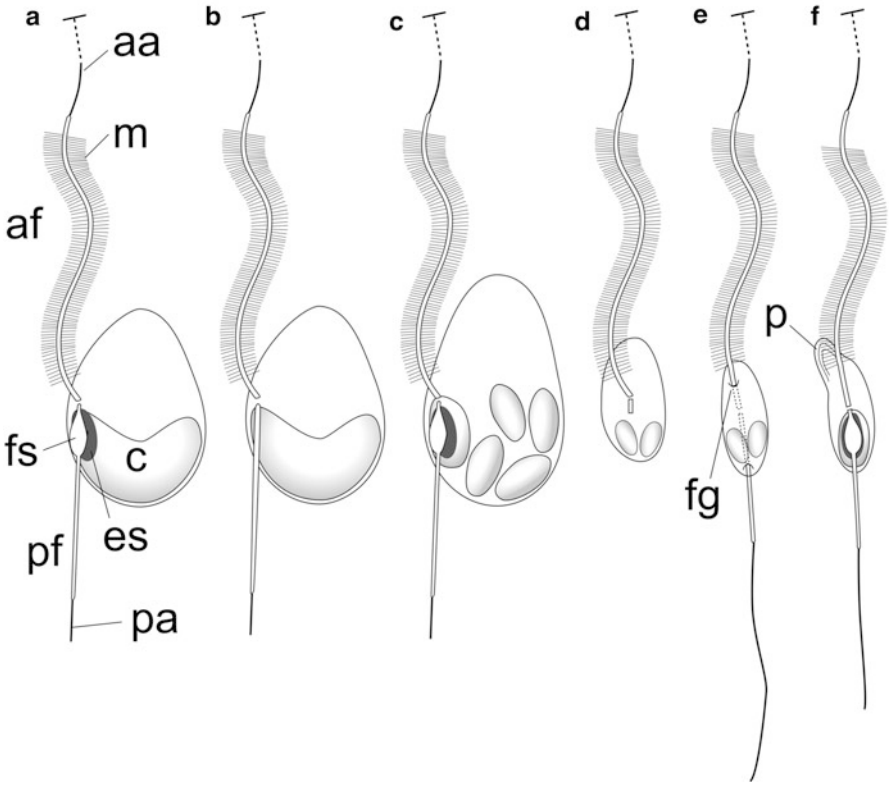

Fig. 7 Schematic representation of brown algal flagellated cells. (**a**) Typical (perhaps plesiomorphic) type with long anterior flagellum (*af*) and short posterior flagellum (*pf*). Chloroplast (*c*) has eyespot (*es*) spatially associated with flagellar swelling (*fs*) on the basal part of the posterior flagellum. Anterior flagellum has long acronema (*aa*), which is easily detached by fixation. Posterior flagellum has relatively short, but more persistent acronema (*pa*). (**b**) Laminarialean type without eyespot and flagellar swelling and lacking phototaxis. (**c**) Female anisogamous gamete with multiple chloroplasts. (**d**) Dictyotalean sperm with remnant posterior flagellum and reduced chloroplast. (**e**) Laminarialean sperm with long posterior flagellum, reduced chloroplasts, and deep flagellar gullet (*fg*). (**f**) Fucalean sperm with proboscis (anterior protuberance) and eyespot

Arnold 1998), but they are also suggested to play a role in polyspermy block and protection against UV radiation (Schoenwaelder 2002).

Classification of the Phaeophyceae

In the ordinal classification of the Phaeophyceae since Kylin (1933), basic construction of the thallus, growth mode, and life history pattern have been regarded as characters reflecting higher-rank phylogeny. Based on the general concept using phenotypic characters, 13–17 orders have been recognized in the Phaeophyceae: Ascoseirales, Chordariales, Cutleriales, Desmarestiales, Dictyosiphonales, Dictyotales,

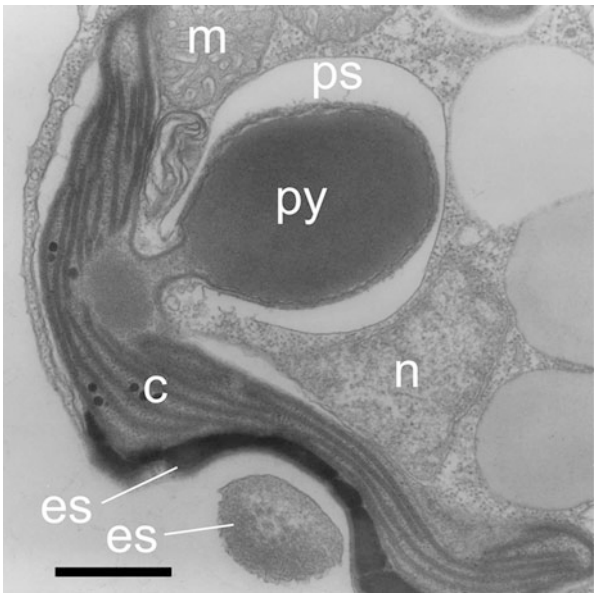

Fig. 8 Chloroplast with protruded type of pyrenoid with pyrenoid sac in *Ectocarpus* gamete. TEM micrograph. Scale bar, 0.5 μm

Discosporanigiales, Durvillaeales, Ectocarpales, Fucales, Laminariales, Ralfsiales, Scytosiphonales, Sphacelariales, Sporochnales, Syringodermatales, and Tilopteridales. However, molecular phylogenetic data showed some incongruence with some of the conventional ordinal assignments. Major updates are as follows: de Reviers and Rousseau (1999) proposed to reduce Durvillaeales to family status within the Fucales, as well as the unification of the Chordariales, Dictyosiphonales, Ectocarpales, and Scytosiphonales into Ectocarpales *sensu lato* (de Reviers and Rousseau 1999). Cutleriales was shown to be sister group of Tilopteridales, and so was merged with Tilopteridales (Silberfeld et al. 2010). Silberfeld et al. (2014b) proposed new subclasses Discosporangiophycidae, Ishigeophycidae, and Dictyophycidae in addition to the subclass Fucophycidae proposed by Cavalier Smith (1986), as well as a new order Phaeosiphoniellales. Kawai et al. (2015a) proposed Stschapoviales and moved Halosiphonaceae and Stschapoviaceae from Tilopteridales to this order together with newly proposed Platysiphonaceae.

The orders and families are listed, as is customary, in sequences of increasing structural complexity. The list of genera, not exhaustive because it is based on only the more accessible recent taxonomic literature, is in alphabetical order. However, the ordinal and familial assignment of ectocarpalean taxa are currently considerably confused in Ectocarpales excluding Scytosiphonaceae, because of the insufficient resolution and the coverage of taxa in relevant molecular phylogenetic studies, although several new families have been described based on molecular data. Therefore, familial assignment is suspended in those taxa in the present chapter.

Representative families and genera in the orders are listed in Table 1. Diagnostic characters of the above-mentioned 17 orders currently recognized within the Phaeophyceae are presented in Table 2.

Table 1 Orders, families, and genera of Phaeophyceae

I. Order Discosporangiales
1. Choristocarpaceae: *Choristocarpus*
2. Discosporangiaceae: *Discosporangium*
II. Order Ishigeales
1. Ishigeaceae: *Ishige*
III. Order Dictyotales
1. Dictyotaceae: *Canistrocarpus*, *Chlanidophora, Dictyopteris, Dictyota, Dictyotopsis, Distromium, Exallosorus, Herringtonia, Homoeostrichus, Lobophora, Lobospira, Newhousia, Padina, Rugulopteryx, Scoresbyella, Spatoglossum, Stoechospermum, Stypopodium, Taonia, Zonaria*
IV. Order Sphacelariales
1. Cladostephaceae: *Cladostephus*
2. Phaeostrophiaceae: *Phaeostrophion*
3. Sphacelariaceae: *Battersia, Herpodiscus, Sphacelaria, Sphacella, Sphacelorbus*
4. Sphacelodermaceae: *Sphaceloderma*
5. Stypocaulaceae: *Halopteris, Phloiocaulon, Protohalopteris, Ptilopogon*
V. Order Onslowiales
1. Onslowiaceae: *Onslowia, Verosphacela*
VI. Order Syringodermatales
1. Syringodermataceae: *Microzonia, Syringoderma*
VII. Order Desmarestiales
1. Arthrocladiaceae: *Arthrocladia*
2. Desmarestiaceae: *Desmarestia, Himanthothallus, Phaeurus*
VIII. Order Ascoseirales
1. Acroseiraceae: *Acroseira*
IX. Order Sporochnales
1. Sporochnaceae: *Austronereia, Bellotia, Carpomitra, Encyothalia, Lucasia, Nereia, Perisporochnus, Perithalia, Sporochnema, Sporochnus, Tomaculopsis*
X. Order Scytothamnales
1. Asteronemataceae: *Asteronema*
2. Bachelotiaceae: *Bachelotia*
3. Splachnidiaceae: *Scytothamnus, Splachnidium, Stereocladon*
XI. Order Ectocarpales sensu *lato*
1. Adenocystaceae: *Adenocystis, Caepidium, Chordariopsis, Utriculidium*
2. Ectocarpaceae (Ectocarpales *sensu stricto* + Chordariales + Dictyosiphonales)
Acinetospora, Acrothrix, Acrotrichium, Actinema, Adenocystis, Ascoseirophila, Asperococcus, Australofilum, Botrytella, Buffhamia, Chilionema, Chordaria, Chuckchia, Cladochroa, Cladosiphon, Cladothele, Clathrodiscus, Climacosorus, Coelocladia, Coilodesme, Corycus, Corynophlaea, Cylindrocarpus, Delamarea, Dermatocelis, Dictyosiphon, Ectocarpidium, Ectocarpus, Elachista, Elachistiella, Entonema, Epinema, Eudesme, Feldmannia, Flabellonema, Fosliea, Geminocarpus, Giraudia, Gononema, Halonema, Halorhipis, Halorhiza, Halothrix, Hamelella, Haplogloia, Hecatonema, Herponema, Heterosaundersella, Hincksia, Hummia, Internoretia, Isthmoplea, Kuckuckia, Kuetzingiella, Kurogiella, Laminariocolax, Laminarionema, Leathesia, Leblondiella, Leptonematella, Levringia, Leblondiella, Liebmannia, Litosiphon, Melastictis, Mesogloia, Mesogloiopsis, Microcoryne, Microspongium, Mikrosyphar, Myriactula, Myriocladia, Myriogloea, Myrionema, Myriotrichia, Nemacystus, Neoleptonema,

(*continued*)

Table 1 (continued)

Omphalophyllum, Papenfussiella, Petrospongium, Phaeophysema, Phaeostroma, Phaeostromatella, Pilinia, Pilocladus, Pleurocladia, Pogotrichum, Polycerea, Polytretus, Proselachista, Protectocarpus, Punctaria, Pylaiella, Rhadinocladia, Saundersella, Sauvageaugloia, Soranthera, Spermatochnus, Sphaerotrichia, Spongonema, Stegastrum, Stictyosiphon, Stilophora, Stilopsis, Streblonema, Streblonemopsis, Strepsithalia, Striaria, Suringariella, Tinocladia, Trachynema, Ulonema, Vimineoleathesia, Xanthosiphonia, Zeacarpa, Zosterocarpus
3. Scytosiphonaceae (Scytosiphonales)
Chnoospora, Colpomenia, Compsonema, Diplura, Endarachne, Endopleura, Hapterophycus, Hydroclathrus, Iyengaria, Jolyna, Myelophycus, Melanosiphon, Petalonia, Rosenvingea, Scytosiphon, Sorapion, Stragularia, Symphyocarpus
XII. Order Laminariales
1. Akkesiphycaceae: *Akkesiphycus*
2. Pseudochordaceae: *Pseudochorda*
3. Chordaceae: *Chorda*
4. Aureophycaceae: *Aureophycus*
5. Agaraceae: *Agarum, Costaria, Dictyoneurum, Thalassiophyllum*
6. Laminariaceae: *Arthrothamnus, Costulariella, Cymathere, Feditia, Laminaria, Macrocystis, Nereocystis, Pelagophycus, Phyllariella, Postelsia, Pseudolessonia, Saccharina, Tauya*
7. Alariaceae: *Alaria, Ecklonia, Eckloniopsis, Egregia, Eisenia, Eualaria, Pleurophycus, Pterygophora, Undaria, Undariella*
8. Lessoniaceae: *Lessonia, Lessoniopsis*
9. *Phaeosiphoniellaceae: *Phaeosiphoniella*
XIII. Asterocladales
1. Asterocladaceae: *Asterocladon*
XIV. Order Fucales
1. Bifurcariopsidaceae: *Bifurcariopsis*
2. Durvillaeaceae: *Durvillaea*
3. Fucaceae: *Ascophyllum, Fucus, Hesperophycus, Pelvetia, Pelvetiopsis, Silvetia*
4. Himanthaliaceae: *Himanthalia*
5. Hormosiraceae: *Hormosira.*
6. Notheiacaea: *Notheia*
7. Sargassaceae*: Acrocarpia, Anthophycus, Axillariella, Bifurcaria, Brassicophycus, Carpoglossum, Carpophyllum, Caulocystis, Cladophyllum, Coccophora, Cystophora, Cystoseira, Halidrys, Hormophysa, Landsburgia, Myagropsis, Myriodesma, Nizamuddinia, Oerstedtia, Phyllotricha, Platythalia, Polycladia, Sargassopsis, Sargassum, Scaberia, Sirophysalis, Stephanocystis, Stolonophora, Turbinaria*
8. Seirococcaceae: *Axillariella, Cystosphaera, Marginariella, Phyllospora, Scytothalia, Seirococcus*
9. Xiphophoraceae: *Xiphophora*
XV. Order Nemodermatales
1. Nemodermataceae: *Nemoderma*
2. Zeacarpaceae: *Zeacarpa*
XVI. Order Tilopteridales
1. Culteriaceae: *Cutleria, Mutimo, Zanardinia*
2. Phyllariaceae: *Phyllariopsis, Saccorhiza*

(*continued*)

Table 1 (continued)

3. Tilopteridaceae: *Haplospora, Tilopteris*
XVII. Order Stschapoviales
1. Halosiphonaceae*: Halosiphon*
2. Platysiphonaceae: *Platysiphon*
3. Stschapoviaceae: *Stschapovia*
XVIII. Order Ralfsiales
1. Heterochordariaceae: *Analipus*
2. Mesosporaceae: *Acrospongium, Hapalospongidion, Mesospora*
3. Neoralfsiaceae: *Neoralfsia*
4. Ralfsiaceae: *Heteroralfsia, Jonssonia, Lithoderma, Myrionemopsis, Petroderma, Porterinema, Pseudolithoderma, Ralfsia*

*Classified in a separate order Phaeosiphoniellales in Silberfeld et al. (2014b)

Order Discosporangiales

The genera *Choristocarpus* and *Discosporangium*, with uniseriate filamentous thalli with apical growth cells, have been classified in Sphacelariales (Prud'homme van Reine 1982). However, recent molecular studies (Draisma et al. 2001; Burrowes et al. 2003; Kawai et al. 2007) revealed that they form a monophyletic clade that first branches off from all other brown algae, sharing the following characters which are considered to be plesiomorphic characters in the brown algae: (1) apical (and diffuse) growth; (2) uniseriate, subdichotomously branched filaments; (3) multiple chloroplasts per cell without pyrenoids; and (4) lack of heterotrichy and phaeophycean hairs. Regarding their higher-rank systematic positions, reinstatement of Discosporangiaceae and Discosporangiales (Schmidt 1937) was proposed, and the inclusion of Choristocarpaceae in the order was also suggested (Kawai et al. 2007). *D. mesarthrocarpum* has unique disk-shaped plurilocular reproductive organs.

Order Ishigeales

The Ishigeales have branched, terete or flattened parenchymatous thalli of up to 10–20 cm high. The genus *Ishige*, including two species distributed in the warm temperate Pacific Ocean, has been classified in Chordariales. However, the lack of prominent pyrenoids in the chloroplast (Hori 1971) and the indication of isomorphic life history (Tanaka in Hori 1993), as well as preliminary molecular phylogenetic data (Tan and Druehl 1994; Peters and Ramírez 2001), made this systematic position doubtful. Later Cho et al. (2004) proposed a new order Ishigeales to accommodate the genus.

Order Dictyotales

The isomorphic sporophyte and gametophyte thalli are foliose and parenchymatous. Dictyotales are unique in brown algae including taxa with calcified thalli (i.e., *Padina* and *Newhousia*). *Dictyota* has a single apical cell, whereas other genera have several to many localized apical cells forming dichotomously branching thalli

Table 2 Characteristic features of brown algal orders

Order	Thallus structure or prominent generation	Chloroplast	Life history pattern	Reproduction (sexual/asexual)	Remarks
Discosporangiales	Uniseriate, filamentous	Multiple, discoid, without pyrenoids	Isomorphic	Isogamy?/unizoids	Most basal taxon in Phaeophyta, only a few species recognized
Ishigeales	Parenchymatous, foliose or terete	Multiple, discoid, without pyrenoids	Isomorphic	Isogamy/unizoids	Only a few species recognized
Dictyotales	Parenchymatous, foliose or membranous	Multiple, discoid, without pyrenoids	Isomorphic	Oogamy/tetraspores in most taxa	Large order including many tropical/subtropical taxa
Sphacelariales	Parenchymatous, filamentous, terete or foliose	Multiple, discoid, without pyrenoids	Isomorphic	Isogamy, anisogamy, oogamy/unizoids, propagules	
Onslowiales	Uniseriate, filamentous, partly with longitudinal walls	Multiple, discoid, without pyrenoids	Isomorphic	anisogamy/unizoids, propagules	
Syringodermatales	Foliose thalli formed by adhesion of filaments; some with longitudinal walls	Multiple, discoid, without pyrenoids	Isomorphic or heteromorphic[a]	Isogamy/unizoids	Only known from relatively deep habitats, life histories remarkably diverse
Desmarestiales	Pseudoparenchymatous, terete or foliose	Multiple, discoid, without pyrenoids	Heteromorphic	Oogamy/unizoids	Some spp. forming large thalli exceeding 5 m, important ecological element in Antarctic region

Ascoseirales	Parenchymatous, terete	Multiple, discoid, without pyrenoids	Only diploid generation is evident	Isogamy	Distributed only in cold water regions of the southern hemisphere
Sporochnales	Pseudoparenchymatous, terete	Multiple, discoid, without pyrenoids	Heteromorphic	Oogamy/uni-zoids	
Scytothamnales	Parenchymatous, terete	Single or multiple, embedded pyrenoid with tubular invaginations	Heteromorphic	Isogamy/uni-zoids	Characterized by distinctive pyrenoids
Ectocarpales *s.l.*	Uniseriate, pseudoparenchymatous or parenchymatous; filamentous, terete, foliose or saccate	Single to multiple, discoid or ribbon-shaped, with projected pyrenoid	Isomorphic[b] or heteromorphic	Isogamy, anisogamy/uni-zoids	Including taxa formerly classified in Chordariales, Dictyosiphonales and Scytosiphonales
Laminariales	Parenchymatous, foliose or terete	Multiple, discoid, without pyrenoids	Heteromorphic	Oogamy/uni-zoids	Largest thalli attaining to 50 m and major component of kelp forests
Asterocladales	Uniseriate, filamentous, partly with longitudinal walls	Multiple, separate pyrenoids grouped in center of cell	Isomorphic	Anisogamy/uni-zoids	
Fucales	Parenchymatous, foliose or terete	Multiple, discoid, without pyrenoids	Only diploid generation is evident	Oogamy	Some spp. forming large thalli exceeding 10 m and major component of algal beds
Nemodermatales	Pseudoparenchymatous, crustose	Multiple, discoid, without pyrenoids	Isomorphic	Anisogamy	Characterized by intercalary or tufted lateral unilocular zoidangia in upright filaments

(*continued*)

Table 2 (continued)

Order	Thallus structure or prominent generation	Chloroplast	Life history pattern	Reproduction (sexual/asexual)	Remarks
Tilopteridales	Parenchymatous, terete or filamentous	Multiple, discoid, without pyrenoids	Heteromorphic, nearly isomorphic or only haploid generation is evident	Oogamy or asexual/uni-zoids	Distributed only in cold or cool water regions of the northern hemisphere
Stschapoviales	Parenchymatous, terete	Multiple, discoid, without pyrenoids	Heteromorphic or regenerating a single type of thallus	Oogamy or asexual/uni-zoids	Distributed only in cold water regions of the northern hemisphere
Ralfsiales	Parenchymatous, crustose, or terete	Single or multiple without pyrenoid	Isomorphic or heteromorphic	Isogamy/uni-zoids	Predominantly crustose

[a]Gametophyte may be considerably reduced and not free-living
[b]In some taxa, sporophyte and gametophyte thallus sizes are not remarkably different but are distinguishable by their gross morphology

or arranged along the entire margin and hence forming fan-shaped thalli. Cells that are cut off from the apical cell undergo further longitudinal and transverse divisions (Katsaros and Galatis 1988; Gaillard and L'Hardy-Halos 1990). Sexual reproduction is anisogamous or oogamous. The sperm have only an anterior flagellum, but have a second flagellar basal body (Manton 1959), except for *Zonaria angustata*, which is reported to have two flagella (Phillips and Clayton 1991).

Order Sphacelariales

The Sphacelariales is a well-defined order (Prud'homme van Reine 1982, 1993) in which branched filaments grow from a conspicuous apical cell. During growth, segments cut off from the apical cell by transverse division subsequently enlarge and undergo further transverse and longitudinal segmentation. Sphacelariales show isomorphic life histories. Isogamy occurs in *Cladostephus,* isogamy or anisogamy in *Sphacelaria,* and anisogamy or oogamy in the Stypocaulaceae. Kawai et al. (2005a; 2015a) suggested classifying *Phaeostrophion* in Phaeostrophiaceae in Sphacelariales, and thereby to emend the order to also include foliose taxa.

Order Onslowiales

Onslowiales comprises two genera *Onslowia* and *Verosphacela*. The isomorphic sporophyte and gametophyte thalli of apical growth are filamentous and irregularly branched, and slightly polystichous with transverse walls (Searles and Leister 1980; Henry 1987; Draisma et al. 2010).

Order Syringodermatales

Syringodermatales include the genera *Syringoderma* and *Microzonia*, formerly included in Dictyotales (Henry 1984; Burrowes et al. 2003). The fan-shaped macrothalli develop by the cohesion of filaments arising from a marginal meristem. The gametophyte morphologies are remarkably divergent among *Syringoderma* species, being either filamentous or reduced to only 4 or 2 cells (Henry and Müller 1983; Henry 1984; Kawai and Yamada 1990).

Order Desmarestiales

In most species, the pseudoparenchymatous thallus is derived from apical meristems situated at the base of a hair (trichothallic). A cortex and a meristoderm (a meristematic surface layer of tissue) are formed from the lateral outgrowths of axial filaments. A parenchyma-like anatomy is formed from this filamentous growth in the Antarctic *Himantothallus* (Moe and Silva 1981). The taxonomy of the species of *Desmarestia* is confused, and a worldwide revision of the 40 or so species is needed (Moe and Silva 1977). Some members show strong acidity by accumulating SO_4^{2-} ion within cells, and the evolution of this character is considered to have occurred once in the order (Peters et al. 1997).

Order Ascoseirales

The Ascoseirales comprise the single Antarctic genus *Ascoseira*, which has a large parenchymatous thallus consisting of a dissected lamina, holdfast, and stipe. Growth

is intercalary with reproductive structures borne in conceptacles that produce large cells containing eight large eggs capable of developing directly into the sporophytic thallus (Moe and Henry 1982) and eight vegetative vestigial cells (Clayton 1987).

Order Sporochnales
The sporophytic thalli are filamentous and growth occurs in meristems located at the base of dense apical tufts of hairs. The pseudoparenchymatous (= formed of filamentous aggregates) fronds are formed from the downgrowth of corticating filaments below the apex. The minute, filamentous gametophytes (microthalli) produce eggs and sperm (Caram 1965).

Order Scytothamnales
The Scytothamnales have branched, terete, parenchymatous thalli, up to 30 cm high, growing from a small holdfast or crustose base. The cells include one or more stellate chloroplasts with a central pyrenoid with tubular invaginations and lacking a pyrenoid sac (Peters and Clayton 1998; Tanaka et al. 2007).

Order Ectocarpales *sensu lato* (including Chordariales, Dictyosiphonales, Ectocarpales *sensu stricto*, and Scytosiphonales)
The taxa formerly classified in Chordariales are mucilaginous, simple, or branched thalli of closely compacted filaments (pseudoparenchymatous). A few genera (in the Elachistaceae, and *Papenfussiella*) also have free filaments. Growth is intercalary in the Elachistaceae, Leathesiaceae, and Chordariaceae and apical in the Acrotrichaceae, Spermatocthnaceae, Splachnidiaceae, and Notheiaceae. Macrothalli are sporophytes with unilocular and, in some species, plurilocular sporangia. Sexual life histories have been described for a number of species (Müller 1981b; Peters 1987).

The taxa formerly classified in Dictyosiphonales were defined by their polystichous character. That is, their cells divide longitudinally as well as transversely to form parenchyma. Longitudinal cell divisions produce a parenchymatous thallus. This is least developed in the Myriotrichiaceae, which possess finely divided, almost filamentous thalli. The macrothallus sporophytes possess both unilocular and plurilocular sporangia in most species. Gametophytes, where known, are filamentous and produce anisogametes (Fiore 1977). Adenocystaceae (Rousseau et al. 2000) is considered to have its closest phylogenetic relationship with this order.

Ectocarpales *sensu stricto* have simple thalli consisting of branched filaments in which growth occurs by intercalary cell division. Reproduction is by zoids produced in plurilocular and unilocular structures. Sexual reproduction is either isogamous or anisogamous, but the life histories of only a few species have been studied in detail (Wynne and Loiseaux 1976). *Ectocarpus siliculosus* and species in the Myrionemataceae (Loiseaux 1967), for example, have more or less isomorphic sporophyte and gametophyte generations (Müller 1967). The Sorocarpaceae, classified previously in the Ectocarpaceae, was erected (Pedersen 1977) for three genera with terminal hairs, sympodial branching, and distinctive aggregates of plurilocular sporangia (sori). Some authors have placed them in the Chordariales. Some authors

have merged Ectocarpales with Chordariales, Scytosiphonales, Tilopteridales, and Dictyosiphonales because the boundaries separating these taxa are indistinct (Russell and Fletcher 1975).

In the taxa formerly classified in Scytosiphonales, the thalli are parenchymatous with variously shaped, simple, or branched forms. Growth is intercalary. The cells contain one plastid. The macrothalli are gametophytes, bearing only plurilocular reproductive structures, some of which are gametangia. Mating is isogamous or anisogamous (Nakamura and Tatewaki 1975; Clayton 1979; 1980). The sporophytes are filamentous or crustose microthalli that produce unilocular sporangia. Taxonomy of the order was revised by Kogame et al. (1999).

Order Laminariales

The Laminariales (see Bold and Wynne 1985) have large parenchymatous thalli differentiated into lamina, stipe, and holdfast. The thallus consists of an outer meristoderm, a cortex, and a central medulla. The trumpet-shaped filaments (hyphae) constituting the medulla are distinctive to the order, comparable to sieve tubes in higher plants. Growth occurs at intercalary meristematic regions. The macrothallus sporophytes reproduce by means of spores formed in unilocular sporangia. Microscopic gametophytes produce sperm or eggs. Egg formation (Lüning 1981) and fertilization (Lüning and Müller 1978) are similar to that in the Desmarestiales, but the laminarialean egg has vestigial flagella (Motomura and Sakai 1988).

Members of Laminariales are major components of lower intertidal to subtidal vegetations in cold water regions, except the Antarctic. Higher rank taxonomy of the order has been considerably revised based on life history and molecular studies (Kawai 1986; Kawai and Kurogi 1985; Kawai and Sasaki 2000; Kawai et al. 2008, 2013; Kawai 2014). Kawai et al. (2008, 2013) reported a novel laminarialean species with distinctively simple sporophyte structure and forming sori on the discoid holdfast. Phylogeography of Laminariales was recently reviewed by Bolton (2010) and Kawai (2014).

Order Asterocladales

Asterocladales comprise two filamentous genera with characteristic chloroplast configurations. Vegetative cells include several elongate plastids per cell, which are linked in a stellate configuration via their stalked and protruding pyrenoids without invaginations, as seen in Scytothamnales (Müller and Parodi 1994; Müller et al. 1998; Uwai et al. 2005; Tanaka et al. 2007).

Order Fucales

The Fucales have fairly large parenchymatous thalli. Branching is either dichotomous, monopodial and radial, or bilateral. The thallus is differentiated into a meristoderm, cortex, and medulla; growth results from the division of apical cells and cell division in associated meristematic regions. Ooogonia and spermatangia are borne on specialized branches known as receptacles. Meiosis occurs in the first division of the sexual parental cells. The haploid gametophyte generation is so greatly reduced that it is not recognizable as such.

Members of Fucales are major components of coastal vegetations of cold water regions of the northern hemisphere (*Fucus, Ascophyllum, Pelvetia*, etc.) and southern hemisphere (*Durvillaea*), and warm temperate to tropical coastal ecosystems (*Sargassum, Cystoseira*, etc.).

Order Nemodermatales

Nemodermatales comprise Nemodermataceae and newly described Zeacarpaceae (Kawai et al. 2016). Both families are monotypic including *Nemoderma tingitanum* and *Zeacarpa leiomorpha,* respectively. It has crustose thalli characterized by the formation of reproductive sori with intercalary or tufted lateral unilocular zoidangia in upright filaments. Each cell includes multiple chloroplasts without pyrenoids. By molecular phylogeny, *N. tingitanum* was shown to be distinctive from other crustose algae, and treatment in a separate order was suggested (Phillips et al. 2008). Later, *Zeacarpa* was shown to phylogenetically most related to *Nemoderma* and also transferred from Ralfsiales to Nemodermatales.

Order Tilopteridales

Tilopteridales comprise Tilopteridaceae, Phyllariaceae, and Cutleriaceae. The family Tilopteridaceae includes three polystichous, filamentous genera (South 1975; Hooper et al. 1988). *Haplospora* sporophytes resemble the gametophytes, and sexual reproduction involves eggs and sperm. The sporophyte of *Haplospora* bears meiotic sporangia that produce a multinucleate nonmotile spore. In *Haplospora* a life history alternating between nearly isomorphic filamentous sporophytes forming monospores and asexual gametophytes forming two types of monospore-like reproductive cells (i.e., eggs and neutral spores) and sperm are reported, whereas the sporophyte is considered to be reduced in *Tilopteris* (Kuhlenkamp and Müller 1985). In either case, sexual reproduction is considered to be reduced. In contrast, some members of Cutleriaceae (e.g., *Cutleria*, *Mutimo*), which used to be classified in its own order Cutleriales, have a life history alternating between heteromorphic terete or membranous gametophytes and crustose sporophytes, whereas *Zanardinia* is isomorphic (Fritsch 1945). Phyllariaceae comprise kelp-like genera such as *Sacchorhiza* and *Phyllariopsis* and have characteristic anatomy with multinucleate conducting filaments (i.e., solenocysts) comparable in function to the trumpet-shaped hyphae in laminarialean kelp.

Order Stshapoviales

Kawai et al. (2015a) proposed to classify Halosiphonaceae, Stschapoviaceae, and Platysiphonaceae in Stschapoviales, mainly based on molecular phylogeny. These are cold water taxa having polystichous, terete thalli with assimilatory filaments in whorls or on the distal end. *Halosiphon* shows a typical heteromorphic life history with large sporophyte and monoecious gametophytes, but *Stschapovia* and *Platysiphon* are suggested to have a modified life history without alternation between two apparent generations, as in Fucales (Kawai and Sasaki 2004; Kawai et al. 2015a, b).

Order Ralfsiales
The validity of Ralfsiales has been challenged, but it was shown to be a monophyletic group after emendation (Lim et al. 2007). The Ralfsiales primarily have crustose thalli, but some have terete erect thalli (e.g., *Analipus, Heteroralfsia*) (Kawai 1989), characterized by discoidal early development of the thallus, intercalary plurilocular gametangia with terminal cells, terminal unilocular zoidangia, and a crustose phase in the life history (Nakamura 1972; Lim et al. 2007). Many members have a single parietal chloroplast without pyrenoids. The new families Mesosporaceae (Tanaka and Chihara 1982) and Neoralfsiaceae (Lim et al. 2007) have been added to the order.

Maintenance and Cultivation

Isolation from Nature

Collecting and Establishing Unialgal and Axenic Cultures: Collected specimens are transported in plastic bags, bottles, or containers suitable to their size, avoiding excess solar irradiation and temperature shocks relative to the prevailing habitat conditions. An insulated cool box or refrigerator is convenient for the temporary storage and transport of brown algae under most climatic conditions, although tropical species may be adversely affected by such low temperatures. Most intertidal taxa are more tolerant of stresses such as desiccation and rapid temperature changes, compared to subtidal taxa. Fertile specimens collected under desiccating conditions tend to release zoids and eggs as soon as they are reimmersed in seawater, such as in the containers used for transportation. Therefore, they may preferably be transported moist in plastic bags or plastic containers, instead of immersed in seawater.

A number of techniques are available for initiating cultures, some of which are more suited to particular orders of the Phaeophyceae (Kawai et al. 2005b). Either vegetative tissue or reproductive cells may be used for establishing unialgal cultures. In both cases, clean specimens without epiphytes and epizoa are preferred, and fertile specimens should be selected in the field. When fertile portions of the specimens are recognizable, only those portions need to be excised and transported to the laboratory, to avoid damage and contamination from the other specimens. Acid-containing taxa (e.g., some *Desmarestia* spp., *Dictyopteris* spp. and *Spatoglossum* spp.) and some other delicate subtidal taxa (e.g., *Dictyota*, *Sporochnus*, etc.) should be transported in containers with a relatively large volume of sea water and separated from other algae, or the thalli will deteriorate very rapidly, which damages the other algae.

For unialgal cultures, sterilized grass vessels or plastic Petri dishes are commonly used. Suitable sizes depend on the targeted algal sizes, but 55–90 mm (diameter) dishes and 200–300 mL vessels are commonly used. Aeration is usually not required for the culture of this size, but is often used for larger cultures.

Unialgal cultures of marine brown algae grow readily in culture media of sea water enriched with basic autotroph nutrients. The most widely used formula is

Provasoli's ES (PES) medium and modified Provasoli's ES medium (PESI), omitting vitamins but adding iodine (Tatewaki 1966). Related literature and recipes of the culture media are listed in Harrison and Berges (2005).

Isolation from vegetative thalli: Most brown algal species have high potential for regeneration and totipotency, so that unialgal cultures can be established for many species from vegetative tissues. However, in practice epiphytic algae and cyanobacteria tend to grow faster than the desired species and overwhelm it. Therefore, isolation by this technique is effective only for minute taxa and some larger ones with apical meristematic growth (e.g., Dictyotales, Sphacelariales, Discosporangiales). For those species, a razor blade may be used to first cut out a small fragment including the apical cell(s) into a Petri dish filled with sterilized seawater. Then, under a dissecting microscope, smaller pieces of tissue including intact apical cell(s) are cut out and transferred into individual wells of a multiwell plate or individual Petri dishes (or test tubes) filled with culture medium, using a clean fine forceps (sterilized by wiping with 70% ethanol) or sterilized capillary pipettes. GeO_2 and antibiotics can be used to eliminate diatom and cyanobacteria contamination, respectively. After 1–2 weeks of culture in an illuminated chamber of suitable temperature, unialgal isolates can be selected using an inverted microscope to carefully inspect each isolate for contaminants.

Isolation from swimming zoids: Many species release zoids (zoospores and gametes) vigorously and synchronously 1 or 2 days after collection, rather than immediately after, if specimens are properly stored in cool and dark conditions. They tend to release zoids soon after reimmersion in seawater, stimulated by temperature rise and illumination. For zoid isolation, place a small fragment of fertile tissue in a small Petri dish, depression slide, or watch glass filled with sterilized seawater and examine the zoid-release under dissecting microscope. When release starts, observe any phototactic behavior of the zoids under a dissecting microscope to determine the orientation of the taxis and isolate clean zoids using a fine pipette into new Petri dish filled with sterile seawater culture medium. Wynne's hanging drop method (Chapman 1973) is useful when mass release of zoids fails and the isolation of individual reproductive structures is precluded. Alternatively, mature reproductive organs (unilocular zoidangia, plurilocular gametangia, etc.) may be cut out from the squashed or fragmented tissues including them and individually isolated and precultured until new offspring (germlings) from them become available. Then the germlings may be reisolated into individual Petri dishes to establish unialgal cultures.

Axenic culture: For axenic cultures, thalli should be cleaned thoroughly using sterile seawater. Guillard's antibiotic mixture, which consists of penicillin G 124.5 mg per liter, streptomycin sulfate 50 mg per liter, and chloramphenicol 20 mg per liter made up in sterile sea water, has been used to purify isolates of laminarialean (Druehl and Hsiao 1969) and *Dictyosiphon* (Saga and Sakai 1982) gametophytes.

Routine sterility tests should be carried out. For this purpose, Fries (1977) recommended transferring pieces of algae into test tubes containing culture medium to which is added 2 g glucose, 2 g galactose, 1 g mannose, 1 g asparagine, 0.5 g yeast extract (Oxoid), and 0.5 g bacteriologic peptone per liter.

Evolutionary History

Fossil Record

The fossil evidence of the evolution of the Phaeophyta is very scanty. This is perhaps because of their generally soft-bodied habit, very limited occurrence of calcified taxa (e.g., *Padina* spp.), and relatively recent evolution compared with red and green algae. The oldest undoubted brown algal fossils are kelps from the Tertiary. Parker and Dawson (1965) described from the upper Miocene fossil kelp, *Julescranea grandicornis,* which is intermediate in appearance between *Pelagophycus* and *Nereocystis. Paleohalidrys, Cystoseirites, Cystoseira,* and *Paleocystophora* have been assigned to the Cystoseiraceae in the Fucales, described from Miocene deposits in California.

Sister Taxa and Divergence Time of Phaeophyceae

It is rather difficult to infer the origin of the brown algae or to clarify the sister relationships with other Phyla, because of the sparse fossil record and lack of known unicellular taxa. The available evidence consists of molecular phylogenetic analyses, and the compositions of accessory photosynthetic pigments (i.e., carotenoids) and cell walls (e.g., presence/absence of cellulose and alginates), fine structure of flagellar apparatus (e.g., presence/absence of transitional helix and rhizoplast), and presence and absence of periplasmic opaque substances. Based on this information, Schizocladiophyceae is considered to be the closest sister group of Phaeophyceae, and both group with Phaeothamniophyceae and Xanthophyceae (Bailey and Andersen 1998; Bailey et al. 1998; Kawai et al. 2003).

The divergence time of Phaeophyceae from Schizocladiphyceae is estimated to be ca. 260 Ma in the Permian Period, based on molecular phylogeny calibrated based on the fossil records of diatoms and brown algae (i.e., *Padina* and *Julescranea*).

Raphidophyceae (Raphidophyta)

9

Takeo Horiguchi

Abstract

The Raphidophyceae are flagellated unicellular algae that live in diverse marine, brackish, and freshwater habitats. Ten genera are currently recognized: *Gonyostomum*, *Merotricha*, *Vacuolaria*, *Chattonella*, *Chlorinimonas*, *Fibrocapsa*, *Haramonas*, *Heterosigma, Psammamonas*, and *Viridilobus* (the first three are freshwater representatives). They are wall-less heterokonts, i.e., the forward flagellum possesses tubular mastigonemes, and both flagella arise from a shallow pit at or near the apex of the cell. All known raphidophytes are photosynthetic and bear multiple plastids containing chlorophylls *a* and c_1 and/or c_2. With the exception of *Chlorinimonas sublosa*, marine species possess fucoxanthin as a major carotenoid, while freshwater representatives lack this pigment. Marine raphidophytes are widely recognized as ichthyotoxic organisms; species such as *Chattonella* spp., *Fibrocapsa japonica*, and *Heterosigma akashiwo* have been associated with finfish kills. Knowledge of the raphidophyte life cycle, cyst formation, and vertical migratory behavior is important for understanding mechanisms of bloom formation. Molecular phylogenetic analyses suggest that (1) the greenish colored freshwater species diverged from brownish colored marine raphidophytes, (2) all three species of the genus *Haramonas* and a species of *Psammamonas* are sand-dwelling and evolved from a marine planktonic ancestor by acquiring characters of benefit to benthic habitats, (3) *Chlorinimonas* is also sand-dwelling, a characteristic that must have been acquired independently from *Haramonas* and *Psammamonas*, and (4) basal lineages of the Raphidophyceae, *Fibrocapsa, Haramonas*, and *Psammamonas*, possess unique carotenoids such as fucoxanthinol (*F. japonica* and *P. australis*)

Summary Classification

●**Raphidophyceae**
●●**Chattonellales**
●●●**Vacuolariaceae** (e.g., *Chattonella*, *Fibrocapsa*, *Gonyostomum*, *Heterosigma*, *Vacuolaria*, *Viridilobus*)

Introduction

General Characteristics

Members of the Raphidophyceae are flagellate unicellular algae. They are wall-less heterokonts: the forward flagellum (approximately the same length as the cell) bears tubular mastigonemes, and both flagella arise from a shallow pit at or near the apex of the cell (Heywood 1978b; Mignot 1976) (Fig. 1). They live as either motile or palmelloid individuals with a usual length of 10–80 μm. They bear multiple plastids containing chlorophylls *a* and c_1 and/or c_2. Marine species possess a xanthophyll, fucoxanthin, as a major carotenoid, although freshwater representatives lack this

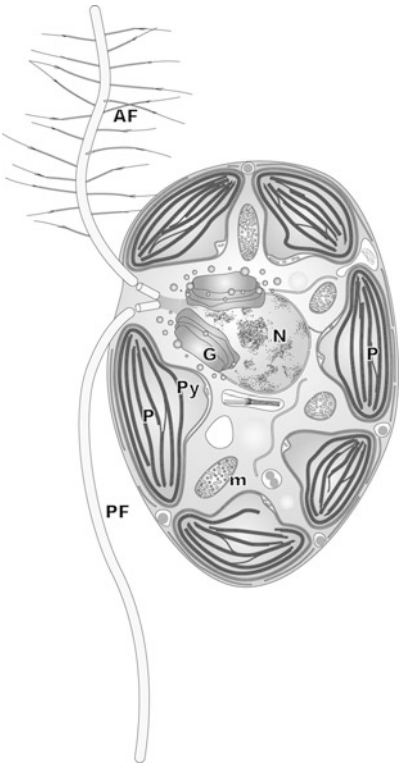

Fig. 1 Schematic illustration of a longitudinal section through a typical marine raphydophyte (*Heterosigma*). A nucleus is surrounded by Golgi body (*G*) and mitochondria (*m*). Plastids (*P*) are located in the periphery of the cell and each chloroplast possesses a projected pyrenoid (*Py*), which is traversed by several thylakoids. The cell possesses an anterior flagellum (*AF*) with tubular mastigonemes and a smooth posterior flagellum (*PF*) (Illustration by Dr. Takeshi Nakayama)

pigment. Sexual reproduction has been documented for a freshwater species (Cronberg 2005; Figueroa and Rengefors 2006). Cyst formation involving alternation of haploid and diploid phases without apparent gamete conjugation in marine raphidophytes has been reported (Yamaguchi and Imai 1994), although another type of cyst formation involving sexual fusion has also been suggested (Demura et al. 2012). The Raphidophyceae is a small group of organisms, with only ten genera (three freshwater and seven marine representatives) currently recognized, all of which are photosynthetic.

Occurrence

Freshwater raphidophyte species usually occur in acidic or neutral pH habitats where the vegetation is abundant. They occur as plankton, among aquatic plants, or adjacent to the mud. Marine species are found in coastal waters, embayments, or in the brackish waters of estuaries. Members of the marine genera *Chlorinimonas*, *Haramonas*, and *Psammamonas* are sand-dwelling (Horiguchi 1996; Yamaguchi et al. 2010; Grant et al. 2013). Although some raphidophyte species are rather rare, e.g., *Haramonas* spp., members of the genera *Gonyostomum*, *Vacuolaria*,

Chattonella, *Heterosigma*, and *Fibrocapsa* are often locally abundant and widely distributed.

Raphidophyte cultures can be obtained from the following sources: Commonwealth Scientific and Industrial Research Organization (CSIRO), The Australian National Algae Culture Collection (ANACC) (Australia), The National Institute for Environmental Studies (NIES) (Japan), The Provasoli-Guillard National Center for Marine Algae and Microbiota (NCMA) (USA), and the Culture Collection of Algae at the University of Texas at Austin (UTEX) (USA). For further information regarding algal collections of the world, see Kasai et al. (2005).

History of Knowledge

Ten genera are currently recognized in the class Raphidophyceae. *Gonyostomum* (Diesing 1865), *Vacuolaria* (Cienkowsky 1870), and *Merotricha* (Mereschkowsky 1879), the three freshwater genera, were first described over a century ago. These genera were grouped into the Chloromonadida (Klebs 1892). Later, Biecheler (1936) recognized that the marine alga *Chattonella* also belongs to this group. Subsequently, the genus *Heterosigma* was established in 1968 by Hada (invalid, no designation of type species) and was later validated by Hara and Chihara (1987). The genus *Fibrocapsa* was established based on material from Japan analyzed by Toriumi and Takano (1973) and the genus *Haramonas* was proposed later (Horiguchi 1996). More recently, the genera *Chlorinimonas* (Yamaguchi et al. 2010), *Viridilobus* (Demir-Hilton et al. 2012), and *Psammamonas* (Grant et al. 2013) have been established.

In the recent phycological literature, these protists are frequently treated as a class of algae, the Raphidophyceae (Heywood 1983; Silva 1980). They have been termed "Chloromonadophyceae" by phycologists and "Chloromonadida" by protozoologists, but these terms are inappropriate since the genus *Chloromonas* does not belong to the Raphidophyceae. Loeblich and Loeblich (1978) include within the family Vacuolariaceae the following genera regarded as valid by most phycologists: *Chattonella*, *Gonyostomum*, *Merotricha*, and *Vacuolaria.* Also included are *Trentonia* and *Swirenkoimonas.* Too little is known to include *Swirenkoimonas* with the raphidophytes. *Trentonia* is probably synonymous with *Vacuolaria* (Fott 1968; Heywood 1983). However, the most controversial aspect of this scheme is treating *Fibrocapsa*, *Heterosigma*, *Olisthodiscus*, and *Hornellia* as synonymous with *Chattonella.* The genus *Hornellia* is probably synonymous with *Chattonella*, since the description of *Hornellia marina* (Subrahmanyan 1954) resembles that of *Chattonella subsalsa* (Biecheler 1936). As noted by Heywood (1990) in the original volume of this handbook, Loeblich and Fine (1977) argued that *Fibrocapsa japonica* (Toriumi and Takano 1973) should be named *Chattonella japonica*, that *Heterosigma inlandica* (Hada 1968) should be named *Chattonella inlandica*, and that *Olisthodiscus luteus* (Carter 1937) should be named *Chattonella luteus.* Heywood (1990) discussed the taxonomic confusion concerning marine raphidophytes at both generic and species ranks. Although Loeblich and Fine

(1977) argued that *Chattonella*, *Heterosigma*, *Fibrocapsa*, and *Olisthodiscus* are congeneric, most researchers now consider these genera to be autonomous (*Olisthodiscus* may in fact not be a raphidophyte at all; see below). In the recent literature, based on molecular phylogenetic study, Yamaguchi et al. (2010) proposed that the class Raphidophyceae should consist of a single order, Chattonellales, which contains a single family, Vacuolariaceae.

Hara and coworkers (Hara and Chihara 1982; Hara et al. 1994) recognized seven species of *Chattonella*, i.e., *C. subsalsa*, *C. antiqua*, *C. marina*, *C. ovata*, *C. minima*, *C. globosa*, and *C. verruculosa*. One original member of the genus *Chattonella*, *C. verruculosa*, is now regarded to be a member of the class Dictyochophyceae and has been transferred to the new genus *Pseudochattonella* (Hosoi-Tanabe et al. 2007). Another new genus, *Verrucophora* was established for a species, formally referred to as *Chattonela* cf. *verruculosa* from the North Sea and the Skagerrak (Edvardsen et al. 2007). The type of species of *Verrucophora*, *V. farcimen*, is closely related to *P. verruculosa*, but not identical. Although Edvardsen et al. (2007) transferred *C. verruculsa* to a new genus, a new nomenclatural combination proposed by Hosoi-Tanabe et al. (2007) seems to have priority. Similarly, another member of the genus *Chattonella*, *C. globosa*, was found to be a member of the Dictyochophyceae and was transferred to a new genus, *Vicicitus* (Chang et al. 2012).

Among true *Chattonella* species, there have also been taxonomic problems. *Chattonella antiqua*, *C. marina*, and *C. ovata* have been distinguished from each other solely based on their morphological characters. Recent genetic analyses, however, revealed that these three species are almost identical (e.g., Bowers et al. 2006; Kamikawa et al. 2007). After careful examination of both morphology and genetic diversity, Demura et al. (2009) concluded that these three species should not be treated as independent species. However, they also found that there were distinct tendencies toward specific differentiation with regard to genetic divergence, morphology, and ecophysiological differences. Therefore, they concluded that these three taxa occupy an intermediate stage between a single, unified species and three distinct and independent species; they proposed to treat them as varieties within a species, i.e., *C. marina* var. *marina*, *C. marina* var. *antiqua*, and *C. marina* var. *obata*. Klöpper et al. (2013) demonstrated that the strains identified as *C. subsalsa* in fact consist of two different species, and the strains from the western Adriatic coast (Mediterranean Sea) more closely match the original species description. Using microsatellite markers, Demura et al. (2014) attempted to reveal putative sources of populations of *C. marina* var. *antiqua* and *C. marina* var. *marina* along Japanese coasts.

A toxic marine species, *Heterosigma akashiwo*, has been the focus of extensive ecological, biochemical, physiological, and molecular studies. Readers are advised to note that in the 1970s and 1980s, this alga was erroneously identified as *Olisthodiscus luteus*, until Hara and Chihara (1987) sorted out the taxonomic confusion. Not like *Heterosigma*, true *Olisthodiscus luteus* (Carter 1937) is benthic and swims without rotating movement. Although often assigned to the class Raphidophyceae, true *Olisthodiscus luteus* is different from members of the class

in many ultrastructural features (Hara et al. 1985; Inouye et al. 1992). Furthermore, preliminary molecular phylogenetic study indicates that *O. luteus* is not a member of the Raphidophyceae (unpublished data by H. Yamaguchi, Yamaguchi et al. 2008). In addition to confusion regarding *O. luteus*/*H. akashiwo*, there has been debate as to which specific epithet should be used. It is now generally accepted that there is only one species in the genus *Heterosigma* and the species name *H. akashiwo* is appropriate and valid (for details, see Hara and Chihara 1987).

Practical Importance

Freshwater raphidophytes are generally rare and, when present, often occur in low densities. However, *Gonyostomum semen* forms dense blooms and affects lakes used for recreation. The alga discharges mucilaginous strands upon contact, thereby covering bathers with a slimy layer causing itching and other allergic reactions (Cronberg et al. 1988; Figueroa and Rengefors 2006). Members of the marine genera *Chattonella*, *Fibrocapsa*, and *Heterosigma* are often locally abundant (Hollande and Enjumet 1956; Subrahmanyan 1954; Hallegraeff and Hara 1995) and are regarded as nuisance algae worldwide.

Marine raphidophytes often cause extensive negative impact on fisheries all over the world. One of the worst cases reported was the killing of >14 million yellowtail fish (*Seriola quinqueradiata*) by *Chattonella antiqua* in Harmina-nada, Seto Inland Sea, Japan, in 1972. This resulted in the loss of 71 billion yen and a loss of 6.3 billion yen was recorded in subsequent years (1977–1979) in the same area (Okaichi 1997). *C. marina* killed 1700 t of bluefin tuna (*Tunnus maccoyii*) (US $40 million loss) in South Australia (Hallegraeff et al. 1998). In New Zealand, significant mortality of Chinook salmon (NZ $17 million loss) caused by *Heterosigma* was documented (Chang et al. 1990).

Habitats and Ecology

Freshwater raphidophytes have been reported from North America (Drouet and Cohen 1935), South America (Skvortzov et al. 1969; Menezes and Bicudo 2010), Australia (Ling and Tyler 2000), Asia (Jao 1978), and Europe (Fott 1968; Kusber 2003; Cronberg 2005). Marine raphidophytes are known from the coasts of all continents except for the Antarctic.

Species of *Gonyostomum* have frequently been reported from the planktonic fraction or from the vicinity of aquatic plants in water of pH 3.2–7.0. *Gonyostomum latum* was found in water of pH 6.7–7.0 (Fott 1968). The most frequently occurring *Gonyostomum*, *G. semen*, has been reported in water of pH 4.4–6.2 (Drouet and Cohen 1935; Heywood 1980); most reports of its occurrence were from the warmer months of the year (e.g., April to October in the northern hemisphere). Since *G. semen* frequently lives in the immediate vicinity of *Sphagnum*, water squeezed from *Sphagnum* moss may provide a good source of this raphidophyte. *G. semen*

seems to have expanded its habitats to more nutrient-rich waters. Blooms of this species appear every summer in many lakes in southern Sweden, in large parts of Finland, Norway, France, and Czech Republic (Cronberg 2005). Recent studies, including genetic analyses, also show expansion of *G. semen* in Northern Europe (Lebret et al. 2013; Hagman et al. 2015). *Vacuolaria* species also occur with aquatic plants in fresh waters of acidic or neutral pH (Heywood 1983). *V. virescens*, the most frequently occurring species, has been reported from water of pH 4.0–8.3 (Graffius 1966), but it is usually found in neutral or slightly acidic conditions. *V. virescens*, reported from bogs, ponds, lakes, and mountain streams (Cienkowsky 1870; Graffius 1966; Poisson and Hollande 1943; Spencer 1971), occurs in the plankton near aquatic plants or in the layer of water adjacent to the bottom mud. *V. virescens*, tolerant of low temperatures, was found to be present in large numbers in a pond with patches of surface ice (Spencer 1971). *V. viridis* has been collected on only a few occasions from swamps and small ponds containing rich aquatic vegetation (Fott 1968). *Merotricha* (only a single species described, *M. bacillata*) has also been found in the plankton or in the vicinity of aquatic plants from bogs, reservoirs, ponds, and the mouth of a river (Graffius 1966; Mereschkowsky 1879; Palmer 1942; Skvortzov et al. 1969).

Chattonella subsalsa, first collected in southern France in organic-rich brackish water (Biecheler 1936), was also present in the port of Algiers, France (Hollande and Enjumet 1956) and in Delaware's Inland Bays, USA (Portune et al. 2009). *C. subsalsa* occurs during the late summer or early autumn in water rich in organic material, frequently at high densities (Biecheler 1936; Hollande and Enjumet 1956; Mignot 1976). *C. antiqua* has been observed from various parts of Japan and has also been found along the Dutch coast (Vrieling et al. 1995). *C. antiqua* was found to grow well at 25 °C, at salinities between 25 ‰ and 41 ‰ under light intensity above 0.04 ly min^{-1}. The pH (7.6–8.3) did not affect growth rate (Nakamura and Watanabe 1983). *C. antiqua* is known to exhibit characteristic diurnal vertical migration, i.e., the cells are concentrated near the surface during day time and near the bottom at night. The species can form red tides during summer, when the thermal stratification is striking and this vertical migration is thought to be advantageous over diatoms. The migratory ascent at daytime keeps them in the euphotic zone and the descent at night provides access to the nutrient-rich bottom waters (Watanabe et al. 1983; Imai and Yamaguchi 2012). Shikata et al. (2013) demonstrated that the blue light regulates diurnal vertical migration behavior in *C. antiqua*. *C. marina* has a wide distribution and has been found in India (Subrahmanyan 1954), Japan (Imai 1989), Hong Kong (Kai et al. 2006), Russia (Morozova and Orlova 2005), a Swedish fjord (Waite and Lindahl 2006), North America (Bowers et al. 2006), Mexico (Band-Schmidt et al. 2004), Australia (Hallegraeff et al. 1998), and New Zealand (Rhodes et al. 2001). *C. ovata* has been reported in Japan (Hara et al. 1994) and Hong Kong (Kai et al. 2006). *C. minima* was originally reported from Seto Inland Sea, Japan, and seems to have very limited distribution. Because of its ability to produce dormant resting cysts, *Chattonella* species seem to adapt well to the temperature regime in temperate seas such as the Seto Inland Sea of Japan where extensive blooms occur (Imai and Itoh 1987). For various aspects of the biology of *Chattonella* spp.,

including biological control of their blooms, see the comprehensive review by Imai and Yamaguchi (2012).

Heterosigma akashiwo also has a global distribution and occurs in subtropical or temperate, marine or brackish waters. Species occurrence includes Canada, Japan, New Zealand, North America, England, Norway, Peru, Portugal, Chile, Singapore, Korea, Ireland, Denmark, China, Spain, Thailand, Namibia, Australia, and Mexico (Ki and Han 2007 and references therein). The optimum pH for growth of *H. akashiwo* was described as 8.5–9.0 (Iwasaki and Sasada 1969). *H. akashiwo* grows well at a salinity range from 20 ‰ to 30 ‰ with maximum growth at 25 ‰ (Haque and Onoue 2002), but the organism can also tolerate low salinity such as <6 (Strom et al. 2013). During the summer, *H. akashiwo* is the dominant species in the phytoplankton of Narragansett Bay, Rhode Island. It grows to maximum densities from May to August when nitrogen concentration is low and phosphate concentration is close to its yearly maximum (Tomas 1979). Laboratory experiments indicate that at saturating and subsaturating nitrogen (N) concentrations, N uptake preference is as follows: $NH_4^+ > NO_3^- >$ urea (Herndon and Cochlan 2007). The organism is known to exhibit characteristic diurnal vertical migration as described for *C. antiqua* (Watanabe et al. 1983; Yamochi and Abe 1984). The occurrence of cysts has been reported (Imai et al. 1993; Kim et al. 2015).

Fibrocapsa japonica, the only species in the genus, was originally isolated in seawater of pH 8.4 and at a temperature of 18.6 °C (Toriumi and Takano 1973). *F. japonica* has a worldwide distribution mainly in coastal warm and cold temperate regions and has been found in North America (Pacific and Atlantic sides), South America (Brazil), Europe (Atlantic and Mediterranean Sea), East Asia, Australia, and New Zealand (De Boer et al. 2005). A culture study using three *F. japonica* strains from different climate regions revealed the species is viable between 4 °C and 32 °C, thus indicating that the species is eurythermal. The species living in cold temperate regions, e.g., the German Wadden Sea, must experience temperatures below 4 °C, and the presence of a resting stage is expected to survive in this region (De Boer et al. 2005).

Three species in the genus *Haramonas* have been described. *H. dimorpha* was found in the bottom sand (mud) of a tropical mangrove river in northeast Australia (Horiguchi 1996) and later it was found in sand samples from Okinawa, subtropical Japan (Horiguchi, unpublished observation). A relatively localized bloom of *H. dimorpha* on the sand surface below the low tide mark on an Australian beach was noted (Chiovitti et al. 2006). *H. viridis* is a cold temperate species described from island of Sylt (eastern North Sea), Germany (Horiguchi and Hoppenrath 2003). The third species, *H. pauciplastida* was found in the beach sand of Vancouver Island, Canada (Yamaguchi et al. 2008). This genus is thus distributed from tropical to cold temperate regions. Another characteristic of *Haramonas* is having dimorphic phases in a life cycle, i.e., spherical nonmotile cells alternate with elongated motile cells (Fig. 2a, b).

The genus *Chlorinimonas* presently contains only one species, *C. sublosa*, which was discovered in sand samples of temperate regions in Japan. In culture, *C. sublosa* stays at the bottom of the culture vessel and does not behave like “typical” plankton.

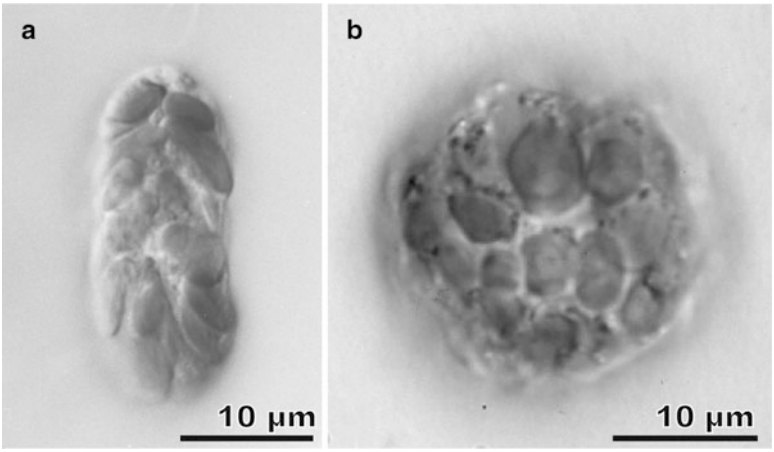

Fig. 2 LM photographs of the marine raphidophyte *Haramonas dimorpha*. (**a**) Typical motile cell. (**b**) Nonmotile spherical cell

The genus *Viridilobus* contains a single species, *V. marinus*, which can form dense blooms in Delaware's Inland Bays in the United States and can even grow when the salinity is almost zero (Demir-Hilton et al. 2012). The genus *Psasmmosa* also consists of a single species, *P. australis*, which is sand-dwelling and possesses two different morphological phases in a cell cycle. It can also produce unique "rafts," formed from 2 to 30 or more cells. The amoeboid movement of cells was also noted (Grant et al. 2013).

Although members of the Raphidophyceae are photosynthetic, mixotrophy, ingestion of bacteria in particular, was observed in *Heterosigma akashiwo* and in *Chattonella ovate*, *C. subsalsa*, and *Fibrocapsa japonica* (see Jeong 2011 and references therein).

Characterization and Recognition

Cell Structure

Raphidophyte cells vary from ovoid or pyriform to approximately spherical in shape; some species are flattened dorsiventrally and bear a furrow on the ventral surface. Biochemical, ultrastructural, and molecular information suggests that raphidophytes belong to the Heterokontophyta (photosynthetic stramenopiles) (e.g., Ali et al. 2002; Horn et al. 2007). The anterior flagellum beats rapidly and is responsible for the forward movement of the cell. The other flagellum moves infrequently and lacks tubular mastigonemes; it trails posteriorly over the ventral surface of the cell.

Plastids of freshwater species are usually bright green in color, while marine representatives are yellowish brown, although there are a few exceptions.

Chlorophylls *a* and c_1 and/or c_2 are present. The carotenoid pigments of freshwater raphidophytes are β, β-carotene, diadinooxanthin, heteroxanthin, and vaucheriaxanthin (Bjørnland and Liaaen-Jensen 1989). Fucoxanthin has been identified in all marine genera as a major carotenoid (Bjørnland and Liaaen-Jensen 1989), except for one species, *Chlorinimonas sublosa*. In the latter species, like freshwater representatives, no fucoxanthin was detected and diadinoxanthin was identified as a major xanthophyll (Yamaguchi et al. 2010). Distribution of minor carotenoids among marine raphidophytes is variable (Mostaert et al. 1998). Multiple plastids are present in the outer region of the cell between the plasmalemma and the layer of cytoplasm surrounding the nucleus (=exoplasm) (Figs. 1, 2a, b, and 3). Plastids are usually planoconvex or discoid in shape and may attain sizes up to 3 µm wide by 5 µm long. Lamellae, consisting of three thylakoids, extend approximately parallel to the longitudinal axis of the plastid (Figs. 1, 3, and 4a). A girdle band is present in *Gonyostomum*, *Vacuolaria*, and *Heterosigma* (Fig. 1) (Heywood 1980; Hara and Chihara 1987) but typical girdle lamellae appear to be absent in *Chattonella*, *Fibrocapsa*, *Haramonas*, and *Chlorinimonas* (Mignot 1967, 1976; Hara and Chihara 1985; Yamaguchi et al. 2008, 2010). Pyrenoids, present in the plastids of most marine species (Figs. 1, 3, and 4a), have not yet been reported in freshwater species (Heywood 1980; Loeblich and Fine 1977; Mignot 1967, 1976; Hara and Chihara 1982, 1985, 1987; Horiguchi 1996; Horiguchi and Hoppenrath 2003; Yamaguchi et al. 2008, 2010; Demir-Hilton et al. 2012). However, some species of freshwater representatives, e.g., *G. depressum*, may in fact possess a pyrenoid (Fig. 4a, Yoshiaki Hara and Hanae Takahira, personal communication 2013). The reserve food material is suggested to be 1, 3-β-D-glucan, which is comparable to chrysolaminarin of diatoms (Chiovitti et al. 2006). No eyespots have been reported.

(**a**) Close-up of plastid of a freshwater raphidophyte, *Gonyostomum depressum*, showing the presence of a pyrenoid (*Py*). *M* mitochondria (Photograph courtesy of Dr. Yoshiaki Hara and Ms. Hanae Takahira) (**b**) Close-up of the pyrenoid region of *Haramonas viridis*, showing the periplastidal network (*arrow*). (**c**) Close-up of raphidophyte mitochondria (*m*) (*Haramonas dimorpha*), which contains tubular cristae

The plastids of raphidophytes are of secondary endosymbiotic origin as in other heterokont algae. The plastid is surrounded by four membranes: the inner and outer envelope membranes (IEM and OEM), the periplastid membrane (PPM), and the outermost membrane, referred to as the chloroplast endoplasmic reticulum (CER) (Ishida et al. 2000). Small vesicles, termed the periplastidal network (Hibberd 1976), are present between the OEM and PPM at the surface of the projected pyrenoid (Figs. 1 and 4b). The process of plastid division in *Heterosigma akashiwo* was investigated, and it was revealed that an electron-opaque annular structure (plastid-dividing ring or PD ring) girdles the constricting isthmus of the dividing plastids. The inner membranes (IEM and OEM) constrict in advance of the outer two membranes, and the PD ring was observed at the outer surface of the inner pair (Hashimoto 1997). The membrane topology and plastid protein targeting system of *H. akashiwo* was investigated as a model system of organisms with multiple plastids of secondary origin (Ishida et al. 2000). The CER membrane is connected to the endoplasmic reticulum (ER) and in turn, the ER membrane is continuous with outer nuclear envelope. Therefore, the chloroplasts (plastids) of raphidophytes are located within the ER lumen, as in single-plastid containing heterokonts (Ishida et al. 2000). Using an in vitro system, Ishida et al. (2000) hypothesized that nuclear-encoded plastid protein precursors that have been cotranslationally transported into the ER lumen are sorted in the ER and transported to the plastid through the ER lumen

(**b**) TEM longitudinal section through a nonmotile cell of *H. dimorpha*, showing the "tubular invagination" (*arrow*). Note that the cell is surrounded by mucilaginous material (*arrowheads*). (**c**) Close-up of the tubular invagination (*TI*) of *H. dimorpha* (Images shown with permission from Phycological Research, Wiley and Sons)

(Ishida et al. 2000; Ishida 2005). *H. akashiwo* has been also used to study various aspects of plastid molecular biology (e.g., Duplessis et al. 2007).

Raphidophyte mitochondria, which possess tubular cristae, are especially numerous in the layer of cytoplasm surrounding the nucleus (Fig. 4c), although some occur in the more peripheral regions of the cell. A distinctive feature is the presence of a large Golgi network over the anterior surface of the nucleus (Figs. 1 and 5a) (Heywood 1980, 1990; Mignot 1967, 1976). A contractile vacuole, which may reach up to 10 µm in diameter, occurs between the Golgi and the kinetosomes in freshwater genera but not marine genera (Heywood 1983; Mignot 1967, 1976; Toriumi and Takano 1973; Hara and Chihara 1982, 1985, 1987; Horiguchi 1996; Horiguchi and Hoppenrath 2003; Yamaguchi et al. 2008, 2010; Demir-Hilton et al. 2012).

Neither scales nor cell walls are present in the raphidophytes, but extracellular material may be produced by extrusome organelles, mucocysts, and trichocysts, which occur in many species. Trichocysts can expel their mucilaginous contents considerable distances (Drouet and Cohen 1935; Toriumi and Takano 1973). Oboe-shaped mucocysts are a characteristic feature of *Chattonella subsalsa* (Biecheler 1936; Klöpper et al. 2013). Material produced by the mucocysts may surround a motile individual with mucilage so that it becomes palmelloid. Members of the genus *Haramonas* produce copious amounts of mucilage (Fig. 5b) (Horiguchi 1996; Horiguchi and Hoppenrath 2003; Yamaguchi et al. 2008).

An unusual structure, the tubular invagination, has been found in all three species of the genus *Haramonas*. The structure can be observed throughout the cell cycle. It opens directly to the outside of the cell (Fig. 5b, c) and appears hollow and devoid of any kind of material. The plasmalemma of the tubular invagination is supported by a

single layer of many underlying small, flattened vesicles, resembling the amphiesma of dinoflagellates (see ▶ Dinoflagellata). These vesicles are, in turn, surrounded by one or two layers of small spherical vesicles, which contain fibrous materials. The function of this structure is currently unknown (Horiguchi 1996; Horiguchi and Hoppenrath 2003; Yamaguchi et al. 2008).

The large nucleus (up to 20 μm in length) and chromosomes (1–12 μm in length at metaphase) have prompted several investigations of nuclear cytology (Heywood 1978a, 1980; Mignot 1967; Poisson and Hollande 1943). Interphase chromatin is often recognizable as fine threads. Chromosomes condense during mitosis and their chromatids become attached to opposite poles by kinetochore microtubules. Spindle microtubules, formed around the kinetosomes, enter the nucleus through gaps at the poles of the nuclear envelope at prophase. By metaphase the chromosomes have become aligned across the equator of the nucleus, and the one or more nucleoli have begun to disperse. Well-spread chromosome preparations from metaphase cells indicate that there are 97 ± 2 chromosomes in *V. virescens* and 65–75 chromosomes in *G. semen* (Heywood 1980). In V. *virescens*, a Golgi and contractile vacuole occur at each pole of the mitotic nucleus; this arrangement ensures their segregation to progeny cells. The original nuclear envelope remains intact over most of its surface until telophase; at this stage new nuclear envelope has begun to be assembled over much of the surface of the chromosome groups (Heywood 1978a). Light microscopic investigation suggests that nuclear envelope behavior is similar in other raphidophytes (Heywood 1978a). Little is known about the biochemistry of raphidophyte nuclei, but their nuclear DNA has been analyzed and found to have a guanine plus cytosine content of 35% in *G. semen* and 34% in *V. virescens* (Rae 1976). Nemoto et al. (1987) reported that light irradiation is necessary for nuclear DNA replication in *Chattonella antiqua* and that the timing of the replication is dependent upon only the timing of the onset of the last irradiation.

Flagella and Flagellar Apparatus

The raphidophytes possess two heterodynamic flagella. The anterior flagellum possesses tripartite tubular mastigonemes, while the posterior flagellum is smooth in surface (Fig. 1) (Karpov 2000). There is no transitional helix in the transition zone of the flagella (Hibberd 1979). Neither flagellar swelling nor flagellar autofluorescence has been detected in the raphidophyte algae (Kawai and Inouye 1989). Only a limited amount of information concerning flagellar apparatuses is available for the Raphidophyceae (Mignot 1967, 1976; Heywood 1980; Vesk and Moestrup 1987; Horiguchi and Hoppenrath 2003; Yamaguchi et al. 2008, 2010). The flagellar root system of *H. akashiwo* was described as comprising three roots, i.e., (1) the rhizoplast, a massive crossbanded fibrous root, which extends from near the proximal ends of both basal bodies to the anterior surface of the nucleus (Fig. 6a), (2) a compound microtubular root with a layered structure, associated with the anterior flagellum and extending the anterior surface, and (3) the rhizostyle, which passes between the two basal bodies leading anteriorly to a vesicle in the flagellar

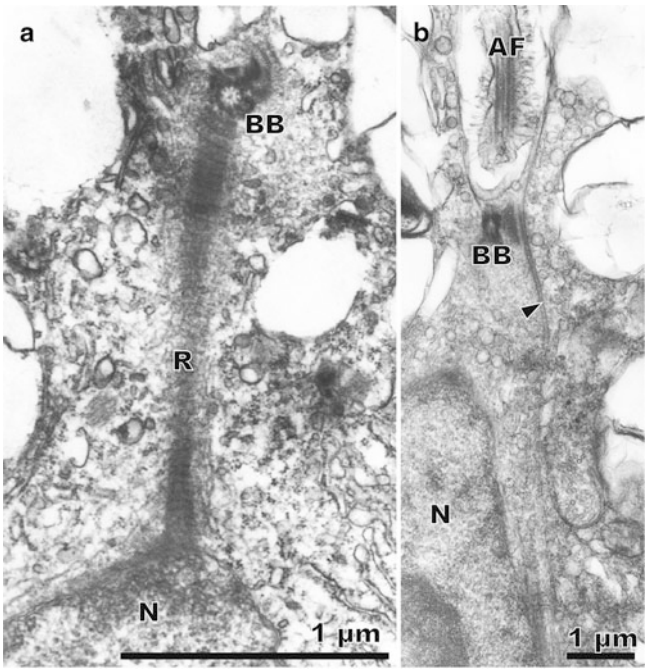

Fig. 6 TEM photographs of the marine raphidophyte *Haramonas viridis*. (**a**) Close-up showing part of the flagellar apparatus, with one of basal bodies (*BB*) and rhyzoplast (*R*) visible, the latter connecting the nucleus (*N*) and basal body. (**b**) Image shows the rhyzostyle (*arrowhead*) running toward the anterior and posterior parts of the cell. *AF* anterior flagellum, *BB* basal body (Images shown with permission from Phycological Research, Wiley and Sons)

groove region and following the nucleus posteriorly, terminating deep in the cytoplasm (Vesk and Moestrup 1987). All raphidophyte species so far examined possess a rhizoplast (Fig. 6a). The presence of a rhizostyle (Fig. 6b) also seems to be a common feature of the class (Vesk and Moestrup 1987; Horiguchi 1996; Horiguchi and Hoppenrath 2003). The presence of a layered structure associated with basal body of the anterior hairy flagellum was reported in *H. akashiwo* (superficially resembling the MLS (multilayered structure) of green plants but with a different structure) (Vesk and Moestrup 1987). This structure has been found in *Chattonella subsalsa* and *Vacuolaria virescens* and *Gonyostomum semen. Haramonas* spp. seem to have similar structures, but details have yet to be confirmed.

Toxicity

Members of marine raphidophytes are widely recognized as ichthyotoxic organisms. The following species have been associated with finfish kills: *Chattonella antiqua*, *C. marina*, *C. subsalsa*, *C. ovata*, *Fibrocapsa japonica*, and *Heterosigma akashiwo*.

The mechanism(s) of toxicity by these raphidophycean flagellates are not fully understood. Production of brevetoxin or brevetoxin-like compounds was reported for *C. antiqua*, *C. marina*, *F. japonica*, and *H. akashiwo* (Khan et al. 1997; Keppler et al. 2006). *C. antiqua*, *C. marina*, and *C. ovata* are known to produce reactive oxygen species (ROS) such as superoxide, hydroxyl radicals, and hydrogen peroxide, and the ROS generated by *Chattonella* spp. was thought to involve gill tissue injury (Ishimatsu et al. 1996; Hiroishi et al. 2005). It was demonstrated that *F. japonica* and *H. akashiwo* also generate superoxide and hydrogen peroxide (Oda et al. 1997). Marshall et al. (2002) demonstrated that *C. marina* cells contain high levels of potentially toxic polyunsaturated fatty acids such as eicosapentaenoic acid (EPA). Later they found that the presence of superoxide together with a low concentration of EPA accelerated fish mortality rates threefold and thus hypothesized that a synergistic effect between ROS and FFA accounts for the ichthyotoxicity of *C. marina* (Marshall et al. 2003). In a study using *C. marina*, *F. japonica*, and *H. akashiwo* (and a few toxic dinoflagellates), Dorantes-Aranda et al. (2015) demonstrated that ROS plays an important role only with *C. marina* and that ROS may also cause a synergistic effect with the lipids in the alga, producing other toxic compounds through lipid peroxidation. They also suggested that other unknown compounds are involved in ichthyotoxicity by *H. akashiwo*, *F. japonica*, and *C. marina*, some of which clearly have a lipid component (Dorantes-Aranda et al. 2015). *H. akashiwo* was known to have allelopathic interactions with a diatom species, *Skeletonema costatum* (Yamasaki et al. 2007).

Life Cycle and Cyst Formation

Members of the Raphidophyceae reproduce asexually by binary fission. Sexual reproduction was demonstrated in a freshwater species, *Gonyostomum semen* (Cronberg 2005; Figueroa and Rengefors 2006). The fusion of gametes was observed under stressed conditions, such as in old cultures or in medium with N or P depletion (Figueroa and Rengefors 2006). The gametes seem smaller and lighter in color than the vegetative cells (Cronberg 2005; Figueroa and Rengefors 2006). There are discrepancies between two reports concerning the sexual process. According to Cronberg (2005), meiosis, i.e., gamete formation, takes place within the cyst (resting cyst) and fused gametes become diploid vegetative motile cells, while Figueroa and Rengefors (2006) reported that the resting cyst is formed by fusion of gametes and a motile diploid vegetative motile cell is released from the resting cyst. The resting cyst is reported to be spherical, 27–39 μm in diameter, and with a few red droplets (Cronberg 2005; Figueroa and Rengefors 2006).

To understand the seasonal occurrence of noxious red tide raphidophytes such as *Chattonella* spp., *F. japonica*, and *H. akashiwo*, information on life cycles and cyst formation is extremely important. Subrahmanyan (1954) documented sexual reproduction and zygote formation in *C. marina* (as *Hornellia marina*), but the fate of the zygote was not observed. As for *Chattonella*, the cysts of this genus were first identified in the Seto Inland Sea, Japan (Imai and Itoh 1986), and it was subsequently

found that the cysts overwinter in the sediments and play an important role in initiating red tides the following summer (Imai and Itoh 1987). The cysts of *Chattonella* are hemispherical in shape with a diameter of 25–35 μm and usually attaching to a solid surface (Imai 1989). Cyst formation was induced by N depletion in the culture medium, and for germination, the cysts required a dormancy period (>4 months) at low temperature (11 °C) (Imai 1989).

By using microfluorometric analysis, Yamaguchi and Imai (1994) reported the life cycle of *Chattonella antiqua* and *C. marina*. The vegetative motile cells are thought to be diploid. The cyst was formed after meiosis, thus the cyst stage is haploid. The germinated small cell becomes a diploid vegetative motile cell, thus suggesting the occurrence of DNA diploidization without cell fusion (asexual diploidization) sometime after excystment (within 2 days) (Yamaguchi and Imai 1994; Imai and Yamaguchi 2012). On the other hand, Nakamura et al. (1990) observed fusion of "small cells (gametes)" and subsequent formation of the cyst (diploid), suggesting the presence of sexual reproduction. Using a microsatellite marker genotyping technique, Demura et al. (2012) confirmed that vegetative cells of 286 strains analyzed were heterozygous for at least some loci and thus diploid. The result suggests that most *Chattonella* strains undergo sexual reproduction. If asexual diplodization were the case, vegetative cells would be expected to be homozygous, even though diploid. The cysts of *F. japonica* were found to be similar in morphology to those of *Chattonella* but smaller (15–20 μm in diameter) and attaching to the solid substrata (Yoshimatsu 1987). Cyst formation in *H. akashiwo* was also reported (Itakura et al. 1996). The cysts, which are covered with sediment particles and can form a cyst cluster, are mostly spherical, about 10 μm in diameter, possessing a distinct wall and a diagnostic feature called the "structure underneath the lid of germination pore" or SLUG (Kim et al. 2015).

Cell Fixation and Molecular Identification of Species

Because of their delicate nature, it can be difficult to fix raphidophyte flagellates without their cell envelope collapsing by commonly used chemical fixatives. Katano et al. (2009) demonstrated that Hepes-buffered paraformaldehyde and glutaraldehyde works well for fixation of *Chattonella* species (and possibly other raphidophytes, too) and that these fixed cells are amenable to flow cytometry.

Members of the Raphidophyceae can easily change morphology, and it is sometimes difficult to identify species with certainty. For example, Imai (2000) reported that in *Chattonella antiqua* cultures, *C. marina*-like cells were occasionally produced. Precise identification of these harmful species is extremely important to fisheries management. Because some of these harmful species seem to have expanded their distribution rather recently, and toxicity can differ between strains, it is important to know the genetic relationships between strains and species located in geographically separated regions. Molecular methods for species identification

have been developed (Connell 2000, 2002; Tyrrell et al. 2001; Akase et al. 2004; Kai et al. 2006; Bowers et al. 2006; Hosoi-Tanabe et al. 2006; Ki and Han 2007; Kamikawa et al. 2007), and microsatellite markers for identification of *Chattonella* spp. (Demura et al. 2007) and *Heterosigma akashiwo* (Nagai et al. 2006) have been developed.

Maintenance and Cultivation

Enrichment of raphidophytes from mixed natural samples has been achieved by phototaxis (Chapman and Haxo 1966; Mignot 1976; Spencer 1971). Clonal cultures have been obtained for most genera (e.g., Heywood 1973; Loeblich and Fine 1977), and in some instances axenic cultures have been established (Cattolico et al. 1976; Iwasaki and Sasada 1969). Raphidophyte cells are usually sufficiently large and distinctive to be distinguished from other protists under a dissecting or inverted microscope and picked out by a micropipette to establish clonal cultures.

Media and conditions for culturing the freshwater species *Gonyostomum semen* and *Vacuolaria virescens* have been described (Chapman and Haxo 1966; Guillard and Lorenzen 1972; Heywood 1973; Spencer 1971). A series of culturing experiments on raphidophytes was reported by Heywood (1973). The medium used in these studies (Table 1) gave satisfactory growth at 22 ± 1 °C when the cultures were aerated with 4% CO_2 in air and were illuminated by Ecko brand 30 W daylight fluorescent tubes at a light intensity of 210 fc. Cultures were maintained in alternating light and dark regimes or in continuous light; under a continuous light regime, a doubling time of 70.5 h was recorded (Heywood 1973). Subsequently, a completely synthetic medium that promoted more rapid growth was developed (Table 2) which allowed a doubling time of 46.0 h at 24 ± 1 °C under continuous light.

For the culturing of marine species, various types of media have been utilized; most such species are easy to maintain in culture. The widely used media include Provasoli's enriched seawater (Provasoli 1968), f/2 culture medium (Guillard 1975), and modified SWM3 medium (Chen et al. 1969; Yamasaki et al. 2007).

Table 1 Composition of GSP medium containing soil and peat extract

KNO_3	100 mg
K_2HPO_4	10 mg
$MgSO_4$-$7H_2O$	10 mg
Ferric citrate	1 mg
Citric acid	1 mg
Soil extract	100 ml
Peat extract	100 ml
Distilled water	800 ml

From Heywood (1990)
pH adjusted between 5.2 and 6.5

Table 2 Composition of raphidophyte medium (in milligrams per liter)

KNO_3	90
K_2HPO_4	29
$MgSO_4{\cdot}7H_2O$	89
NH_4CL	20
$ZnSO_4{\cdot}7H_2O$	20
$CaCO_3$	8
H_3BO_3	1
$MnSO_4{\cdot}4H_2O$	6
$FeSO_4{\cdot}7H_2O$	4
$Na_2MO_42H_2O$	2
$CoSO_45H_2O$	2
$CuSO_45H_2O$	0.1
EDTA	50
Biotin	1
Thiamine	1
Vitamin B_{12}	0.01

From Heywood (1990)
For *Vacuolaria virescens* the pH was adjusted between 6.3 and 6.5
For *Gonyostomum semen* the pH was adjusted between 5.5 and 5.8

Evolutionary History

There is presently no raphidophyte fossil record. Molecular phylogenetic analyses clearly indicate that members of the Raphidophyceae belong to the division Heterokontophyta (autotrophic stramenopiles) (Potter et al. 1997; Ali et al. 2002; Horn et al. 2007). This phylogenetic placement is justified particularly well by the ultrastructure of their flagella, i.e., an anterior flagellum with tubular mastigonemes. However, the exact phylogenetic affinities of the Raphidophyceae to other members of the Heterokontophyta have not been elucidated.

Yamaguchi et al. (2010), Demir-Hilton et al. (2012), and Grant et al. (2013) published phylogenetic trees of the Raphidophyceae based on the SSU rRNA gene, which has been sequenced from representatives of most raphidophyte genera. Figure 7 summarizes the phylogenetic relationships between genera within the class. The genus *Fibrocapsa* appears to have diverged first within the lineage. The three species of *Haramonas* together with *Psammamonas australis* formed a robust clade as the next deepest diverging lineage, followed by a clade containing the three freshwater genera. Sister to the freshwater raphidophyte clade, a clade containing the marine genera *Chlorinimonas*, *Heterosigma*, and *Chattonella* is resolved. The tree allows some insights into the evolution of raphidophycean algae to be inferred. First, the greenish colored freshwater species diverged from brownish colored marine raphidophytes (Figueroa and Rengefors 2006; Yamaguchi et al. 2010). It is highly likely that the freshwater species are derived from a marine raphidophyte, and loss of fucoxanthin and gain of diadinooxanthin, heteroxanthin, and vaucheriaxanthin

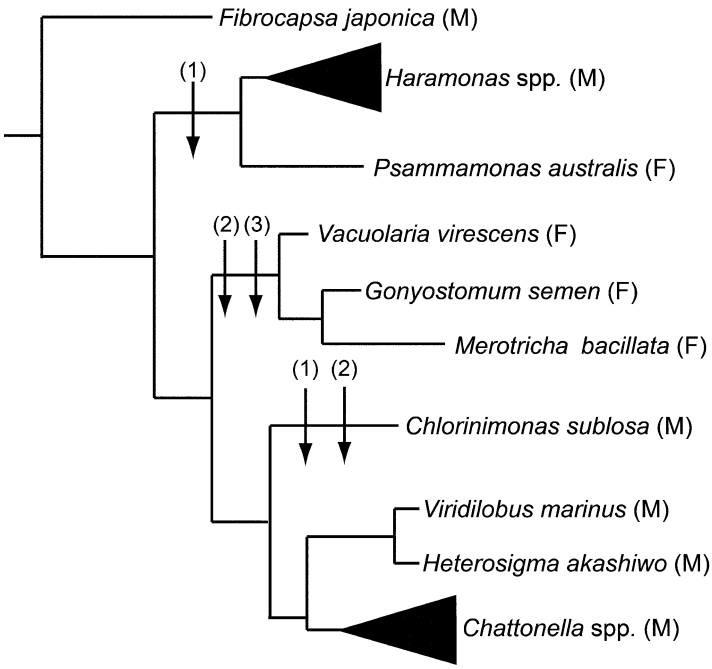

Fig. 7 Schematic diagram depicting the evolutionary relationships between raphidophyte genera based on SSU rDNA phylogenies (see text). (*M*) marine species, (*F*) freshwater species. (*1*) Indicates gain of sand-dwelling habit. (*2*) Indicates loss of fucoxanthin and gain of diadinoxanthin. (*3*) Indicates gain of freshwater-dwelling habit

(Bjørnland and Liaaen-Jensen 1989) took place only once in the lineage leading to freshwater raphidophytes. Second, although being a marine species, *Chlorinimonas sublosa* lacks fucoxanthin and possesses diadinoxanthin like in freshwater representatives. If this SSU-based tree topology is correct, replacement of photosynthetic pigments must have occurred independently in this lineage. Third, all three species of the genus *Haramonas* and a species of *Psammamonas* are sand-dwelling in habit. Since all other marine raphidophytes are planktonic, these three species appear to be derived from a single marine planktonic ancestor, and to have acquired characters that helped them adapted to a benthic habitat. Fourth, *Chlorinimonas* is also sand-dwelling a characteristic it presumably acquired independently from the *Haramonas*/*Psammamonas* lineage. Finally, basal lineages of the Raphidophyceae, viz., *Fibrocapsa*, *Haramonas*, and *Psammamonas*, possess unique carotenoids such as Fucoxanthinol (*F. japonica* and *P. australis*) and 19′-butanoyloxyfucoxanthin (*H. dimorpha*); the significance of the presence of these pigments is currently unknown (Mostaert et al. 1998; Grant et al. 2013). Molecular data from more raphidophyte taxa and additional genes will hopefully provide a more complete framework for understanding the evolutionary history of this fascinating and important algal group.

Chrysophyta

10

Jørgen Kristiansen and Pavel Škaloud

Abstract

The *chrysophytes* (more than 1,200 described species) are unicellular or colonial algae characterized by *heterokont* flagella and chloroplasts with *chlorophyll a* and *c,* and by their endogenous silicified *stomatocysts*. They occur mainly as phytoplankton in temperate freshwaters, and their distribution is ecologically determined, mainly by temperature and pH.

Cells are naked or in many cases surrounded by an envelope, e.g., of species-specific silica scales manufactured from the chloroplast ER and *Golgi* vesicles and transported to the cell membrane and extruded. Photoreceptor systems include a swelling on the short flagellum and a corresponding stigma in one of the chloroplasts. Photosynthesis results in *chrysolaminaran*. But in many species, e.g., in colorless species, organic compounds can be taken up from the water or by phagocytosis. Life history includes mitotic divisions and *encystment*. In many species, *sexuality* – cell fusion followed by *encystment* of the zygote – has been observed. Classification was traditionally based on morphological criteria, including ultrastructure, but in recent years molecular methods have resulted in profound changes in our concepts of relationships and evolution.

Introduction

General Characteristics

The Phylum Chrysophyta is a group of golden-brown microscopic algae and related colorless forms, most of them flagellates (Fig. 1). About 1,200 species in about 112 genera (Kristiansen and Preisig 2001) have been estimated, but many more species will certainly be described. The classification of the phylum with the classes Chrysophyceae and Synurophyceae is shown in Table 1, but the latter class, erected in 1987, should now again be included in the Chrysophyceae due to several recently published molecular investigations (Takishita et al. 2009; Del Campo and Massana 2011; Yang et al. 2012). On the other hand, several taxa previously associated with

Mallomonas, J. Gloeochrysis, K. Phaeoplaca, L.*, *Hydrurus, M. Synura* (After Kristiansen 2005, with alterations)

chrysophytes have been shown to belong to other evolutionary lineages and separated as independent classes: Phaeothamniophyceae, Dictyochophyceae, Pelagophyceae, and Bicosoecophyceae. Accordingly, they are not included here.

A survey of all the genera has been given in the "Encyclopedia of Chrysophyte Genera" (Kristiansen and Preisig 2001).

Occurrence

The great majority of described species are found in plankton of fresh water. Some others are epibiotic or neustonic (i.e., attached to the water surface). A few species are benthic, e.g., found attached to the bottom in streaming mountain rivers. Relatively few known species occur as marine plankton. For example, species of the colorless genus *Paraphysomonas* may play an important role during the formation of sea ice (Ikävalko 2001). However, a recent culture-independent analysis of chrysophyte diversity revealed the existence of several unknown, marine clades (del Campo and Massana 2011) raising the question of the major predominance of chrysophytes in freshwater habitats.

Some chrysophyte species are very common and cosmopolitan, others are rare with peculiar disjunct distributions; however, our knowledge is still very fragmentary but rapidly increasing. Due to the rising number of investigations undertaken almost all over the world, the knowledge of the global distribution of the chrysophytes has increased considerably, especially for the silica-scaled forms, because of their reliable EM identification and documentation based on the silica scales. Thus a number of distribution types have been established (Kristiansen 2001). Of the ~250 species of silica-scaled chrysophytes, about 50 species are widely distributed or cosmopolitan. They have dispersed to suitable localities almost all over the world (Kristiansen 2000). The other species have more or less restricted distributions determined by climatic, historic, ecological, and dispersal factors. The following distribution types have been recognized: Northern temperate-subarctic-arctic species, species with bipolar distribution, and tropical species. A large group of species are endemic, having only been found within a restricted area. In fact, almost all new species start as endemic for the type locality, but most of them sooner or later will also be found in other localities and thus loose endemic status. In 2004, of the 172 described *Mallomonas* species, 69 were considered endemic (Kristiansen and Lind 2005).

The distribution of a species is due to dispersal, mainly of stomatocysts, by birds and by air. Thus the distribution pattern at a given time depends on several factors: dispersal capacity of the species, available vectors, suitable available habitats, and, perhaps most important, sufficient time (Kristiansen 2008). This is in contrast to the ubiquity hypothesis advocated mainly by Finlay and Clarke (1999) that all species are everywhere, only the environment determines the occurrence. This problem is still under discussion, and a sort of compromise has been offered by Řezáčová and Neustupa (2007). However, the ubiquity hypothesis has been contradicted, e.g., by studies in North America where quite similar neighboring water bodies had different floras of silica-scaled chrysophytes (Siver and Lott 2012b).

In addition, the rapidly increasing amount of molecular investigations has revealed the existence of cryptic lineages within the presumably cosmopolitan species, showing restricted distribution patterns. For example, the cosmopolitan *Synura petersenii* s.l. (Fig. 2) has been shown to consist of at least 10 well-defined species, some of them occurring in geographically separated areas (Boo et al. 2010; Kynčlová et al. 2010; Škaloud et al. 2012, 2014). Probably the most striking example is the distribution pattern of *S. hibernica* restricted to an extremely small biogeographic area of western Ireland (Škaloud et al. 2014).

Literature

Important identification works: The most comprehensive identification work today on freshwater chrysophytes is in the "Süsswasserflora von Mitteleuropa" by Starmach (1985) and Kristiansen and Preisig (2007), the latter based on electron microscopy of silica scales. In addition, there are regional floras from, e.g., British Isles and North America, where the chrysophytes have been treated by Kristiansen and Preisig (2011), Siver (2003), and Nicholls and Wujek (2003), respectively.

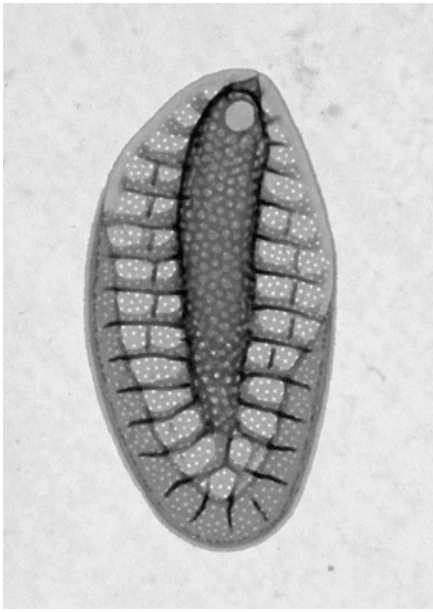

Fig. 2 Silica scale of *Synura petersenii*. × 20,000

A survey of all chrysophyte genera has been compiled by Kristiansen and Preisig (2001). A general account of chrysophytes and their biology has been given by Kristiansen (2005). Further useful references are Pienaar (1980), Kristiansen and Takahashi (1982), and Round (1986).

The scale-bearing species, as seen in the electron microscope, were first surveyed by Takahashi (1978) and, more recently, the Synurales by Kristiansen and Preisig (2007). This was supplemented by the work on *Paraphysomonas* and related genera by Preisig and Hibberd (1982, 1983) and by Scoble and Cavalier-Smith (2014). A recent review on the taxonomy of silica-scaled chrysophytes has been published by Škaloud et al. (2013).

History of Knowledge

Knowledge of the chrysophytes was initiated by the Danish naturalist O. F. Müller who, in his famous work *Animalcula Infusoria* (1786), depicted and named the colorless *Volvox vegetans,* which is now known as *Anthophysa vegetans.* A systematic survey of microorganisms, among them many chrysophytes, culminated in Ehrenberg's (1838) magnificent work, in which species of *Synura, Dinobryon,* and *Uroglena* were depicted and described.

The first precise descriptions of chrysophytes are found in the authoritative work of Stein (1878); many of his illustrations are still used in modern textbooks.

Many species were subsequently described and placed with other flagellates in the animal kingdom. Pascher (1913, 1914, and in a long series of papers) established the botanical position of these algae. He defined the class Chrysophyceae, showing also how chrysophytes resemble the diatoms, the brown algae, and others. He demonstrated parallel evolution in the major algal groups: like other algal taxa, the Chrysophyceae evolved from flagellates to multicellular organization levels, which retained swarmers of the ancestral flagellated types. Based on these principles, Bourrelly (1957) published his *Recherches sur les Chrysophycées,* including all available light microscopy information on these protists. Later, Bourrelly (1965) considered flagellar number as the main taxonomic criterion.

Knowledge of the chrysophytes has advanced considerably since then by the introduction of electron microscopic techniques that reveal cell structure, flagellar systems, and cell envelopes. Understanding of their taxonomy has greatly progressed, so that life cycles and sexuality can be recognized, and studies on the ecology and distribution of the individual species can be carried out. Chlorophylls and the accessory pigments have been identified and their functions elucidated by improved biochemical methods (Kristiansen 2005). However, our knowledge is still fragmentary and based on investigations of rather few species. Introduction of molecular methods has greatly enhanced our understanding of taxonomic relationships, as will be discussed in the final chapter.

Practical Importance

The practical use of chrysophytes is restricted to the laboratory: *Ochromonas* species have served as experimental organisms for many investigations of general biological importance, viz., the freshwater species *Ochromonas danica* for secretion of organic compounds such as vitamins into the environment (Aaronson et al. 1971). *Poteriochromonas malhamensis* has been used for determining the toxicity of lead compounds (tetraethyl lead) as antiknock additives to gasoline (Röderer 1980).

Because of their narrow ecological spectra, silica-scaled chrysophytes can serve as indicators for changes in trophic conditions, in particular of pH in lakes (Smol et al. 1984; Siver and Hamer 1990). Silica structures, such as stomatocysts and scales (Figs. 3 and 4), are used in sediment studies in geology and limnology, often together with pollen analysis, to study the history of lakes (e.g., Nygaard 1956; Munch 1980; Smol 1980; Adam and Mahood 1981; Carney and Sandgren 1983; Cronberg 1986; Siver and Smol 1993; Siver and Marsicano 1996). Changes in pH (acidification) and anthropogenic influence can readily be followed.

Some chrysophytes, e.g., the genera *Synura* and *Uroglena*, may become a nuisance when they occur in great quantities, because they excrete fishy-smelling ketones and aldehydes (Collins and Kalnins 1972). They may foul drinking water reservoirs (Watson et al. 2001; Watson and Satchwill 2003).

Fig. 4 Silica scale of *Mallomonas acaroides*

Habitats and Ecology

Chrysophytes occur mainly as phytoplankton, and standard phytoplankton methods are used in their collection. Although planktonic species are obtained in plankton nets of suitable mesh, e.g., 20 μm, a great many nanoplankton species pass through. These must be obtained directly from water samples brought to the laboratory. Most chrysophytes are very fragile; thus, transport to the laboratory should take place in a thermos or on ice and living material should be examined as soon as possible. Immediate preservation of field samples for light microscopy and counting is made by Lugol's solution modified with the addition of acetic acid; glutaraldehyde is used for electron microscopy.

Material from water samples should be concentrated (by filtration or centrifugation) for examination in the laboratory. To determine species diversity and abundance, an inverted microscope is indispensable. Lugol-fixed material is inspected in sedimentation chambers of defined volume viewed from below in an inverted microscope for quantification; this is also a way to detect many very small forms.

To detect and identify many of the scale-covered species, electron microscopic examination is required. Material is dried on formvar-coated grids and often shadow casting with a heavy metal (e.g., gold-palladium or chromium) is necessary to enhance contrast and to show three-dimensional structures in TEM. SEM is increasingly used for identification (e.g., Siver 1991).

Most chrysophytes occur as plankton in lakes and ponds. Only few, such as *Hydrurus*, are found attached to stones in running waters (Parker et al. 1973). Some few species occur as neuston attached to the surface layer; *Chromophyton* may cover small forest ponds with a golden layer, in the quantity of two million cells per cm^2 (Molisch 1901; Frølund 1977).

Typical freshwater chrysophyte habitats are humic, neutral, or slightly acidic lakes and ponds with a moderate supply of nutrients. Here the chrysophytes may constitute the main phytoplankton biomass. In more acidic, low nutrient, or alkaline waters, few species occur but sometimes at high cell numbers. Ponds surrounded by agricultural land, unless polluted by cattle, are often very rich in chrysophytes. Species of scaled chrysophytes can be arranged along a trophic gradient in relation to their trophic demands, their trophic scores (Siver and Marsicano 1996).

Many species have well-defined occurrence ranges regarding pH; they can thus be arranged as acidobiontic, acidophilic, indifferent, alkaliphilic, and acidobiontic species (compare Kristiansen 1975 and 2005). The ecological tolerances of species differ greatly even between species of which many are distinguishable only by electron microscopy (Fig. 5). *Synura sphagnicola* (Fig. 6), for example, occurs only in acidic water, while other *Synura* species occur only in alkaline water or are more broadly adapted, e.g., the nearly ubiquitous *S. petersenii*. However, as already mentioned, this species has been shown to include a number of cryptic species with presumably different ecological preferences.

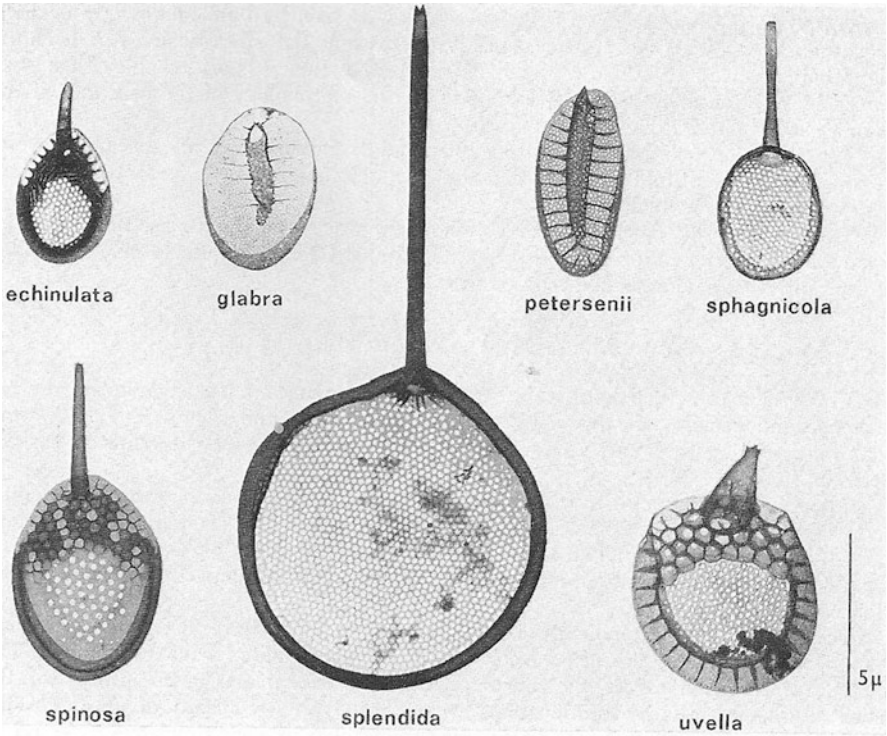

Fig. 5 Scales of species of *Synura*, originally defined on structural characters, but now additional molecular information is necessary

Most species have their main occurrence in spring, often just after ice break. Many species are restricted to cold or cool water, thus in temperate regions occurring in spring and autumn, others prefer warmer water in summer.

There are only few true marine species described (Scoble and Cavalier-Smith 2014). Until recently, the sea was considered to be crowded with chrysophytes, but as several "splinter groups", e.g., Dictyochophyceae (Ostroff et al. 1980; Moestrup and Thomsen 1990), Phaeothamniophyceae (McLachlan et al. 1971), and Pelagophyceae (Lewin et al. 1977) have been shown to have other affinities (Moestrup 1995), the number of marine species has been reduced considerably. Among the most abundant former marine chrysophytes are the silicoflagellates (Dictyochophyceae). However, as already mentioned, the marine diversity of true chrysophytes is probably much greater than previously realized (del Campo and Massana 2011).

Species of *Paraphysomonas* (Preisig and Hibberd 1982) are found both in fresh and sea water, and they may occur in quantities during sea ice formation (Ikävalko 2001). As colorless phagotrophic organisms attached to "marine snow," they may play an important role in the marine food web (Lim et al. 1999).

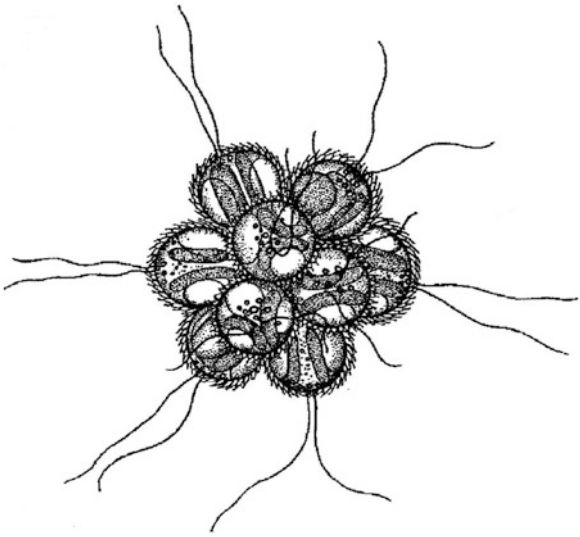

Fig. 6 *Synura sphagnicola* a motile, colonial scale-bearing chrysophyte. × 400 (From Korshikov 1927)

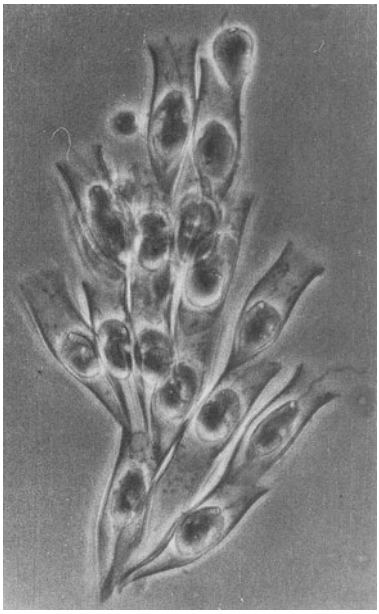

Fig. 7 *Dinobryon cylindricum* var. *alpinum,* a colonial, loricate chrysophyte. × 600

All chrysophytes form endogenous cysts (statospores, stomatocysts) during their life history. In *Dinobryon cylindricum* (Fig. 7), encystment occurs either in the exponential phase of population growth (intrinsic, mainly sexual resting cysts) or in the stationary phase (extrinsic, induced by nutrient depletion). Two clones must be

present in order to produce sexual cysts in *Dinobryon cylindricum,* whereas asexual cysts are produced by individuals, pioneers in a new habitat. These *Dinobryon* produce asexual cysts at a low rate, which gradually slows down during the end of the growth period. They produce sexual cysts rapidly during rapid growth. These two strategies result in almost the same number of cysts. The cysts sink into the sediment; the germination rate during the next spring is unknown (Sandgren 1983a, b). *Dinobryon* stomatocysts in surface waters of an arctic lake germinated during the same summer, whereas those in the sediment only germinated the next spring, when turnover exposed them to light (Sheath et al. 1975).

Chrysophytes excrete a great variety of organic compounds (Aaronson et al. 1971), corresponding to 20% of the carbon they fix by photosynthesis. These compounds include carbohydrates, enzymes, and vitamins and are utilized by bacteria and heterotrophic protists. Small chrysophytes, together with cryptomonads and prymnesiophytes, make up an important part of the nanoplankton of many lakes where they are the main food for zooplankton.

Because *Dinobryon* has an effective phosphate-uptake mechanism, it is especially abundant in waters with low phosphate concentrations (Lehmann 1976). However, most species (excluding Synurales) are mixotrophic, partly covering carbon and phosphorus demand by ingestion of bacteria (Sanders and Porter 1988).

Silica is required for scale-bearing species. *Synura* and *Paraphysomonas* require silica in the water at a concentration of at least 1 μM in order to grow well; they are able to deplete a medium almost completely of silica. Very low silica content results in unstable colony structure and failure to form cysts and scales. The silica requirement is further demonstrated by the inhibitory effect of germanium dioxide on growth (Klaveness and Guillard 1975; Lee 1978).

Most of the chrysophytes have chlorophyll *a*- and *c*-containing chloroplasts and can photosynthetically utilize inorganic carbon from CO_2 in the synthesis of organic compounds. An exogenous supply of organic carbon compounds, e.g., vitamins of the B group, mainly B_{12}, is also necessary. This will normally be present in the water, either excreted by bacteria, released by the decomposition of algal cells, or brought by sewage. Organic compounds are also obtained by phagocytosis of particulate food by many species. Colorless forms are exclusively dependent on phagocytosis and/or uptake of dissolved organic compounds (Pringsheim 1952).

Characterization and Recognition

Cell Structure

The Chrysophyta, a group of protists containing single-celled individuals as well as quite complex colonial forms, can briefly be defined by the following biochemical and structural criteria: chloroplasts with chlorophylls *a* and *c* (Andersen and Mulkey 1983) but lacking *b,* fucoxanthin as the most important accessory pigment, β-1, 3-glucan (chrysolaminaran) as storage product, swarmers with heterokont flagella (i.e., one long hairy and one shorter smooth, the latter in many cases only to be

detected by EM). Endogenous silicified cysts (stomatocysts) are present throughout the class.

The basic morphological type in the Chrysophyceae is the motile cell or swarmer (flagellate), from which other structural types or organization levels presumably evolved (Pascher 1914). The swarmer cell is naked or surrounded by an envelope; it occurs either solitary or in colonies. It is provided with one or two visible flagella; contractile vacuoles, most often located anteriorly, are present, and in most cases a chloroplast with a stigma (eyespot) is also present (Kristiansen 1986, 2005).

Many species have a tendency to form lobed or branched cytoplasmic extensions. In some species, the cell is amoeboid during the greater part of its life history (rhizopodial organization level), and either motile or sessile. The palmelloid level of organization is characterized by immotile cells located within mucilage as the dominant stage of the life cycle. Many motile species have such a stage during their life cycle as well. The coccoid level of organization, in which the cell is immotile and surrounded by a distinct wall, is displayed by a few genera.

Chrysophyte cells exhibit a number of structural characteristics by which they can be distinguished from other protists (Figs. 8 and 11), including distinctive flagellar basal bodies and subsurface microtubules, golgi appressed to the nucleus,

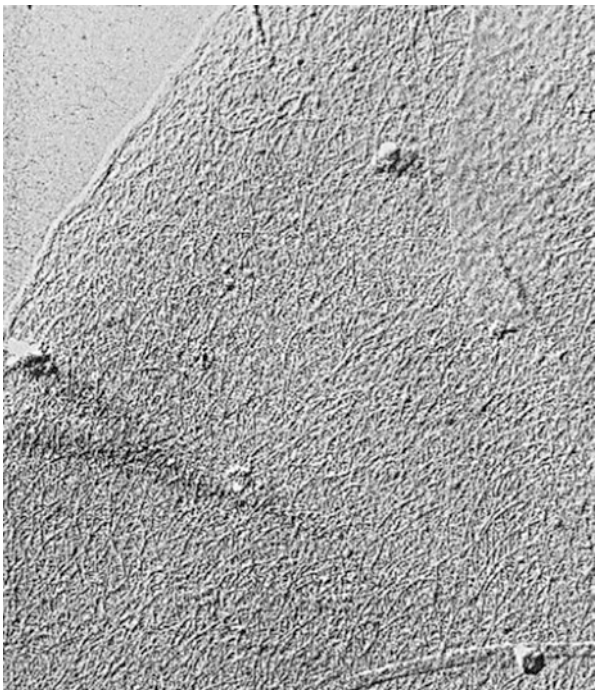

Fig. 9 Detail of the lorica of *Dinobryon pediforme,* showing the fibrillar construction. ×40,000

chloroplast endoplasmic reticulum, and a flagellar swelling opposite the distal face of the plastid with the stigma (Bold and Wynne 1978).

Most chrysophytes occur as naked cells. The cell membrane is in direct contact with the water; in *Ochromonas,* it is covered with a fuzzy layer and with surface blebs and vesicles. These may serve to trap bacteria and other particles that are subsequently engulfed as food (Kahan et al. 1978).

In many chrysophytes, the cells are surrounded by a wall or lorica of several different shapes. For example, it is vase- or beaker-shaped in *Dinobryon,* flask-shaped in *Lagynion,* or globular in *Chrysococcus.* The lorica consists of imbricate scales in *Epipyxis;* in *Bitrichia,* it has a peculiar double construction. In *Lagynion,* the lorica is fixed to a substratum. A ring-shaped part of the lorica fastens *Chrysopyxis* around an algal filament (Kristiansen 1972). The lorica is an interwoven system of fine fibrils consisting of cellulose; or in some cases it consists of chitin (Herth et al. 1977). In *Dinobryon,* the cellulosic fibrils are secreted during rotation of the protoplast and thus show a more or less helical arrangement (Franke and Herth 1973; Herth 1979; Fig. 9). In *Chrysococcus,* the dark and opaque lorica is impregnated with manganese and iron compounds. In *Ochromonas,* simple lorica forerunners have been observed (Schnepf et al. 1968).

Cells of several genera, mainly in the order Synurales, are covered by an armor of silica scales, spines, and bristles. By means of X-ray microanalysis, they have been proved to be composed of silica, which is consistent with the inhibition of scale formation by germanium dioxide (Klaveness and Guillard 1975; Lee 1978). An

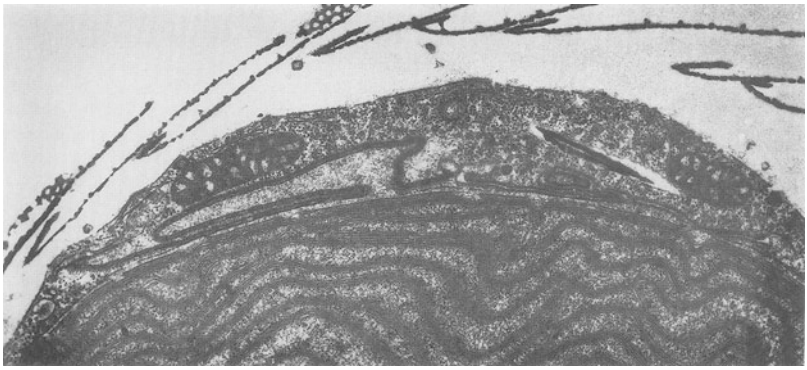

Fig. 10 *Synura petersenii,* formation of silica scales from the chloroplast. *Above*, part of the scaly armour is seen. × 17,500

additional organic component has been demonstrated in *Synura* scales (McGrory and Leadbeater 1981).

Silica scales and associated structures are produced internally; two different but related mechanisms are involved. In the Synurales, scale deposition vesicles are produced from the chloroplast endoplasmic reticulum (CER) on the outer side of the chloroplast. In *Synura* (Schnepf and Deichgräber 1969), the adjacent part of the CER bulges into such vesicles (of golgi body origin), functioning as molds for the scales (Fig. 10). "Hairy" golgi body vesicles that transport material fuse with the scale-producing vesicle. The mature scale is extruded from the cell and brought into correct position in relation to the other scales and the cell surface. *Mallomonas* bristles are formed in a similar way. They are initiated as flat sheets and then rolled into hollow tubes, which are then hinged to the scales (Wujek and Kristiansen 1978; Mignot and Brugerolle 1982). Beech et al. (1990) have shown the mechanism in *Mallomonas splendens*, how the bristles are extruded and brought in correct position and then with their foot glued to the scale.

In the Paraphysomonadida, scale production takes place somewhat differently. One vesicle produces scales while another vesicle from the endoplasmic reticulum functions as a mold (Preisig and Hibberd 1983).

Scale structure is species specific and very complicated, and it was understood only after electron microscopy came into common use. A scale generally consists of a perforated basal plate provided with ribs, spines, and other ornamentation (Fig. 5). In *Mallomonas,* some scales bear long, often complicated, bristles (Asmund and Kristiansen 1986; Kristiansen 2002). Scanning EM shows the three-dimensional structure of the scales (e.g., Siver 1991). Scales are deposited on the cell surface in an imbricate, often screwlike pattern. Several scale types are produced in the same cell and deposited on the surface in a definite sequence, as apical, body, and caudal scales (e.g., Belcher 1969b). Organic surface scales of a complicated flowerpot-like shape that cover both cell and flagella have been reported in *Sphaleromantis* (Manton and Harris 1966). A species of *Chromulina* is covered with simple oval scales (Pienaar 1977).

The flagellar system shows a complicated structure and an interesting evolution. The primitive heterokont condition is the presence of two dissimilar flagella: one flimmer (mastigonemate, hairy) flagellum and one shorter, smooth flagellum, both inserted apically in the cell. In more advanced forms, the short flagellum may be somewhat or almost completely reduced and/or transformed into a photoreceptor (Hibberd 1976).

Basal bodies are located anteriorly in the cell, in most cases at an angle to each other. Only in *Mallomonas* and *Synura* are they parallel. These basal bodies are interconnected by a system of fibers and connected by a fibrous band to the stigma region of the chloroplast (Kristiansen and Walne 1976). Systems of microtubules spread as microtubular roots below the cell membrane, and a rhizoplast proceeds into the cell and connects with the nuclear envelope (Figs. 11 and 12). In the transitional region above the basal body, the transitional helix (Hibberd 1979) is a general feature.

The longer, hairy flagellum is most often forwardly directed, beating with uniplanar sine waves starting from the base (Jarosch 1970). It has two rows of mastigonemes (flagellar hairs*)* causing the pulling effect of its movement. In *Ochromonas,* the mastigonemes are single in one row, in tufts in the other. Each mastigoneme consists of a base and a stiff shaft and bears two terminal and several lateral filaments (Bouck 1971). These mastigonemes are produced in the perinuclear space between the nucleus and chloroplast (Leedale et al. 1970). They are transported via golgi vesicles to the base of the flagellum. These vesicles fuse with the plasmalemma, thus the mastigonemes become extracellular and are transferred to the plasmalemma of the flagellum (Hill and Outka 1974). The short flagellum bears fine lateral filaments. The short flagellum, generally directed laterally, beats in helical waves. It may bear a swelling or be completely transformed into a photoreceptor. In some genera it is reduced so that it is only visible by electron microscopy (Belcher 1969a; Belcher and Swale 1967), accordingly these have originally been considered uniflagellate.

Small and simple flagellar scales occur in *Synura* and *Mallomonas* (Hibberd 1973; Bradley 1966). In *Sphaleromantis*, they are similar to the rather complicated body scales, making the flagella appear coarse and stiff (Manton and Harris 1966).

Photoreceptor systems are present in almost all motile chrysophytes; they consist of a swelling on the short flagellum with the photoreceptor and a stigma (often called the "eyespot") functioning as a screen. The stigma, located anteriorly in a chloroplast lobe in juxtaposition to the photoreceptor (Fig. 12), consists of a number of red (carotene) lipid droplets densely arranged just within the chloroplast membranes. A stigma is present in most motile chrysophytes; it does not occur in *Chrysamoeba,* some species of *Chrysococcus* (Belcher and Swale 1972a), in Synurales, and in most colorless forms (Hibberd 1976).

The swelling is placed proximally on the smooth flagellum and often has a complicated internal structure. In *Sphaleromantis* (Manton and Harris 1966), *Chromulina* (Belcher and Swale 1967), and *Chrysococcus* (Belcher 1969a), this flagellum is very short, so that it almost exclusively consists of a photoreceptor and is placed in a pocket in direct juxtaposition to the stigma. In *Mallomonas*, it is reduced

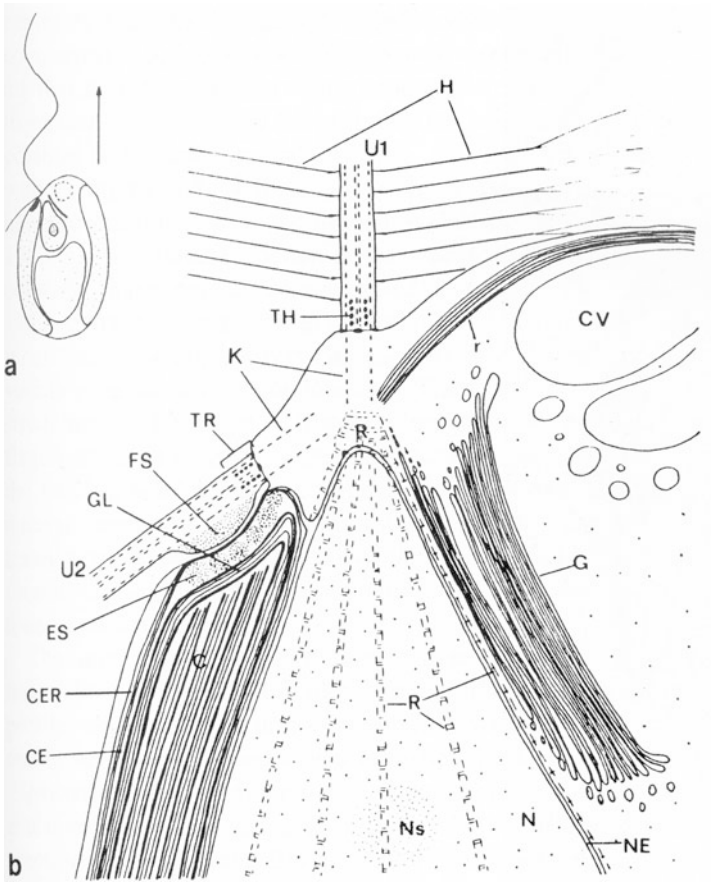

Fig. 11 Basic organization of a chrysophycean cell. J. Hibberd 1976, *Bot. Journ. Linn. Soc.* 72: 55–80, Copyright 1976, The Linnean Society of London)

to a peduncle, hardly protruding beyond the scale cover, and bearing the photoreceptor (Bourrelly 1957). Since no stigma is present in this genus, the shading effect may be due to the chloroplast itself.

In colorless forms, where the chloroplast has been lost or reduced to a leucoplast, there is most often also a reduction of the photoreceptor system. In the genus *Paraphysomonas,* a colorless counterpart to *Spiniferomonas*, there are all transitions from stigma-bearing species with complete photoreceptor system to species without

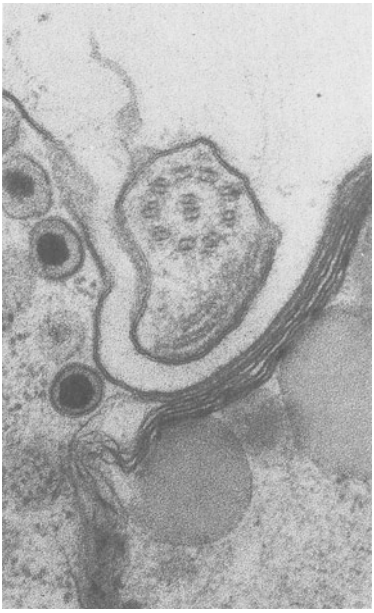

Fig. 12 Flagellar swelling with photoreceptor in juxtaposition to stigma-bearing part of the chloroplast (*Dinobryon*), × 64,000 (EM: J. Kristiansen, from Kristiansen and Walne (1977), with permission from British Phycological Society)

stigma but still with the leucoplast in juxtaposition to the flagellar swelling, and finally to species without stigma and swelling, and with no spatial relationship between leucoplast and flagellum (Preisig and Hibberd 1982, 1983). A similar reduction series is present in *Spumella,* a colorless counterpart to *Ochromonas* (Mignot 1977).

The nucleus surrounded by a double nuclear membrane is normally located in the center of the cell. In most cases, the outer nuclear membrane is continuous with the chloroplast ER, and the nucleus is thus intimately associated with the chloroplast (Fig. 13).

Close to the nucleus is the golgi body (Fig. 14). In most cases it consists of a single but very conspicuous set of vesicles often visible even in the light microscope. There are several golgi structures in *Hydrurus*. A close association exists between the nucleus and the forming face of the golgi: vesicles cut off from the outer nuclear membrane fuse to form golgi cisternae. Vesicles released from the edges of these cisternae are associated with the formation of scales, transport of flagellar hairs, and exocytosis of various substances.

The mitochondria have tubular cristae. The number of mitochondria per cell is difficult to discern. Many mitochondria profiles may be seen in thin sections, but they usually represent one or very few long and coiled mitochondria.

Microtubules occur mainly as peripheral systems below the cell membranes, emanating as microtubular bundles from the basal bodies as flagellar roots. They serve as a cytoskeleton to maintain cell shape. *Ochromonas* cells treated with colchicine, which prevents the assembly of microtubules, lose their specific shape

Fig. 13 Transverse section of a *Dinobryon* cell, showing the nucleus and the chloroplast wihin the chloroplast ER. On the inner face of the chloroplasts the periplastidial reticulum is seen. × 16,100. EM

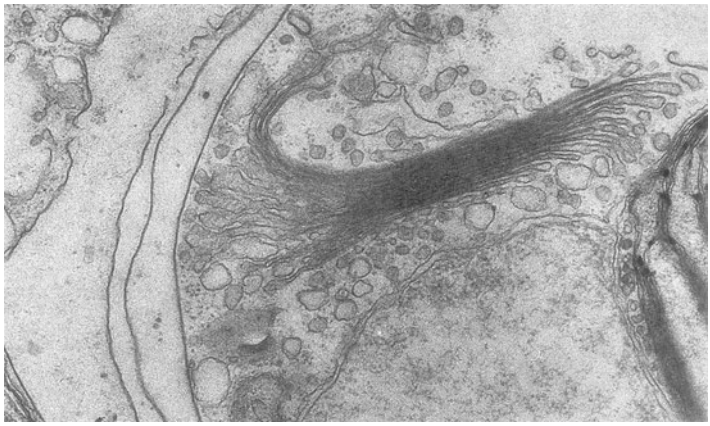

Fig. 14 The relation between the golgi body (*above*), nucleus (*below*), and chloroplast (*right*) in *Dinobryon.* × 30,200. EM

and become spherical (Bouck and Brown 1973). Massively developed microtubular systems occur in the tetrahedral swarmers of *Hydrurus* and *Chrysonebula* (Hoffman et al. 1986; Hibberd 1977a). A bundle of microtubules is situated in the stalk of *Poteriochromonas* (Péterfi 1969).

Most species possess one or two plastids (Fig. 12). The plastids are often lobed and located in close connection with the nucleus. They are surrounded by four membranes (Gibbs 1962), the outermost of which, called the chloroplast endoplasmic reticulum, is continuous with the outer nuclear membrane. The compartment between the next membrane and the inner chloroplast membranes contains the periplastidial reticulum, which functions in the transport of proteins into the plastid (Gibbs 1979).

The chloroplast contains photosynthetic lamellae, each consisting of three thylakoids. A girdle lamella is present, except in *Mallomonas* and *Synura.* The chloroplast DNA is ring-shaped and located just within the girdle lamella. Pyrenoids are either immersed or semi-immersed in the plastid; they are sometimes traversed by thylakoids. Only in *Hydrurus* are they stalked. Colorless chrysophytes have leucoplasts, e.g., *Spumella, Heterochromulina,* and *Paraphysomonas.* In *Anthophysa* and some species of *Paraphysomonas,* the small leucoplast even possesses a stigma (Belcher and Swale 1972b; Preisig and Hibberd 1983).

The chloroplasts of the chrysophytes contain chlorophyll *a* as the main photosynthetic pigment. In addition, chlorophylls of the *c*-group occur, normally both *c*1 and c2, but in *Mallomonas* and *Synura* only *c*1. The golden-brown color of the plastid is due to the occurrence of accessory pigments, mainly xanthophylls; the most important is fucoxanthin, comprising up to 75% of the total pigment in *Ochromonas danica.* Diatoxanthin has been demonstrated in *Sphaleromantis* and *Ochromonas,* diadinoxanthin in *Sphaleromantis* (Aaronson and Baker 1959). β-carotene is present in all chrysophytes. Carotene is concentrated in the part of the plastid differentiated as the stigma.

The product of photosynthesis is chrysolaminaran (chrysose or leucosin). It is a β-1,3-glucan and is deposited as a peculiarly refringent storage product in a posterior vacuole. Lipids are deposited in small vesicles in the cytoplasm. The chrysophytes are known to produce a great variety of fatty acids.

It is doubtful if any entirely photoautotrophic chrysophytes exist. In darkness, *Ochromonas* can grow osmotrophically on dissolved organic compounds, in which case the plastids will eventually be reduced (Pringsheim 1952). Many photosynthetic naked chrysophytes are capable of phagocytosis. Cell membrane flow transports trapped particles to the apex where phagocytosis occurs. Chrysophytes take up any particles, even inorganic ones. Bacteria, small algae, and quite large diatoms that completely distort the cell may be ingested. The phagocytic vacuole is then transported to a special digestion vacuole at the posterior end of the cell (Cole and Wynne 1974). Rhizopodial species are especially adapted for this feeding method. The food uptake mechanism has been studied in detail first in *Ochromonas* (Doflein 1922), showing how bacteria were trapped in a cytoplasmic basket and then engulfed. In *Epipyxis* (Wetherbee and Andersen 1992; Andersen and Wetherbee 1992), food particles, e.g., bacteria, are captured by the flagella and brought into the cytoplasmic feeding basket supported by one of the flagellar roots and from there transported into a digestion vacuole.

Life History

The swarmer is the predominant stage in the life cycle at the monadoid level of organization. However, swarmers also occur as a regular phase in the life cycles of most species at other levels. Swarmers fall into two main types: *Ochromonas*-like swarmers have two flagella, while in *Chromulina* swarmers only one is visible. A special swarmer of tetrahedral shape occurs in *Hydrurus* (Joyon 1963) and *Chrysonebula.* In some coccoid and filamentous forms, the cell divides into several immotile offspring cells (called autospores) liberated by rupture of the parent cell wall.

Sexuality was believed to be rare among the chrysophytes; although it mostly escapes attention and requires much patience to demonstrate, it is likely to be more prevalent. Sex is most often observed in small loricate monads (i.e., surrounded by a special envelope) such as *Kephyrion, Stenocalyx, Chrysolykos,* and the solitary *Dinobryon* species. Undifferentiated cells act as gametes, fuse apically, and produce a globular zygote. The empty loricae of the gametes, which remain attached to the zygote, make it easily recognizable (Fott 1959).

In colonial species of *Dinobryon,* sexuality has also proved to be of great importance. Cyst formation involves autogamic processes (fusion of nuclei formed by a prior mitosis) or gametic fusion of cells liberated from male colonies with loricate cells in female colonies to form zygotic cysts (Sandgren 1981).

In *Synura* and *Mallomonas*, normal scale-bearing cells act as gametes, with posterior fusion (Wawrik 1972). *Synura* is heterothallic; sexuality is induced at high cell density. Single cells liberated from male colonies act as gametes and copulate with cells in female colonies; subsequently the zygotes encyst and remain in the colony (Sandgren and Flanagin 1986).

The endogenous cyst, the stomatocyst (often also called the "statospore"), the characteristic resting stage of the Chrysophyceae, has a very special morphology: a globular, silicified wall with an opening called a porus, closed by a pectic plug. In many species the porus is surrounded by a collar. The stomatocyst wall may be smooth or bear ornamentation, including protuberances such as spines in various arrays depending on species (Fig. 3). In *Hydrurus* and a few other genera, a distinctive stomatocyst occurs that is ellipsoidal with an equatorial ring.

The stomatocysts are usually classified following an artificial taxonomy based upon size and shape, the outer wall ornamentation, as well as pore and collar morphology (Kamenik 2010). Guidelines for the description and nomenclature of stomatocysts have been worked out by Cronberg and Sandgren (1986), and the stomatocyst atlas by Duff et al. (1995) contained 240 taxa. But already in 2001 an enlarged edition was necessary (Wilkinson et al. 2001).

Stomatocyst formation has been studied in detail in *Ochromonas*, *Mallomonas*, and *Dinobryon* by electron microscopy (Hibberd 1977b; Andersen 1982; Sandgren 1980a, b). Two basic types of cyst formation are known, but they have in common the internal formation of the silica wall in the silicalemma, a silica-depositing vesicle

derived from the Golgi body. At maturity, the porus is closed by a plug of fibrillar pectic material.

In *Ochromonas tuberculata* and *Mallomonas caudata*, the uninucleate cell transforms directly into a cyst. The internal silica wall is formed by deposition on a basal lamella, and the porus is formed by resorption of part of the already deposited wall. The cyst also contains one nucleus. The external cytoplasm disintegrates after having deposited the external wall structures. In *Ochromonas sphaerocystis*, the external cytoplasm does not disintegrate but is retracted through the porus. In *Dinobryon,* the process is more complicated. The cell moves to the lorica mouth and secretes a surrounding encystment chamber. After formation of the silica-depositing vesicle, the cyst wall is produced with the porus preformed. After the wall ornamentation has been deposited, the remaining external cytoplasm is retracted through the porus and the plug is formed.

Cyst germination has been examined in only a few species. The plug dissolves and a motile naked cell escapes. In *Ochromonas,* a single normal swarmer separates; in *Leukochrysis* and *Kybotion,* small amoeboid cells emerge. In *Mallomonas,* the germination products are small scaleless monads. In *Dinobryon,* a special germination chamber is formed from the porus of the stomatocyst. The cell divides twice to form four cells that wander into this germination chamber, from where they are eventually released as naked, free-swimming monads (Sheath et al. 1975).

Cell division is longitudinal, and in motile cells it starts from the anterior end of the cell. In scale-bearing forms, the scaly armor appears to be reestablished as division proceeds. Mitosis, studied in detail only in *Ochromonas* and a few others, is of a special type: the rhizoplasts from the two basal bodies act as poles for the organization of the spindle microtubules (Slankis and Gibbs 1972).

Maintenance and Cultivation

General algal culture methods, including those for chrysophytes, are described in Andersen (2005) and references given there. Table 2 presents culture media used with success for chrysophytes.

For ultrastructural and many taxonomical investigations, pure cultures are not always necessary. Enough material may be obtained in other ways: by collecting naturally occurring high concentrations (blooms) or by concentration of motile cells (e.g., *Synura*) using their phototactic behavior.

Crude cultures to enrich for rare chrysophytes may consist only of the natural sample placed in a cool north-facing window, and successively several chrysophyte species will appear, e.g., attached to the water surface. In many cases, enrichment cultures with nutrients added are more adequate. For freshwater nanoplanktonic species of *Spiniferomonas,* Preisig and Hibberd (1982, 1983) added modified Chu 10 medium to their natural water samples, after larger organisms had been filtered off.

Table 2 Examples of culture media

Chromulina placentula	Chu 10 modif.	Belcher and Swale 1967
Chrysococcus cordifieris	Pringsheim biphasic	Belcher and Swale 1972a
Chrysococcus rufescens	Pringsheim biphasic	Belcher 1969a
Dinobryon divergens	Dy-III-medium	Lehmann 1976
Mallomonas papillosa	Pringsheim biphasic	Belcher 1969b
Ochromonas danica	Aaronson and Baker	Aaronson and Baker 1959
Ochromonas minuta	Pringsheim org. Medium	Hill and Outka 1974
Ochromonas sphaerocystis	Chu 10 modif.	Andersen 1982

Phaeaster pascheri	Pringsheim biphasic	Belcher 1969c
Poteriochromonas spp.	Pringsheim org. Medium	Schnepf et al. 1968
Synura petersenii	WC modif.	Klaveness and Guillard 1975
	Waris modif. Enriched	Schnepf and Deichgräber 1969
Standard chrysophyte medium	Dy-V-medium	Andersen et a1. 2005

Naked marine chrysophytes can be cultured by the addition of modified Erdschreiber medium to original water samples.

Many chrysophytes, because they are extremely fragile and delicate, do not tolerate the procedures necessary to get them into unialgal or axenic culture. For unialgal cultures, vitamins, and other organic growth factors must be included in the media. In chemically defined media necessary for most physiological investigations, these organic compounds must be added as specific vitamins, amino acids, etc. Media based on soil or liver extract, although they contribute a wide and undefined spectrum of vitamins and other organic and inorganic nutrients, unpredictably support growth of some organisms and not of others.

Erdschreiber solution, rich in phosphate and nitrate with added soil extract, is one of the media frequently used. Pringsheim's biphasic soil water medium is one of the most successful for growing freshwater chrysophytes, e.g., *Mallomonas papillosa, Chrysococcus cordiformis,* and *Phaeaster pascheri.* The soil in the bottom of the culture vessel slowly releases small amounts of nutrients.

Bold's Basal Medium, an inorganic synthetic medium, has been adapted for chrysophytes such as *Synura petersenii* and *Ochromonas tuberculata*; organics such as vitamin mixtures, leaf-, soil or peat-extract are added.

Chu 10, an inorganic medium containing silica, with addition of organic compounds is useful for silica-scale-bearing algae.

A standard medium for all chrysophytes is Dy V (Andersen 2005), based on Lehman's original Dy III medium for *Dinobryon* (Lehman 1976).

Highly enriched media, such as Pringsheim's organic medium (Pringsheim 1952) containing glucose, liver extract, yeast extract, and tryptone have been used for the cultivation of mixotrophic forms such as *Ochromonas minuta* and

Poteriochromonas malhamensis. In nonaxenic cultures, *Ochromomas* feeds on the bacteria that grow in the medium.

Colorless chrysophytes (e.g., *Anthophysa vegetans* and *Spumella elongata*) can grow in soil-water medium if the necessary extra organic nutrition such as starch or a barley seed are added (Belcher 1976). The phagotrophic *Paraphysomonas* species feed on bacteria naturally growing in nonaxenic culture (Lee 1978) or in sea or lake water enriched with liver extract or Chu 10 (Caron et al. 1999; Preisig and Hibberd 1982).

Chrysophyte cultures are maintained by numerous Culture Collections. Among these may be mentioned the following: UTEX, Austin, Texas, USA; NIVA, Oslo, Norway; CCAP, Oban, Scotland, UK; CAUP, Prague, Czech Republic; NCMA, Bigelow, Maine, USA; EPSAG, Göttingen, Germany.

Evolutionary History

Fossil Records

The siliceous structures of Chrysophyceae are very resistant and therefore common in many geological deposits, providing a better understanding of the evolutionary origin and stratigrafic distribution of these algae. Chrysophycean cysts (stomatocysts) are more heavily silicified than the other siliceous structures (scales and bristles), and so they are more likely to be present in the older sediments. On the other hand, natural classification is almost impossible as the stomatocyst descriptions are rarely accompanied by descriptions of their vegetative cells (Duff et al. 1995).

Cysts from freshwater deposits are grouped into an artificial family Chrysostomataceae, whereas those from marine sediments are grouped into the equally artificial Archaeomonadaceae. Since different genera could produce similar or even identical stomatocysts (Findenig et al. 2010), their fossil records are primarily important for the timing of the evolutionary origin of chrysophytes. Siliceous scales and bristles are generally preserved for a shorter geologic period (Siver et al. 2009; Siver and Wolfe 2005). However, in contrast to the stomatocysts, they could also be used to trace the evolutionary history and diversification of particular chrysophyte genera, or even species.

Although the oldest known chrysophyte-like structures have been reported from the Cambrian sediments (Allison and Hilgert 1986), their affinity to the Chrysophyceae is doubtful as they do not resemble any siliceous structures of modern taxa. Therefore, they may belong to any unrelated or even extinct lineage. The oldest certain fossils of chrysophytes are represented by siliceous stomatocysts of Archaemonadaceae, recovered from Tertiary or Upper Cretaceous marine deposits (Riaux-Gobin and Stumm 2006). At present, the oldest stomatocysts are from Southern Ocean sediments of Lower Cretaceous (Aptian-Albian, $\sim$ 112 Ma),

which may indicate the initiation of silicification within chrysophyte algae (Harwood and Gersonde 1990). In addition, since the stomatocysts are commonly found in fossil marine sediments, chrysophytes are presumed to have a marine origin (Tappan 1980).

The oldest records of fossilized chrysophyte scales and bristles have been reported from the Paleogene age. Recently, the oldest known microfossils of scales have been recovered from a Paleocene kimberlite deposit (∼ 60 Ma) by Siver et al. (2013a). The scales could be assigned to the genus *Synura*, though two of four taxa discovered represent presumably extinct species. Scales and bristles of other genera of silica-scaled chrysophytes (*Mallomonas*, *Spiniferomonas*) are known from younger, Middle Eocene freshwater deposits (∼ 47 Ma; Siver and Wolfe 2005, Siver et al. 2009; Siver and Lott 2012a). Other chrysophyte fossils are very rare. Identifiable remnants of *Dinobryon*, *Lagynion*, and *Cyrtophora* have been found in coprolites from Wyoming, dating from the Upper Eocene (Tappan 1980).

In general, the fossil record of chrysophytes is still very incomplete and poorly understood; there is much work to be done before it can be utilized to infer the timing of their evolutionary origin and to trace the diversification of particular lineages. Therefore, the origin and divergence times of extant genera are primarily estimated based on molecular clock calculations. According to the reconstruction of stramenopile diversification times, chrysophytes most likely originated in the Permian (∼ 279 Ma; Brown and Sorhannus 2010). This estimation is in accordance with the study of Jo et al. (2013), who estimated the origin of the chrysophytes as ∼ 250 Ma. Interestingly, the diversification of *Mallomonas* species was dated to -133-119 Ma (Jo et al. 2013; Siver et al. 2013b, 2015), implying that this genus evolved much earlier than the paleontological record indicates.

Classification

The first systematics of chrysophyte algae was introduced by Pascher (1913), who stressed the organization levels as foundations for taxonomy, with the flagellar number being of major importance. Uniflagellate organisms were placed in the Chromulinales, whereas those organisms possessing two flagella of reportedly equal length were classified in the Isochrysidales. Organisms having two unequal flagella were grouped in the Ochromonadales. A year later, Pascher (1914) established the class Chrysophyceae, encompassing those protists with golden brown pigmentation. However, he took a different approach to their classification, placing emphasis upon vegetative life forms (flagellate, capsoid, or amoeboid) rather than the number and shape of flagella. In his newly proposed system, all flagellates were classified in the order Chrysomonadales.

Pascher's classification was widely accepted in the years that followed. Bourrelly (1957, 1965) divided the Chrysophyceae into three subclasses: the

Acontochrysophycidae (no flagella), the Heterochrysophycidae (one flagellum or two unequal flagella), and the Isochrysophycidae (two equal flagella). Within the Heterochrysophycidae, he recognized two orders: the Chromulinales (one flagellum) and the Ochromonadales (two flagella). All chrysophycean genera forming siliceous scales and spines were united in the family Synuraceae, within the Ochromonadales. Later on, Silva (1980) has pointed out that the name Mallomonadaceae has priority over Synuraceae.

The subsequent ultrastructural studies have shown that the number of flagella is a quantitative character based on reduction of the short flagellum, having no taxonomic value (Kristiansen 1986). Preisig and Hibberd (1983) used the ultrastructural features to split the silica-scaled chrysophytes into the families Mallomonadaceae (the parallel insertion of flagellar basal bodies, presence of girdle lamella and flagellar scales, and lack of stigma) and Paraphysomonadaceae. In his review, Kristiansen (1986) followed this classification scheme, raising the families to an order status, the Mallomonadales and Ochromonadales. Increasing evidence of morphological and chemical (unique chlorophyll composition) differentiation of Mallomonadales culminated in their establishing as an independent class, the Synurophyceae (Andersen 1987). (Table 1).

However, several recently published phylogenies of Stramenopiles or chrysophyte algae (e.g., Ben Ali et al. 2002; Takishita et al. 2009; Del Campo and Massana 2011; Yang et al. 2012; Škaloud et al. 2013; Scoble and Cavalier-Smith 2014) show the close affinity of Synurophyceae with Chrysophyceae, with the former class often nested within the paraphyletic Chrysophyceae. Therefore, the two classes should be combined again, with the synurophyte algae being members of the order within Chrysophyceae, the Synurales.

Phylogeny

Phylogenetic relationships among the chrysophyte taxa were first inferred by Andersen et al. (1999), who investigated SSU rDNA sequences. Both the NJ (neighbour-joining) and MP (maximum parsimony) analyses resolved the seven distinct clades. Later, Andersen (2007) improved the dataset considerably by including several new chrysophyte taxa and conducted Bayesian phylogenetic analyses of the nuclear SSU rDNA and rbcL genes. The newly published sequences of the genus *Chrysosphaerella* were inferred as distantly related to *Paraphysomonas*, indicating the artificial concept of the Paraphysomonadaceae.

A detailed SSU rDNA phylogeny of chrysophyte algae, based on the data set including nearly all available sequences from cultured species and environmental DNA, was published by Klaveness et al. (2011). More recently, Scoble and Cavalier-Smith (2014) published a detailed phylogenetic reconstruction of Chrysophyta based on 239 SSU rDNA sequences, showing the existence of diverse chrysophyte-related environmental clades EC1 and EC2. In their investigations of heterotrophic *Spumella*-like flagellates, Findenig et al. (2010) and Grossmann et al. (2016)

demonstrated a significant cryptic diversity of these organisms forming a number of distinct lineages across the Chrysophyta. Accordingly, 7 new genera (*Acrispumella*, *Apoikiospumella*, *Chromulinospumella*, *Cornospumella*, *Pedospumella*, *Posteriospumella*, and *Segregatospumella*) and 2 new orders (Apoikiida and Segregatales) have been described.

According to the phylogenetic reconstruction based on recently available SSU rDNA and *rbc*L sequences of morphologically well-characterized taxa, nine orders can be presently recognized within the Chrysophyta (Fig. 15):

Ochromonadales Pascher 1910

This order represents the most diverse lineage, comprising a number of flagellate genera, including the solitary flagellates (e.g., *Ochromonas*, *Spumella*), colonial forms (e.g., *Uroglena*, *Chrysonephele*), or loricate monads (e.g., *Dinobryon*, *Poterioochromonas*). The morphologically similar loricate genera *Dinobryon* and *Epipyxis* occupy separate, phylogenetically distant positions within the order. Similarly, the phylogenetic reconstruction indicates several independent losses of plastid during the evolution of the lineage.

Chromulinales Pascher 1910

The order comprises the solitary (e.g., *Chromulina*, *Oikomonas*) and colonial (*Chrysosphaerella*, *Cyclonexis*) flagellates, as well as the amoeboid organisms (*Chrysamoeba*). The colonial genus *Chrysosphaerella* produces siliceous spines and scales.

Apoikiida Boenigk et Grossmann 2016

The order includes two heterotrophic, bacterivorous biflagellated genera: a colonial genus *Apoikia* forming swimming colonies of cells held together by mucilage and a solitary genus *Apoikiospumella*.

Chrysosaccales Bourrelly 1954

This order includes the morphologically diverse assemblage of taxa, including the *Ochromonas*- or *Chromulina*-like flagellates, coccoid chrysophytes (e.g., *Chrysosphaera*), cells embedded in mucilage (*Chrysosaccus*) or amoeboid loricate organisms (*Lagynion*).

Hydrurales Pascher 1931

The order presently comprises three morphologically distinct genera – colonial, freshwater *Hydrurus* forming macroscopic thalli usually growing in cold water, pseudoparenchymatous marine chrysophyte *Phaeoplaca*, and the *Ochromonas*-like flagellate isolated from Antarctic sea ice.

Hibberdiales R. A. Andersen 1989

The order groups the colonial organisms having the palmelloid level of organization. Cells either secrete a buoyant mucilaginous material to which the cells adhere (*Kremastochrysis*), are closed in a spherical capsoid colonies (e.g., *Hibberdia*,

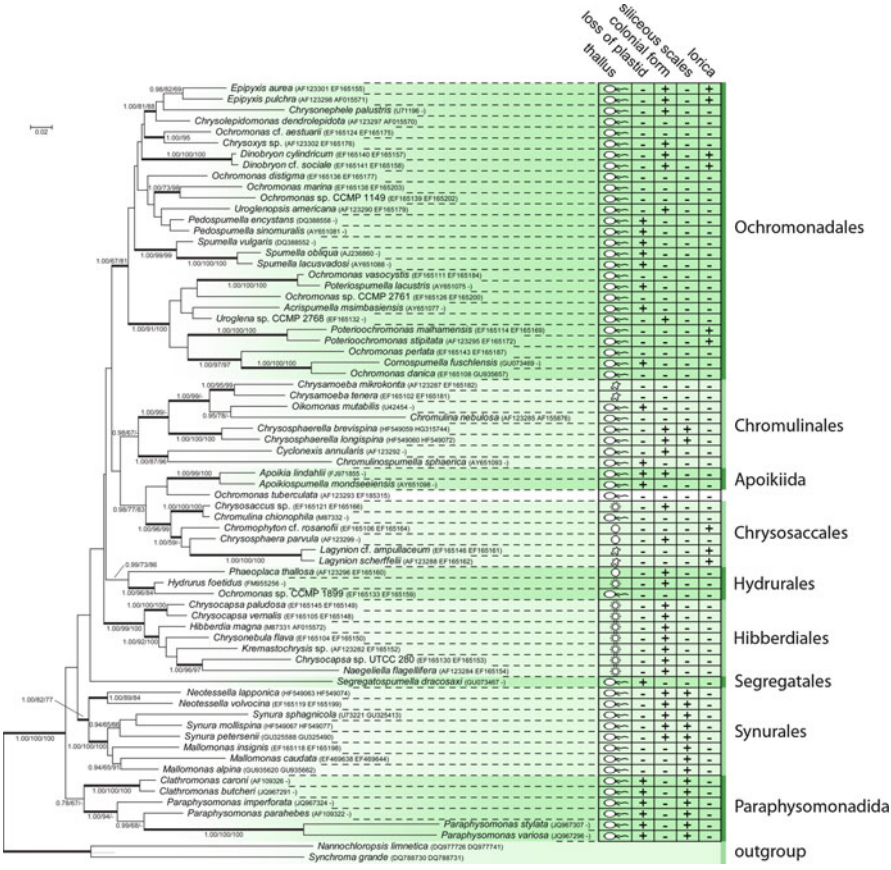

Fig. 15 Phylogeny of Chrysophyta, obtained by a Bayesian analysis of the combined and partitioned SSU rDNA + *rbc*L dataset using a GTR+G+I model for all partitions. Values at the nodes indicate statistical support estimated by three methods – MrBayes posterior-node probability (*left*), maximum-likelihood bootstrap (*middle*), and maximum parsimony bootstrap (*right*). Thick branches represent nodes receiving the highest PP support (1.00). GenBank accession numbers for the concatenated sequences (SSU rDNA and rbcL, respectively) accompany each species name. Scale bar shows the estimated number of substitutions per site. Basic characteristics of depicted chrysophyte taxa are provided in a graphical form. Thallus: the vegetative form is graphically indicated, including the monadoid, amoeboid, coccoid, and palmelloid organization. Other symbols indicate the presence/absence of plastid loss, colonial form, siliceous scales, and loricate structures

Chrysonebula), or they are grouped in a center of mucilaginous matrix extending a number of gelatinous tubes (*Naegeliella*).

Segregatales **Boenigk et Grossmann 2016**

The order currently comprises a single organism *Segregatospumella dracosaxi*, a bacteriovorous heterotrophic flagellate living in fresh water.

Synurales R. A. Andersen 1987

The order comprise three genera of autotrophic scale-bearing flagellates, namely, the solitary *Mallomonas* and the colonial *Synura* and *Neotessella*. The two former genera comprise the most common chrysophycean members of the freshwater planktonic communities worldwide.

Paraphysomonadida Scoble et Cavalier-Smith 2014

The order includes solitary, heterotrophic, flagellated genera *Paraphysomonas* and *Clathromonas*. Cells are covered with siliceous spine, basket, or plate scales. In addition, the order probably comprises a diverse, morphologically uncharacterized, environmental clade EC1.

Even though DNA sequence data are still lacking for several morphologically distinct genera (e.g., *Eusphaerella*, *Spiniferomonas*), the reconstructed phylogeny enables some inferences about evolutionary trends in the chrysophytes. First, the Synurales has the position as a nested group within the Chrysophyceae. Therefore, its recognition as a separate class, the Synurophyceae, is obviously not correct (see the "Classification" section) and should not be followed.

Second, the basal position of the Paraphysomonadida, a group with a significant portion of marine organisms, corroborates the hypothesis that the chrysophytes are of a marine origin (Tappan 1980).

Third, the silica-scaled chrysophytes do not form a monophyletic group, indicating either at least two independent origins of the ability to produce the siliceous structures (at the base of the Chrysophyta and within the Chromulinales) or multiple independent losses of this ability during the chrysophyte evolution.

Fourth, the phylogenetic reconstruction also indicates at least 10 independent reductions and losses of plastids, after which many distinct genera evolved.

Fifth, the morphologically simplest chrysophyte genera, *Ochromonas* and *Chromulina*, are both polyphyletic. The genus *Ochromonas* forms at least nine independent lineages, within the orders Ochromonadales, Hydrurales, and in a sister position to the order Apoikiida. The *Ochromonas* swarmer type might therefore be considered as the most primitive chrysophycean form from which the other morphological types evolved.

In general, the evolutionary history of the chrysophytes seems to be very complex, with several independent origins of morphologically similar taxa. Sequencing of additional taxa, together with extending the fossil data, will undoubtedly yield deeper insight into the evolution of this remarkable group of protist organisms.

Eustigmatophyceae

11

Marek Eliáš, Raquel Amaral, Karen P. Fawley, Marvin W. Fawley, Yvonne Němcová, Jiří Neustupa, Pavel Přibyl, Lilia M. A. Santos, and Tereza Ševčíková

Abstract

Eustigmatophyceae (eustigmatophytes) are a distinct lineage of ochrophyte (stramenopile) algae with a relatively small number (~30) of described species, but with evidence for a substantial taxonomic diversity yet to be explored. Eustigmatophytes are all unicellular coccoid algae, usually spherical or ovoid, but sometimes with a more distinctive shape (e.g., stipitate, tetrahedral, or with branched projections). Most eustigmatophytes live in freshwater, but some are common in terrestrial habitats and one subgroup is mostly marine. Reproduction

occurs primarily via autosporogenesis, but many members of this class form zoospores with an anterior mastigoneme-bearing flagellum and a (sometimes missing) posterior bare flagellum. Sexual reproduction has not been directly observed, but genomic evidence suggests its presence in some species. Eustigmatophytes are distinguished from other ochrophytes by a suite of cytological features (not all are necessarily present in all taxa): a pigmented lipidic body (reddish globule), a swelling at the base of the anterior flagellum associated with an extraplastidial stigma (eyespot), lamellate vesicles (with a putative reserve product), and plastids without a girdle lamella and lacking continuity with the nuclear envelope. Also characteristic is the lack of chlorophyll *c* and violaxanthin as the dominant xanthophyll. Because of their tendency to accumulate large amounts of lipids, including polyunsaturated fatty acids, eustigmatophytes are extensively used for biotechnology applications. The potential for commercial use has sparked a renewed interest in the basic biology of Eustigmatophyceae, including initiation of genome sequencing projects, although attention remains highly biased toward a single lineage comprising the genera *Nannochloropsis* and *Microchloropsis*.

Introduction

General Characteristics

Eustigmatophytes are a distinct group of ochrophyte (heterokont or stramenopile) algae. In the vegetative state, these organisms appear as solitary green or yellow-green coccoid cells or less frequently in loose colonies, with primarily autosporic reproduction. They may resemble some xanthophyte or chlorophyte algae but differ by a unique combination of ultrastructural and biochemical characteristics. A conspicuous characteristic of most eustigmatophyte vegetative cells is a cytoplasmic reddish globule consisting of unknown lipidic substances. Eustigmatophyte plastids lack a girdle lamella. The outer plastid membrane, a cisterna of the plastid endoplasmic reticulum, is typically not continuous with the nuclear envelope; however, this connection has been preserved in some species. Vegetative cells as well as zoospores possess vesicles containing a probable reserve material deposited in a lamellar pattern. Zoospores occasionally form in many species and bear one or two subapical flagella. One longer flagellum always has mastigonemes and a characteristic basal swelling. Typically, a red extraplastidial eyespot (stigma) is present at the extreme anterior, although some taxa recently assigned to the class do not possess this feature. Eustigmatophyceae lack chlorophylls *b* and *c*. Violaxanthin is the dominant xanthophyll and is involved in both light harvesting and in a photoprotective xanthophyll cycle. The Eustigmatophyceae is usually considered a small class, as only around 30 species in 15 genera have been described. However, recent studies have shown that many additional eustigmatophytes await recognition or description.

Occurrence

Eustigmatophytes thrive worldwide primarily in freshwater and terrestrial habitats, with the exception of the marine and brackish species of the genera *Nannochloropsis*

and *Microchloropsis*. These organisms are generally inconspicuous because of their small size and are rarely a dominant component of the microbial community.

Literature

There is no recent monograph on the group. The works by Hibberd (1980, 1982, 1990) are still useful as summaries of the first phase of modern research on eustigmatophytes. Hibberd (1981) also published a thorough taxonomic revision and a formal classification of eustigmatophytes that is the starting point for current taxonomic and systematic work on the group. Santos (1996) published the most current general review of eustigmatophytes. Useful information on the morphology and ecology of eustigmatophyte species, including identification keys, can be found in algal floras and compendia (Ettl and Gärtner 1995; John 2011; Ott et al. 2015). Many eustigmatophyte species are included in older floristic works as members of the "Heterokonten" or the Xanthophyceae (Pascher 1939; Ettl 1978).

History of Knowledge

The class Eustigmatophyceae was established by Hibberd and Leedale (1971) after they investigated 12 genera of coccoid algae from the Xanthophyceae and found unique ultrastructural features (Hibberd and Leedale 1970, 1972). The pigment composition of eustigmatophytes was also important in the definition of the new class, because their signature pigments differ significantly from those in xanthophytes (Whittle and Casselton 1969, 1975a, b). The taxonomic revision of eustigmatophyte diversity by Hibberd (1981) led to the recognition of 12 species in six genera. Subsequently, the advent of molecular phylogenetic methods confirmed that the Eustigmatophyceae is a monophyletic lineage distinct from the Xanthophyceae and all other classes of ochrophytes (Bhattacharya et al. 1992; Karlson et al. 1996; Andersen et al. 1998).

Since the seminal work of Hibberd (1981), knowledge of eustigmatophyte diversity has expanded with the transfer of additional species from the Xanthophyceae (Schnepf et al. 1996; Přibyl et al. 2012; Fawley and Fawley 2017) and the descriptions of new taxa (Lubián 1982; Karlson et al. 1996; Krienitz et al. 2000; Suda et al. 2002; Trzcińska et al. 2014; Fawley et al. 2015), including four new monotypic genera (Preisig and Wilhelm 1989; Neustupa and Němcová 2001; Hegewald et al. 2007; Nakayama et al. 2015). Recent culture-based and environmental DNA cloning studies have shown that the diversity of the Eustigmatophyceae is much greater than previously expected (Fawley et al. 2014). After 2010, research on eustigmatophytes entered a new phase with the determination of the first complete genome sequences and development of tools for targeted genetic manipulation in the representative genus, *Nannochloropsis* (Kilian et al. 2011; Pan et al. 2011; Radakovits et al. 2012; Vieler et al. 2012a; Corteggiani Carpinelli et al. 2014; Wang et al. 2014, 2016).

Practical Importance

Eustigmatophytes became the focus of attention and intensive research in recent years due to the potential commercial production of biofuels and bioproducts by some species. Most biotechnology-oriented studies have been performed on the minute marine species of the genus *Nannochloropsis* (including species belonging to the recently segregated genus *Microchloropsis*; Fawley et al. 2015). There has been exponential growth in the number of research papers published on this topic in recent years (e.g., Zou et al. 2000; Krienitz and Wirth 2006; Li et al. 2011; Simionato et al. 2011; Doan and Obbard 2012; Bartley et al. 2014; Xiao et al. 2015); most of the relevant literature concerning the lipid-related biotechnological research has been reviewed by Ma et al. (2016). Briefly, *Nannochloropsis* spp. are valued primarily for the ability to produce two types of lipidic substances – neutral lipids, i.e., various forms of triacylglycerol (TAG) and long-chain polyunsaturated fatty acids (LC-PUFAs), especially eicosapentaenoic acid (EPA). Depending on the cultivation conditions, the intracellular lipid levels in *Nannochloropsis* spp. may reach up to 55–60% of dry weight biomass and may exhibit elevated content of higher saturated fatty acids, being thus suitable for transesterification to biodiesel. *Nannochloropsis* spp. have also been extensively investigated for the production of commercially valuable carotenoid pigments (Lubián et al. 2000), sterols (Suen et al. 1987; Volkman et al. 1993; Patterson et al. 1994), and vitamin E (α-tocopherol; Durmaz 2007). *Nannochloropsis* spp. may also be used as cell reactors for the production of heterologous proteins (Chen et al. 2008) and have long been used as a food source in aquaculture (Duerr et al. 1998; Pfeiffer and Ludwig 2007; Patil et al. 2007; Ferreira et al. 2009).

Industrial use of other genera of the Eustigmatophyceae has been investigated to a lesser extent. *Monodopsis subterranea* (= *Monodus subterraneus*) and *Trachydiscus minutus* both produce large quantities of EPA (Cohen 1994; Hu et al. 1997; Qiang et al. 1997; Lu et al. 2001; Iliev et al. 2010; Řezanka et al. 2010; Cepák et al. 2014; Jo and Hur 2015). Members of the closely related genera *Vischeria* and *Eustigmatos* have also been noted for producing EPA, but also high amounts of β-carotene, and their lipid metabolism also make them promising biofuels producers (Volkman et al. 1999; Li et al. 2012a, b; Aburai et al. 2013; Zhang et al. 2013; Gao et al. 2016). Eustigmatophytes in general may also be regarded as promising antioxidant sources, for example, as documented by a recent survey of various strains from the Coimbra Collection of Algae (ACOI; Assunção et al. 2016).

Environmental bioremediation uses may also be envisaged for eustigmatophytes. For example, cells of *Microchloropsis gaditana* (as *Nannochloropsis gaditana*) were reported to accumulate practically 100% of the copper or zinc present in the medium (Moreno-Garrido et al. 2002). The eustigmatophyte strain nak-9, subsequently described as *Vacuoliviride crystalliferum* (Nakayama et al. 2015), was reported to exhibit a high efficiency in eliminating radioactive caesium from the medium by cellular accumulation (Fukuda et al. 2014). Inoculation of rice grown in hydroponic conditions with *Nannochloropsis* sp. ameliorated the impact of arsenic toxicity on plant growth (Upadhyay et al. 2016). Using municipal wastewater as a source of

nutrients for cultivation of *Nannochloropsis* sp. for biotechnological applications was also tested (e.g., Jiang et al. 2011).

Habitats and Ecology

Habitat preferences may differ substantially even within eustigmatophyte lineages and numerous transitions between freshwater and terrestrial habitats seem to have occurred during eustigmatophyte evolution. A transition to the marine environment probably occurred only once, in the lineage leading to an ancestor of the genera *Nannochloropsis* and *Microchloropsis*. An ancestor of the freshwater species *Nannochloropsis limnetica* must then have secondarily transitioned from marine to freshwater habitats (Fawley and Fawley 2007). Little is currently known about possible biogeographical patterns exhibited by eustigmatophyte species.

Members of the closely related genera *Vischeria* and *Eustigmatos* have been frequently isolated from soils (Petersen 1932; Vischer 1945; Neustupa and Němcová 2001) and from various subaerial habitats, such as tree bark (Nakano et al. 1991; Neustupa and Škaloud 2010), rocks (Czerwik-Marcinkowska and Mrozinska 2009), or desert crusts (Flechtner et al. 1998; Büdel et al. 2009), but they are also found in freshwater (Ott et al. 2015). The genus *Monodopsis* also occurs in soils worldwide as well as in freshwater (Ettl and Gärtner 1995; Ott et al. 2015). *Pseudellipsoidion edaphicum* was isolated from soil in Central Europe, whereas the related species *Pseudocharaciopsis ovalis* was reported from both soil and freshwater habitats (Neustupa and Němcová 2001).

Most members of the clade *Goniochloridales* (Fig. 1) and some other eustigmatophytes (e.g., *Pseudotetraëdriella kamillae*) are freshwater phytoplankton or associated with vegetation in freshwater (Ettl 1978; Schnepf et al. 1996; Přibyl et al. 2012; Fawley et al. 2014). The predominantly marine genus *Nannochloropsis* also comprises a freshwater species, *N. limnetica*, a member of picoplankton communities in lakes and ponds (Krienitz et al. 2000; Fietz et al. 2005; Fawley and Fawley 2007). An extremely abundant population of *N. limnetica* dominating the phytoplankton community and reaching up to 5.7×10^9 cells l^{-1} was reported in a hypertrophic lake in Germany (Krienitz et al. 2000), and it seems to be abundant primarily in periods of cold water (Fawley and Fawley 2007).

Mesotrophic and eutrophic lakes and ponds with neutral or slightly basic pH have proved to be a rich source of phylogenetically diverse eustigmatophyte strains (Fawley et al. 2014). On the other hand, many members of the Eustigmatophyceae are found associated with vegetation in acidic conditions and *Sphagnum* bogs (Ott et al. 2015; Karen and Marvin Fawley, pers. observation). *Chlorobotrys regularis* is frequently found in low-pH habitats such as *Sphagnum* bogs (Hibberd 1974), but some strains of *Chlorobotrys* isolated and held in the ACOI collection were isolated from lakes and ponds. Two unidentified eustigmatophytes were recorded by sequencing environmental 18S rDNA libraries from a peat bog in Switzerland (Lara et al. 2011; Fig. 1). Most recently, *Tetraëdriella subglobosa*, originally found by Pascher (1930) in acidic pools in Czechoslovakia, proved to be a

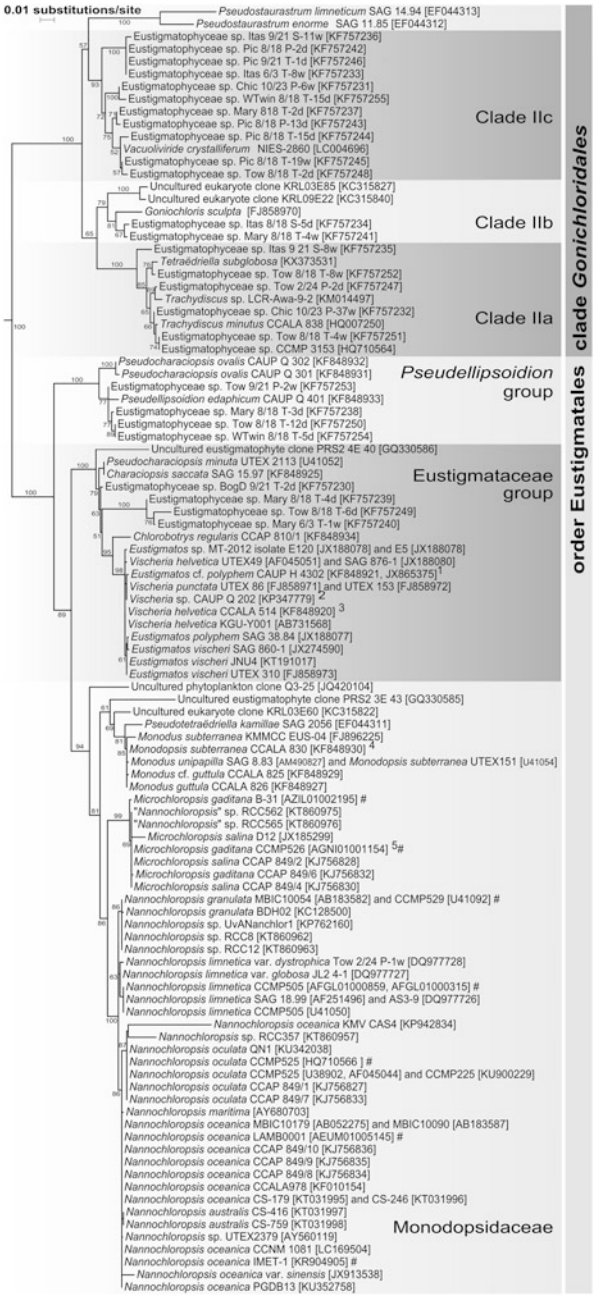

Fig. 1 The phylogenetic diversity of Eustigmatophyceae deduced from 18S rRNA gene sequences. The tree was inferred using the maximum likelihood method (RAxML) from an alignment of nearly all available eustigmatophyte 18S rRNA gene sequences plus sequences from selected non-eustigmatophyte ochrophytes used as an outgroup (not shown). The main eustigmatophyte

eustigmatophyte upon its re-isolation from an acidic pool near the shore of Lake Mácha, Czech Republic (Fawley and Fawley 2017).

The only known eustigmatophytes inhabiting marine or brackish habitats belong to the picoplanktonic genera *Nannochloropsis* (including also the freshwater species *N. limnetica*) and *Microchloropsis*. These species can form blooms in rock pools and enriched or polluted waters (Ryther 1954; Bourrelly 1958). An extensive bloom of *Microchloropsis* (=*Nannochloropsis*) *gaditana* was reported from brackish Comacchio lagoons in Italy (Andreoli et al. 1999a), whereas *Nannochloropsis granulata* was encountered as a large-scale bloom-causing species in China (in Bohai Sea and Yellow Sea; Zhang et al. 2015).

Eustigmatophytes may also be found in various less usual habitats. Frost et al. (1997) reported an unidentified eustigmatophyte endosymbiont living inside the freshwater sponge *Corvomeyenia everetti*. An unknown eustigmatophyte was detected in a wastewater treatment pond by sequencing an environmental library of the *rbc*L gene (Ghosh and Love 2011). A *Nannochloropsis* species related to *N. limnetica* was reported from a permanently ice-covered lake in Antarctica (Bielewicz et al. 2011). *Trachydiscus minutus* was found to constitute a dominant planktonic alga in a eutrophic cooling pond of a nuclear power plant (Přibyl et al. (2012). A new eustigmatophyte, *Eustigmatos calaminaris*, was recently described from Zn- and Pb-loaded calamine mine spoils (Trzcińska et al. 2014). Finally, *Vacuoliviride crystalliferum* was isolated from green-colored sediment in a bottle of glue (Nakayama et al. 2015).

Characterization and Recognition

General Appearance

Eustigmatophytes are spherical, polyhedral, stellate, ovoid, fusiform, or discoid in shape and vary in size generally between 2 and 25 μm in the longest dimension, although some species may have much larger cells (for example, some *Characiopsis*-like organisms, personal observation). The morphological diversity

Fig. 1 (continued) lineages are annotated following the scheme proposed by Fawley et al. (2014). The number sign (#) marks strains for which nuclear genome sequence has been reported (see Table 1). Number in superscript at some taxa indicate that taxa (strains) with identical 18S rRNA gene sequences exist that were not included in the figure: [1]*Eustigmatos vischeri* CCAP 860/7 [KJ713283]; [2]*Chloridella neglecta* SAG 48.84 [KF848924] and *Eustigmatos magna* CCMP387 [U41051]; [3]*Eustigmatos polyphem* CAUP Q 102 [KF848922], *Vischeria stellata* SAG 33.83 [KF848919], *Chloridella simplex* CCALA 279 [KF848923], and "*Ophiocytium majus*" CCAP 855/1 [AM490835]; [4]*Monodus guttula* CCALA 828 [KF848928], *Monodus* sp. CAUP D 901 [KF848926], and *Monodopsis* sp. MarTras21 [KP347780]; [5]*Microchloropsis gaditana* MBIC10418 [AB052271], MBIC10063 [AB183586], CCMP527 [AFGN01000274] #, *Microchloropsis salina* CCMP537 [AF045049] #, and CCMP1776 [AFGQ01000729, AFGQ01000649] #

of eustigmatophytes is documented in Fig. 2. Most vegetative cells are free floating, but *Pseudocharaciopsis* spp. and other *Characiopsis*-like algae may normally or occasionally be attached. Eustigmatophytes form green or yellow-green cultures, so some may be confused with coccoid members of the Xanthophyceae or Chlorophyta (green algae). However, eustigmatophytes can be distinguished by the presence of a red-orange pigmented body in the cytoplasm that is especially prominent in older vegetative cells. This lipidic body also has a characteristic yellow fluorescence when excited with ultraviolet light (Přibyl et al. 2012). Some eustigmatophytes also have highly sculpted cell walls (Santos and Santos 2001; Přibyl et al. 2012; Fawley et al. 2014; Fawley and Fawley 2017), although careful examination is required to detect the sculpting on small cells. Because many xanthophytes were described before the recognition of the distinctions between the two classes, some taxa currently classified as Xanthophyceae will likely be reassigned to the Eustigmatophyceae upon more detailed study.

Vegetative Cell Structure

Careful light and, for most species, electron microscopical observations of eustigmatophyte vegetative cells (Hibberd and Leedale 1972; Lee and Bold 1973; Hibberd 1974; Preisig and Wilhelm 1989; Santos and Leedale 1995; Schnepf et al. 1996; Neustupa and Němcová 2001; Hegewald et al. 2007; Přibyl et al. 2012; Nakayama et al. 2015) have revealed key morphological and ultrastructural characteristics for the whole group, as well as features specific to particular taxa. Most eustigmatophytes contain a single-lobed parietal plastid (Fig. 2); however, multiple plastids have been observed in *Pseudellipsoidion* (Neustupa and Němcová 2001), *Pseudocharaciopsis ovalis* (Hibberd 1981), and *Pseudotetraëdriella* (Hegewald et al. 2007). The plastid lamellae are evenly spaced (Fig. 3a–c) and are composed of three unappressed thylakoids. Additional thylakoids commonly appear between some of the lamellae, particularly at the edge of the plastid, forming granum-like stacks. The plastids do not contain a girdle lamella, and the longitudinal lamellae terminate close to the plastid envelope (Fig. 3a–c). The plastid envelope consists of four membranes with the outermost representing the plastid endoplasmic reticulum (PER). Connection of the PER with the nuclear envelope, otherwise a general characteristic of ochrophyte algae, has been reported only from the genera *Nannochloropsis* (incl. *Microchloropsis*) and *Monodopsis* (Antia et al. 1975; Santos and Leedale 1995; Karlson et al. 1996; Krienitz et al. 2000; Suda et al. 2002).

Pyrenoids are present in vegetative cells of several species, but never in the zoospores. In some eustigmatophytes, the pyrenoid is polyhedral (*Vischeria* spp., *Eustigmatos* spp., *Chlorobotrys regularis*) or globular (*Pseudocharaciopsis minuta*) and separated from the plastid itself by a narrow stalk (Fig. 3b), whereas the genera *Monodopsis* and *Vacuoliviride* form a bulging pyrenoid without a stalk (Santos and Leedale 1995; Nakayama et al. 2015). A pyrenoid has been reported for two species of the genus *Nannochloropsis* (Antia et al. 1975), but its presence could not be confirmed by subsequent studies (Santos 1996). The organism studied by

Mohammady et al. (2004) under the name *Nannochloropsis salina* and exhibiting a prominent pyrenoid with a starch envelope is undoubtedly a green alga. The pyrenoid matrix of eustigmatophytes appears finely granular or homogeneous and is not penetrated by either plastid lamellae or individual thylakoids (Fig. 3b). The plates of refractive material that can be seen lying against the faces of the pyrenoids in the light microscope are represented in sections by flattened vesicles containing material that appears very finely lamellate after fixation. Smaller vesicles with apparently identical contents, called lamellate vesicles or refractile granules, also lie freely in the cytoplasm of both the vegetative cells and zoospores (Fig. 3g). These highly characteristic structures of all eustigmatophytes (Santos 1996) probably represent a storage material in the form of a β-1-3-linked polysaccharide (Schnepf et al. 1996).

Mitochondria contain tubular cristae as in other stramenopiles (Fig. 3c, f). A mitochondrion-dividing ring reminiscent of those known from the red alga

(**g**) Lamellate vesicles containing material that appears very finely lamellate after

Cyanidioschyzon merolae has been described in the eustigmatophyte *Nannochloropsis oculata* (Hashimoto 2004). The nucleus is more or less spherical (Fig. 3b) but is relatively inconspicuous in the light microscope and can usually be clearly identified only in younger cells. Much more conspicuous is a vacuole with granular contents exhibiting Brownian movement. A highly characteristic structure of most eustigmatophytes, especially of older cells, is the so-called reddish globule (e.g., Fig. 2a, b, j, n). Its color varies from pale yellow-brown to dark red-brown and becomes larger and darker with age. In some species, the reddish globule is composed of a number of smaller droplets (Fig. 3a), but it is homogeneous in *Chlorobotrys regularis* (Hibberd 1974) or with a core less electron dense than the rest of the globule in *Vacuoliviride crystalliferum* (Nakayama et al. 2015). Prior to reproduction, the reddish globule does not divide but is completely inherited by one of the daughter autospores (Neustupa and Němcová 2001). A unique, rod- or V-shaped crystalline structure associated with the reddish globule was observed in *Vacuoliviride crystalliferum* (Nakayama et al. 2015).

The cell wall of eustigmatophytes is in one piece (Fig. 3b, h), but more than one layer can be seen, especially in older cells. The cell wall is generally smooth, but ornamentation with sculpting is seen in some members of the *Goniochloridales* (Fig. 2b, m; Přibyl et al. 2012; Fawley et al. 2014; Fawley and Fawley 2017). The composition of the eustigmatophyte cell wall has not been thoroughly investigated for most taxa, but it seems to be composed primarily of cellulose (Okuda et al. 2004; Vieler et al. 2012a). Recently, the cell wall of *M. gaditana* was studied in great detail and found to exhibit a bilayer structure consisting of a cellulosic inner wall protected by an outer hydrophobic alganean layer comprising long, straight-chain, saturated aliphatic hydrocarbons with ether cross-links (Scholz et al. 2014). The genus *Chlorobotrys* is unique in having a refractile wall exhibiting a high degree of flexibility and in being surrounded by concentric mucilaginous layers separated by tripartite membrane-like structures (Fig. 2a), probably composed of pectic materials with very little cellulose (Hibberd 1974). Biomineralization of manganese on the stalk surface was observed in *Pseudocharaciopsis minuta* (Wujek 2012).

Zoospore Structure

Eustigmatophyte genera, with the exception of *Nannochloropsis*, *Microchloropsis*, *Monodopsis*, *Chlorobotrys*, *Vacuoliviride*, and *Tetraëdriella*, are known to produce naked, somewhat amoeboid, oval, or lageniform (flask-shaped) zoospores, with one or two subapically inserted flagella (Figs. 2c and 3c–f). The zoospores generally harbor a single anteriorly positioned nucleus, a single plastid always without a pyrenoid, one or more mitochondria, a number of vesicles with lamellate or spiral

Fig. 3 (continued) fixation (enlarged lower-left figure), *Pseudocharaciopsis ovalis*. (**h**) Section of a vegetative cell of *Pseudocharaciopsis ovalis* (*cw* cell wall, *pl* plastid, *m* mitochondrion, *rg* reddish globule). content, and a Golgi body (Hibberd and Leedale 1972; Lee and Bold 1973; Preisig and Wilhelm 1989; Santos and Leedale 1992; Schnepf et al. 1996).

The zoospores of some eustigmatophytes bear just one emergent flagellum (Fig. 3c–f), but at least in those species studied by electron microscopy a second bare kinetosome (basal body) lies closely associated with the one subtending the flagellum. A pair of unequal flagella was found in the zoospores of *Pseudocharaciopsis* spp. (Lee and Bold 1973; Hibberd 1981; Neustupa and Němcová 2001) and *Botryochloropsis similis* (Preisig and Wilhelm 1989), where the posterior flagellum is shorter, very narrow, and not readily apparent in the light microscope. Except for a short proximal part, the posterior flagellum exhibits a simplified structure of the axoneme consisting of only two central microtubules. The single flagellum of the unimastigote zoospores and the anterior flagellum in bimastigote zoospores bear tripartite tubular hairs (mastigonemes) of the same type as found in other ochrophytes (Fig. 3d, e) and exhibit a characteristic basal swelling appressed against the anterior region of the cell body containing the eyespot, if present (Hibberd and Leedale 1972; Santos and Leedale 1991; Schnepf et al. 1996).

The eyespot (stigma) is by far the most conspicuous feature of the eustigmatophyte zoospores and is often considered to be characteristic for the group. However, it is reportedly absent from zoospores of all members of the clade *Goniochloridales* studied so far (*Pseudostaurastrum limneticum*, *Goniochloris sculpta*, and *Trachydiscus minutus*; Schnepf et al. 1996; Přibyl et al. 2012) and also from one member of the Eustigmatales (*Pseudotetraëdriella kamillae*; Hegewald et al. 2007). The eyespot is red-orange in color and its size differs depending on the species (being very large and filling almost the whole of the extreme anterior end of the zoospore in some eustigmatophytes). It lies outside and quite separate from the plastid (Fig. 3c). It is composed of a number of osmiophilic globules of variable size, and neither the eyespot as a whole nor the globules are membrane bound. One large D-shaped droplet lies closely against the cell membrane opposite to the flagellar swelling. The basal swelling/eyespot complex is a probable photoperceptive system with the eyespot serving to enhance contrast. The identity of the actual photoreceptor substance is unknown, but it is thought to emit a green autofluorescence observed in the basal swelling/eyespot region upon excitation with a blue-violet light (Santos et al. 1996).

The transitional region between the basal body and the axoneme consists of a transverse partition and a transitional helix with three to five gyres surrounding the proximal few nanometres of the central pair of the axoneme (Fig. 3c). Flagellar roots have been reconstructed for zoospores of *Vischeria stellata* (Santos and Leedale 1991). Roots R1 and R2 originate on the opposite sides of the flagellum-bearing basal body and run anteriorly supporting the anterior part of the cell associated with the flagellar swelling. Root R3 is attached with dense material between the basal bodies and runs close to the plasma membrane down to the posterior end of the cell, whereas root R4 extends from the bare basal body. The fibrous rhizoplast connects the basal bodies and extends deep into the cell, where it splits into several branches spreading over the nuclear surface (Santos and Leedale 1991).

Reproduction and Life Cycle

Eustigmatophytes reproduce primarily by the formation of autospores (Fig. 2d, f). There may be two D-shaped or four or eight polyhedral autospores per autosporangium; in the more elongate species, the autospores are arranged more or less longitudinally within the parent cell wall before release. Details of cytokinesis in eustigmatophytes have yet to be worked out, but nuclear and plastid division were followed at the ultrastructural level in *Nannochloropsis oculata* (Murakami and Hashimoto 2009). The nucleus divides by closed mitosis, and the inner nuclear envelope constricts and pinches off before the outer nuclear envelope.

An alternative reproduction mode in eustigmatophytes is zoosporogenesis. Some species produce zoospores in relatively small quantities, and the genera *Nannochloropsis*, *Microchloropsis*, *Monodopsis*, *Vacuoliviride*, and *Chlorobotrys* (Hibberd 1974; Antia et al. 1975; Santos 1996; Nakayama et al. 2015) even appear to lack this ability completely. On the other hand, reproduction solely by zoospores was described in *Pseudostaurastrum limneticum* (Schnepf et al. 1996) and *Pseudotetraëdriella kamillae* (Hegewald et al. 2007). Factors inducing zoosporogenesis have not been systematically investigated, but zoospore production in *Trachydiscus minutus* is induced by darkness, suppressed by light, and depends on the temperature (Přibyl et al. 2012). In *Characiopsis*-like eustigmatophytes, zoospores are formed briefly after subculturing old cultures (personal observation). Profound morphological variability in vegetative cell shape, including formation of thick-walled resting cells, was reported as part of the life cycle of *Pseudocharaciopsis ovalis* and *Vischeria* sp. strains (Neustupa and Němcová 2001). Similarly, Fietz et al. (2005) observed thick-walled resting stages in *Nannochloropsis limnetica* germinating by releasing a single cell.

Sexual reproduction is unknown in eustigmatophytes and was suggested to be absent in *Nannochloropsis oceanica* based on evidence from genome sequencing (Pan et al. 2011). However, analyses of the genome sequence of two strains of *Microchloropsis* (=*Nannochloropsis*) *gaditana* unveiled a suite of genes encoding homologs of proteins involved in meiosis, including the meiosis-specific proteins Spo11, Hop1, Hop2, Mnd1, Dmc1, and Msh5 (Radakovits et al. 2012; Corteggiani Carpinelli et al. 2014). This suggests the possible existence of a cryptic sexual cycle in this species.

Genomics, Molecular Biology, and Biochemistry

Knowledge of eustigmatophyte biology at the biochemical and molecular level is heavily biased toward the genus *Nannochloropsis* (sensu *lato*), with very limited information available for other eustigmatophytes. A major change in this field came with the advent of eustigmatophyte genome sequencing, which yielded data now being explored by in silico analyses and inspiring direct experimental research. The latter has been boosted by development of a suite of methods of genome

manipulations for different species of *Nannochloropsis* and *Microchloropsis*. Exogenous DNA can now be readily introduced into the cells by electroporation and integrated with high efficiency and specificity into the nuclear genome by homologous recombination with the target region (Chen et al. 2008; Kilian et al. 2011; Radakovits et al. 2012; Vieler et al. 2012a; Li et al. 2014a; Kaye et al. 2015; Iwai et al. 2015). These techniques enable gene knockout, overexpression, or expression of modified or foreign genes in *Nannochloropsis* or *Microchloropsis* genomes. For example, overexpression of an endogenous Δ12 desaturase driven by a stress-inducible promoter led to enhanced deposition of LC-PUFAs in TAG, demonstrating the power of genetic manipulations for improving the biotechnological utility of eustigmatophytes (Kaye et al. 2015). Moog et al. (2015) used predicted localization signals of several authentic proteins of *N. oceanica* to drive tagged variants of green fluorescent protein (GFP) into different compartments of transformed *N. oceanica* cells. This study thus opens up new possibilities for cell biological research of eustigmatophytes. Most recently, CRISPR/Cas9 technology has been successfully applied to *N. oceanica* for targeted genome editing (Wang et al. 2016).

Below, general characteristics of eustigmatophyte nuclear and organellar genomes are briefly reviewed, and examples of interesting insights into the molecular fabric of eustigmatophyte cells enabled by in silico analyses of genome data are discussed. An overview of the most important aspects of the eustigmatophyte metabolism as unveiled in recent years by a combination of in silico and direct experimental approaches is then provided.

Nuclear Genomes

Thanks to the efforts of several research groups utilizing the increasingly available next-generation sequencing technologies, more or less complete nuclear genome sequences have become available for most *Nannochloropsis* species (the only exception being the recently described *Nannochloropsis australis*) and for both *Microchloropsis* species (Table 1). Genome sequences for more multiple strains have even been reported for *Nannochloropsis oceanica* and *Microchloropsis gaditana*. The reported genome size varies from ~25 to ~35 Mbp, and the number of predicted genes ranges from ~6,600 to ~12,000. The differences in these values within the two genera and even between strains of the same species are striking and may partly reflect technical issues stemming from different strategies employed for sequencing, assembly, and annotation of the genomes. These uncertainties notwithstanding, *Nannochloropsis* and *Microchloropsis* species apparently belong to the category of algae with small genomes (for comparison, see, e.g., Kim et al. 2014), with relatively high gene density and low intron density (Radakovits et al. 2012; Vieler et al. 2012a; Corteggiani Carpinelli et al. 2014; Wang et al. 2014). Whether this can be generalized to eustigmatophytes as a whole is presently unknown.

The most complete information about genome organization is available for *M. gaditana* B-31, which was estimated to have 30 chromosomes based on the number of putative telomeric ends identified in the assembly (Corteggiani Carpinelli et al. 2014) and for *N. oceanica* IMET1, which was suggested to have 22 chromosomes using pulsed-field gel electrophoresis (Wang et al. 2014). The telomeric

Table 1 Sequenced nuclear genomes of eustigmatophytes. Note that the species here assigned to the genus *Microchloropsis* are treated as species of the genus *Nannochloropsis* in the respective references and database records

repeat of *M. gaditana* B-31 corresponds to the "human-type" motif TTAGGG (Corteggiani Carpinelli et al. 2014), but whether it is common in eustigmatophytes in general is uncertain, because direct testing of the presence of this telomeric sequence in *Eustigmatos polyphem* and *Vischeria punctata* by Southern hybridization failed to confirm this (Fulnečková et al. 2013). Based on the analysis of Pan et al. (2011), *Nannochloropsis oceanica* LAMB0001 is monoploid (haploid), while the ploidy of other eustigmatophytes with sequenced genomes was not investigated closer. An analysis of gene orientation along the *M. gaditana* genome revealed a pattern suggesting frequent deployment of a single bidirectional promoter to control

the expression of two neighboring genes with head-to-head orientation (Jinkerson et al. 2013)

Comparative analyses of the gene complements of *Nannochloropsis* and *Microchloropsis* spp. revealed a surprising level of differences. Corteggiani Carpinelli et al. (2014) clustered genes annotated in genomes of two strains of *Microchloropsis (=Nannochloropsis) gaditana* and two strains of *Nannochloropsis oceanica* and found that only ~4600 clusters comprise homologs present in all four strains, although the total number of annotated genes were between ~9000 and ~11,000 in each strain. This was not only because of differences between the two species, as the strains of the same species also differed in the presence/absence of hundreds of genes. An analysis by Wang et al. (2014) including six strains and five *Nannochloropsis-Microchloropsis* species found an even smaller set of ~2700 core genes shared by all the taxa, whereas the pan-genome, i.e., the totality of all clusters of homologous genes and gene singletons in the six strains was a surprising ~38,000 genes. While these numbers are certainly impacted by genome annotation artifacts, it seems well established that there is considerable diversity within the *Nannochloropsis-Microchloropsis* group at the level of gene repertoire (Wang et al. 2014), which is in stark contrast to the low differences between the strains and species in their 18S rRNA gene sequences (Fig. 1). The evolutionary origin and functional significance of this diversity is yet to be worked out.

In addition to these general aspects of the gene content of eustigmatophyte genomes, many crucial insights into the molecular underpinnings of various structures and processes in eustigmatophyte cells have been obtained by in silico analyses of the sequenced genomes. Analyses of different functional gene categories generally show standard sets of genes expected for a unicellular alga, although relative enrichment of some gene categories, including genes related to lipid metabolism, organic acid metabolism, and stress response, was noted (Radakovits et al. 2012; Vieler et al. 2012a; Corteggiani Carpinelli et al. 2014; Wang et al. 2014). Most attention has been paid to investigating genes related to metabolism, which is discussed in a separate section below. Here, some of the more interesting findings concerning other aspects are highlighted.

Above all, genome analyses provided some insights into regulatory and signaling processes in eustigmatophyte cells. For example, several studies addressed the repertoire of transcription factors and found that the MYB family is the dominant group in eustigmatophytes, whereas some families common in many other eukaryotes, e.g., homeobox and MADS-box genes, are missing (Vieler et al. 2012a; Hu et al. 2014; Thiriet-Rupert et al. 2016). Eustigmatophytes proved to possess the core components of the machinery for RNA-mediated silencing, including Argonaute, Dicer, and RNA-dependent RNA polymerase (Corteggiani Carpinelli et al. 2014). This suggests the ability to employ RNA interference as a defense mechanism against parasitic genetic elements (transposons or viruses), but the machinery may also be involved in processing of miRNAs and deploying them for regulation of endogenous gene expression, as putative miRNA genes were identified in the *N. oceanica* genome (Vieler et al. 2012a). Eustigmatophyte genomes also harbor homologs of blue light receptors common in eukaryotes in general

(cryptochromes) or specific for ochrophytes (aureochromes), suggesting the ability to sense blue light in the environment (Vieler et al. 2012a; Thiriet-Rupert et al. 2016).

Analyses of the *N. oceanica* genome by Vieler et al. (2012a) also led to a discovery that subsequently proved to be important concerning the evolution and function of mitochondria in eukaryotes. These authors pointed to the fact that the nuclear genome encodes homologs of bacterial MinC and MinD proteins with predicted mitochondrial targeting signals and speculated that these might be novel components of mitochondrial division machinery, given the known function of Min proteins in bacterial cell division. Leger et al. (2015) subsequently showed that not only eustigmatophytes but also a number of other eukaryotic lineages possess a previously unnoticed mitochondrial Min system (comprised of MinC, MinD, and MinE proteins) apparently inherited from the bacterial ancestor of mitochondria and presumably involved in regulating mitochondrial division mediated by the mitochondrial FtsZ protein. This example suggests that eustigmatophytes may prove useful as model organisms for investigating general questions of eukaryotic molecular and cell biology.

Organellar Genomes

In contrast to the nuclear genome sequences so far restricted only to the genera *Nannochloropsis* and *Microchloropsis*, organellar genomes have been surveyed more broadly in eustigmatophytes. Specifically, sequences of both organellar genomes have been published not only for most *Nannochloropsis* species (except *N. australis*) and for both *Microchloropsis* species (Radakovits et al. 2012; Wei et al. 2013; Corteggiani Carpinelli et al. 2014; Starkenburg et al. 2014) but also for three species from different branches of the eustigmatophyte phylogeny: *Monodopsis* sp. MarTras21 (representing a sister lineage of the *Nannochloropsis-Microchloropsis* group), *Vischeria* sp. CAUP Q 202 (representing the more distantly related Eustigmataceae group), and *Trachydiscus minutus* (a representative of the clade *Goniochloridales*) (Ševčíková et al. 2015, 2016; Yurchenko et al. 2016). This sampling allows for inferring not only the general characteristics of eustigmatophyte organellar genomes but also their evolutionary plasticity within the group.

Eustigmatophyte mitochondrial genomes (mitogenomes) are conventional in their architecture (circular-mapping molecules), size (from ~38 to ~46 kbp), and gene content (26–29 tRNA genes, 3 rRNA genes, and 37–40 protein coding genes plus nonconserved ORFs specific for particular eustigmatophyte subgroups) (Starkenburg et al. 2014; Ševčíková et al. 2016). An early study proposed that eustigmatophyte mitochondria use the standard genetic code, in contrast to the mitochondria of superficially similar xanthophytes employing a deviant genetic code with the codon AUA coding for methionine rather than isoleucine (Ehara et al. 1997). This has been corroborated by full genome sequencing, which also revealed the presence of a gene for the Ile-tRNA cognate to the AUA codon in eustigmatophyte mitogenomes (Ševčíková et al. 2016). *Trachydiscus minutus* and members of the *Nannochloropsis-Microchloropsis* lineages independently lost the nucleus-encoded mitochondrion-targeted translation termination factor mRF2 and consequently do not use UGA as a termination codon, but no indication of UGA

being reassigned in these taxa as a sense codon (as in mitochondria of many other eukaryotes) was found. An unusual feature of eustigmatophyte mitogenomes is the presence of the *atp1* gene. This is an ancestral condition retained also by non-ochrophyte stramenopiles such as oomycetes, whereas all other ochrophyte classes have lost the mitochondrial *atp1* gene and the Atp1 protein is encoded by a nuclear copy. Eustigmatophyte mitogenomes also uniquely share a truncated *nad11* gene encoding only the C-terminal part of the Nad11 protein, while the N-terminal part is encoded by a separate gene in the nuclear genome. Whereas the gene order of most eustigmatophyte mitogenomes is highly similar, the *Vischeria* sp. CAUP Q 202 genome has been extensively reshuffled, coinciding with the loss of several mitochondrial genes and accelerated evolution of mitochondrial gene sequences in the *Vischeria* lineage (Ševčíková et al. 2016).

All sequenced eustigmatophyte plastid genomes (plastomes) are typical circular-mapping molecules (from ~115 to ~126 kbp in size) with short and long single-copy regions separated by inverted repeats, with the number of genes subsumed to the inverted repeat somewhat differing between the species (Starkenburg et al. 2014; Yurchenko et al. 2016). Their gene content is highly similar (25–28 tRNA genes, 3 rRNA genes, the *ssrA* gene for tmRNA, 124–128 genes coding for typical conserved plastid proteins, and a varying number of nontypical or nonconserved genes) and generally resembles that of other ochrophytes, with several notable exceptions. Firstly, eustigmatophytes plastomes are interesting in that they possess the gene *ycf49*, so far additionally found only in plastomes of cyanidiophyte red algae and the glaucophyte *Cyanophora paradoxa* (Ševčíková et al. 2015). Secondly, the gene for the ClpC protein has been split into three separate genes, encoding the N-terminal domain and the two AAA+ domains as separate polypeptides that presumably assemble into a functional protein (Starkenburg et al. 2014; Ševčíková et al. 2015; Yurchenko et al. 2016). The split of the N-terminal domain is shared with the sole-sequenced plastome of a chrysophyte, *Ochromonas* sp. CCMP1393, supporting the notion that Eustigmatophyceae and Chrysophyceae are related ochrophyte lineages (Ševčíková et al. 2015). Thirdly, the plastomes of *Vischeria* sp. CAUP Q 202 and *Monodopsis* sp. MarTras21 were surprisingly found to harbor a six-gene cluster (inserted between the *ycf54* and *rpl21* genes) acquired from a bacterial donor via horizontal gene transfer (Yurchenko et al. 2016). In silico analyses of these genes revealed that they constitute a novel putative operon, denoted *ebo*, which is quite widespread in bacteria and encodes enzymes of an uncharacterized pathway of secondary metabolism. The significance of the *ebo* operon for eustigmatophyte biology is not yet clear, but its presence in members of two main subgroups of the Eustigmatales indicates it must have been acquired early in eustigmatophyte evolution and secondarily lost in the *Nannochloropsis-Microchloropsis* lineage (Yurchenko et al. 2016).

Metabolism

For most eustigmatophyte species, biochemical analyses have been generally restricted to the composition of plastid pigments (Whittle and Casselton 1975a; Preisig and Wilhelm 1989; Santos 1996; Schnepf et al. 1996; Karlson et al. 1996;

Krienitz et al. 2000; Lubián et al. 2000; Suda et al. 2002). The group is unique among ochrophyte algae in that no form of chlorophyll *c* is detectable by HPLC. All species contain β-carotene. Violaxanthin is the major xanthophyll along with vaucheriaxanthin (-ester) and sometimes other minor forms (zeaxanthin, canthaxanthin, astaxanthin), but fucoxanthin, diadinoxanthin/diatoxanthin, or heteroxanthin are not detected. Violaxanthin is both a light-harvesting pigment (Owens et al. 1987; Keşan et al. 2016) and a component of the xanthophyll cycle protecting the photosynthetic apparatus against an excess of light via non-photochemical fluorescence quenching (Lubián and Montero 1998; Gentile and Blanch 2001; Bína et al. 2017). The major light-harvesting antenna of eustigmatophytes, homologous to the better-known diatom FCP (Fucoxanthin Chlorophyll Protein), is accordingly called VCP (Viola−/Vaucheriaxanthin Chlorophyll Protein) (Sukenik et al. 2000; Carbonera et al. 2014; Litvín et al. 2016). Very recently, the molecular architecture and subunit composition of the photosystem I (PSI) supercomplex were reported for two species of the *Nannochloropsis*-*Microchloropsis* group, revealing unprecedented features of the PSI antenna complexes (Basso et al. 2014; Alboresi et al. 2017; Bína et al. 2016).

Carbon metabolism in eustigmatophytes appears fairly standard and includes glycolysis and gluconeogenesis, the Krebs cycle, oxidative and reductive pentose phosphate pathway, as well as the glyoxylate cycle (Radakovits et al. 2012; Vieler et al. 2012a). Analyses of the predicted gene complements in *M. gaditana* and *N. oceanica* suggested the operation of several carbon-concentration mechanisms in these algae that would enable both C_3- and C_4-type carbon assimilation (Radakovits et al. 2012; Vieler et al. 2012a). Genes for enzymes of polysaccharide metabolism were also annotated in eustigmatophyte genomes and include those for biosynthesis and degradation of both the main cell wall component, i.e., cellulose, and the main storage polysaccharide, i.e., a β-1,3-glucan (chrysolaminarin) (Vieler et al. 2012a; Corteggiani Carpinelli et al. 2014; Scholz et al. 2014). Genes predicted to encode enzymes responsible for the synthesis of sulfated fucans were also identified, suggesting that like in some other ochrophytes, these polysaccharides may also be present in the eustigmatophyte cell wall (Corteggiani Carpinelli et al. 2014). Precursors for isoprenoid biosynthesis are formed solely by the plastid-located non-mevalonate (DOXP) pathway, as no homologs of enzymes of the cytosolic mevalonate pathway were found in the *M. gaditana* genome (Radakovits et al. 2012). Several vitamin B12-dependent enzymes were found to be encoded by the *M. gaditana* genome, suggesting that vitamin B12 may be beneficial or even essential for eustigmatophyte growth under some conditions (Jinkerson et al. 2013).

A new frontier in eustigmatophyte research was defined by the recent identification of phytohormones, specifically abscisic acid (ABA), cytokinins (CKs), and gibberellin (GA), in *Nannochloropsis oceanica* (Lu et al. 2014; Lu and Xu 2015). The *N. oceanica* genomes encode homologs of enzymes mediating the synthesis of ABA and CKs in plants, and the pathways of ABA and CK synthesis are transcriptionally up- and downregulated, respectively, upon nitrogen depletion.

CKs stimulate cell cycle progression in *N. oceanica* whereas ABA acts as a growth repressor, indicating an antagonistic role of the two regulators in response to nitrogen deprivation. Like some other algae and many anaerobic non-photosynthetic protists, *Nannochloropsis* and *Microchloropsis* have genes encoding the enzyme [FeFe]-hydrogenase (*hydA*) as well as factors involved in hydrogenase maturation (*hydE*, *hydF*, and *hydG*; Radakovits et al. 2012; Vieler et al. 2012a). In agreement with these *in silico* insights, *N. oceanica* was found to produce H_2 when grown at anaerobic conditions and supplied with an abiotic electron donor (Vieler et al. 2012a), but the actual physiological role of hydrogenase in eustigmatophytes remains unknown.

Of all metabolic pathways in eustigmatophytes, the most attractive for researchers have been those concerning the synthesis and degradation of fatty acids and lipids. The significance of these metabolic processes in eustigmatophytes is immediately apparent from the fact that the complement of genes encoding enzymes of lipid metabolism is markedly expanded in *Nannochloropsis* and *Microchloropsis* genomes compared to other algae (Radakovits et al. 2012; Wang et al. 2014). Multiple paralogs are found for many of the enzymes, and phylogenetic analyses suggested that the expansion could have partly originated from acquisition of new genes by horizontal gene transfer (Wang et al. 2014).

This genetic constitution underpins the long-known ability of eustigmatophytes to accumulate large amounts of neutral lipids, i.e., forms of TAG with varying profiles of esterified fatty acids (Ma et al. 2016). TAG accumulates in lipid droplets in eustigmatophyte cells. In *Nannochloropsis* sp., an abundant hydrophobic lipid droplet surface protein (LDSP) was characterized (Vieler et al. 2012b). It is unique in its primary sequence but is structurally similar to other lipid-droplet-associated proteins (oleosins) from other organisms. Physiological experiments established stress factors as the main trigger for TAG accumulation, with TAG accumulation serving as a carbon sink under conditions limiting cell growth. Nitrogen limitation stands out as the most effective factor. Recent studies provided a detailed view of changes in gene expression and the activity of different biochemical pathways leading to an increased TAG production upon nitrogen depletion (Li et al. 2014b; Meng et al. 2015). High light intensity also stimulates TAG production, and the molecular mechanism of this phenomenon was recently studied in fine detail using a combination of transcriptomic, lipidomic, and metabolomic approaches (Alboresi et al. 2016).

Not only the production of TAG as such but also certain features of the metabolism of fatty acids make eustigmatophytes highly attractive for biotechnological exploitation. This concerns primarily the ability to synthesize substantial amounts of nutritionally valuable LC-PUFAs. Of these, the most important is EPA (C20:5 n-3), which is found not only in the highly studied *Nannochloropsis*-*Microchloropsis* group but seems to be abundant in eustigmatophytes in general (Cohen 1994; Volkman et al. 1999; Řezanka et al. 2010; Ma et al. 2016). The actual EPA content in eustigmatophyte cells varies considerably depending on environmental conditions such as nutrient status, salinity, light intensity, or temperature (Sukenik 1991, Cohen

1994, Lu et al. 2001, Hoshida et al. 2005, Khozin-Goldberg and Cohen 2006, Pal et al. 2011). EPA is mostly present in the membrane lipids (glyco- and phospholipids) (Cohen 1994; Khozin-Goldberg and Cohen 2006; Vieler et al. 2012a; Ma et al. 2016), but in *T. minutus*, its considerable amounts were identified in TAG as well (Řezanka et al. 2011). An analysis of the *N. oceanica* genome revealed a complete set of genes encoding membrane-bound ER-localized desaturases, namely, putative Δ9-, Δ12-, Δ6-, Δ5-, and ω3-desaturases, which implies the synthesis of EPA outside of the plastid and its import into the plastid for glycolipid synthesis (Vieler et al. 2012a). Arachidonic acid (C20:4 n-6) is also present in smaller quantities in at least some eustigmatophytes (Řezanka et al. 2014). The fatty acid profile of members of the *Vischeria/Eustigmatos* group proved to be unusual due to a high concentration of long-chain hydroxy fatty acids (Volkman et al. 1999).

Systematics

Although eustigmatophytes were sometimes considered as a separate division or phylum Eustigmatophyta (Hibberd 1981, 1990; Ettl and Gärtner 1995; John 2011) or as a taxon (named Eustigmatales) with no explicitly assigned taxonomic rank (Adl et al. 2012), most often they have been treated as the class Eustigmatophyceae within the broadly defined phylum (division) Ochrophyta (Heterokontophyta) (Santos and Leedale 1991; Andersen 2004; Cavalier-Smith and Chao 2006; Graham et al. 2008; Yang et al. 2012; Ševčíková et al. 2015). The formal taxonomic scheme for eustigmatophytes established by Hibberd (1981) recognized a single order, Eustigmatales, divided into four families (Eustigmataceae, Chlorobotrydaceae, Pseudocharaciopsidaceae, Monodopsidaceae). Each family was characterized by a unique combination of character states concerning the presence/absence of zoospores, number of flagella, presence/absence of mucilage, and cell shape. One additional family, the Loboceae, was established to accommodate the newly described alga *Pseudotetraëdriella kamillae* (Hegewald et al. 2007).

However, the "one order/five families" system is incongruent with the phylogenetic relationships within the Eustigmatophyceae and cannot accommodate the diversity as revealed by recent sampling that has yielded a large number of uncharacterized or unidentified isolates (Fig. 1). Above all, the traditional classification does not capture the division of eustigmatophytes into two phylogenetically deeply diverged lineages (Fig. 1). The first lineage includes all eustigmatophyte taxa known to Hibberd (1981) and hence can be equated to his order Eustigmatales. The second lineage comprises taxa that were recognized as eustigmatophytes or described only in the past 25 years, so it naturally constitutes a new candidate eustigmatophyte order. However, in order to formally erect the order based on the International Code of Nomenclature for algae, fungi, and plants (Melbourne Code; http://www.iapt-taxon.org/nomen/main.php), the family-level classification of this group needs to be resolved. Hence, some of us employed the International Code of

Phylogenetic Nomenclature (PhyloCode; https://www.ohio.edu/phylocode/index.html) as an alternative to describe the second principal eustigmatophyte group as the clade *Goniochloridales* (Fawley et al. 2014).

A comprehensive classification of the two main eustigmatophyte groups that would be consistent with the phylogenetic relationships as revealed by molecular phylogenetic analyses is yet to be worked out. Some of the existing families and genera have proven to be para- or polyphyletic, and taxa need to be established to accommodate some newly recognized or described lineages. However, extensive revisions of many taxa are hampered by the lack of cultures corresponding to type species. As mentioned above, further work is also required to resolve the concept of families in the *Goniochloridales.* One to several separate families are conceivable based on the current picture of the phylogenetic diversity of the group (Fig. 1). In the Eustigmatales, three main lineages are apparent that can perhaps be conveniently recognized as three families. One of them fits the delimitation of the family Monodopsidaceae, provided that the family Loboceae, proposed to accommodate *P. kamillae* (Hegewald et al. 2007), is abandoned to avoid paraphyly of Monodopsidaceae. In fact, the formal description of Loboceae is invalid according to the International Code of Nomenclature for algae, fungi, and plants, as the name is not typified by a genus name. The current circumscription of the families Eustigmataceae, Chlorobotrydaceae, and Pseudocharaciopsidaceae appears to be too narrow from the phylogenetic point of view (Fig. 1). They may possibly be merged into a single monophyletic family characterized by the presence of a bulging pyrenoid connected to the plastid with a narrow stipe. On the other hand, a new family needs to be established for a clade comprising *Pseudellipsoidion edaphicum* and *Pseudocharaciopsis ovalis* together constituting a strongly supported third monophyletic clade of Eustigmatales (Fig. 1). To facilitate communication about the eustigmatophyte phylogenetic diversity before formal taxonomic revisions of the eustigmatophyte families are completed, informal names were proposed for different (presumably) monophyletic subgroups of both Eustigmatales and *Goniochloridales* (Fawley et al. 2014). For simplicity, these informal groups are only indicated in Fig. 1 and are not discussed further.

The following overview of eustigmatophyte classification includes all genera and species previously assigned to this group on the basis of ultrastructural, biochemical, and/or molecular evidence.

Order Eustigmatales

Genus *Eustigmatos* D.J. Hibberd 1981

Type species: *Eustigmatos vischeri* D.J. Hibberd

Very similar to *Vischeria* but the cell wall is always smooth and featureless. Four species (*E. vischeri*, *E. magnus*, *E. polyphem*, *E. calaminaris*) very closely related to or intermixed with *Vischeria* spp. in molecular trees (Fig. 1),

suggesting that the genus *Eustigmatos* should be merged with the genus *Vischeria*.

Genus *Vischeria* Pascher 1938

Type species: *Vischeria stellata* (Chodat) Pascher (basionym: *Chlorobotrys stellata* Chodat).

The cells isodiametric, the zoospores elongate lageniform, with a single emergent flagellum, the cell wall typically raised into projections or ridges. Three species (*V. stellata*, *V. punctata*, *V. helvetica*) studied in detail and confirmed as eustigmatophytes (Hibberd 1981), nine other species described by Pascher (1939) are yet to be reinvestigated.

Genus *Chlorobotrys* Bohlin 1901

Type species: *Chlorobotrys regularis* (West) Bohlin (basionym: *Chlorococcum regulare* West).

The cells occur in pairs or colonies, surrounded by lamellate mucilage. Zoospores not observed. One species, *C. regularis*, was confirmed as a eustigmatophyte (Hibberd 1974); several other described species (Ettl 1978) are yet to be studied in detail.

Genus *Pseudocharaciopsis* K.W. Lee and H.C. Bold 1974

Type species: *Pseudocharaciopsis texensis* K.W. Lee & Bold, considered a junior synonym of *Pseudocharaciopsis minuta* (A.Braun) Hibberd (basionym: *Characium minutum* A.Braun ex Kützing)

The cells ovoid/ellipsoidal and capable of producing a stipe. The zoospores with two emergent flagella. 18S rRNA gene sequences determined for the two *Pseudocharaciopsis* species (*P. minuta* and *P. ovalis*) indicate that this genus is polyphyletic (Fig. 1). In addition, a strain identified as *Characiopsis saccata*, hence representing the genus *Characiopsis* currently classified in the class Xanthophyceae, is closely related to *P. minuta* (Fig. 1). The taxonomy of the genera *Pseudocharaciopsis* and *Characiopsis* is thus in an urgent need of revision (see also below).

Genus *Monodopsis* D.J. Hibberd 1981

Type species: *Monodopsis subterranea* (J.B. Petersen) D.J. Hibberd (basionym: *Monodus subterranea* J.B. Petersen)

Unicellular forms with spherical, ovoid, ellipsoid, or cylindrical cells, 5–10 μm in diameter. Zoospores not observed. One validly described species (*M. subterranea*). The combination *Monodopsis unipapilla* was mentioned in the literature (Santos and Leedale 1995; Santos 1996) but not yet validly published, for a species originally known as *Monodus unipapilla* and closely related to *M. subterranea* (Fig. 1). Other species of the traditionally xanthophyte genus *Monodus* may need reclassification to *Monodopsis*. One such candidate is *Monodus guttula*, nominally represented by two strains with sequenced 18S rRNA gene (Fig. 1) whose identification yet need to be critically examined.

Genus *Pseudotetraëdriella* E. Hegewald 2007

Type species: *Pseudotetraëdriella kamillae* E. Hegewald & J. Padisák

The vegetative cells with four lobes, zoospores elongate-ovate with one emergent flagellum and without an eyespot, globular resting spores. So far monotypic.

Genus *Nannochloropsis* D.J. Hibberd 1981

Type species: *Nannochloropsis oculata* (Droop) D.J. Hibberd (basionym: *Nannochloris oculata* Droop)

The cells spherical, ovoid, ellipsoid, or cylindrical, <5 μm in maximum dimension. Zoospores not observed. Previously included two species now classified in the separate genus *Microchloropsis* (see below). The five formally described species occur in marine habitats (*N. oculata*, *N. granulata*, *N. oceanica*, *N. australis*) or in freshwater (*N. limnetica* with several varieties described; Fawley and Fawley 2007). One more species, "*Nannochloropsis maritima*", appeared recently in the literature (Hu et al. 2013) and is represented by an 18S rDNA sequence in GenBank (accession number AY680703), but it has not been formally described.

Genus *Microchloropsis* M.W. Fawley, I. Jameson & K.P. Fawley 2015

Type species: *Microchloropsis salina* (D.J. Hibbard) M.W. Fawley, I. Jameson & K.P. Fawley (basionym: *Nannochloropsis salina* D.J. Hibberd)

Cells small (2–8 μm), cylindrical or rarely spherical with a single parietal chloroplast. Pyrenoids absent. Some cells with an orange or red lipid body free in the cytoplasm. Refractive granules or short rods usually present in the cytoplasm. Reproduction by autospore production. Young autospores usually hemispherical but become cylindrical or spherical as they mature. Two described species (*M. salina* and *M. gaditana*).

Genus *Pseudellipsoidion* J. Neustupa and Y. Němcová 2001

Type species: *Pseudellipsoidion edaphicum* J. Neustupa & Y. Němcová

The vegetative cells with ellipsoidal and globular morphology, zoospores of irregular or oval shape with one emergent flagellum. Pyrenoid absent. So far monotypic.

Clade *Goniochloridales*

Genus *Goniochloris* Geitler 1928

Type species: *Goniochloris sculpta* Geitler

Vegetative cells dorsoventrally flattened and irregularly triangular in frontal view, with the cell surface sculptured. Reclassification of this genus from the Xanthophyceae to the Eustigmatophyceae is based on the 18S rRNA gene sequence from the type species *G. sculpta* (Fig. 1; Přibyl et al. 2012). The taxonomic assignment of the number of remaining known *Goniochloris* species (Ettl 1978) awaits further studies.

Genus *Pseudostaurastrum* Chodat 1921

Type species: *Pseudostaurastrum enorme* (Ralfs) Chodat (basionym: *Staurastrum enorme* Ralfs)

Tetrahedral or plate-like cells with typically four branched projections. Two species (*P. enorme*, *P. limneticum*) have been studied by modern methods confirming their classification within the Eustigmatophyceae; a few other described species (Ettl 1978) are very likely related given the highly characteristic morphology.

Genus *Trachydiscus* H. Ettl 1964

Type species: *Trachydiscus lenticularis* H. Ettl

Disc-shaped cells with the cell surface sculptured by numerous cell wall protuberances (warts, bulges, or papillae). Reclassification of this genus from the Xanthophyceae to the Eustigmatophyceae is based on a cytological, biochemical, and molecular genetic evidence for the species *Trachydiscus minutus* (Fig. 1; Přibyl et al. 2012). However, the additional six known *Trachydiscus* species, including the type species, are morphologically rather different from *T. minutus*, so it must yet to be confirmed whether they (and hence formally the genus *Trachydiscus* as such) belong to the Eustigmatophyceae and specifically to the *Goniochloridales*.

Genus *Tetraëdriella* Pascher 1930

Type species: *Tetraëdriella acuta* Pascher

Cells pyramidal or tetragonal with walls ornamented by regularly arranged rows of depressions. The genus *Tetraëdriella* is traditionally classified in Xanthophyceae (Ettl 1978) but is here included in eustigmatophytes, specifically as a member of Goniochloridales, based on the recent reinvestigation of the species *Tetraëdriella subglobosa* including evidence from its 18S rRNA gene sequence (Fawley and Fawley 2017; see also Fig. 1). The morphological features of other *Tetraëdriella* species, including the types species, suggest that they are related to *T. subglobosa.* Ultrastructural and molecular evidence for eustigmatophyte affinity of several other *Tetraëdriella* species was presented at a conference (Santos and Santos 2001) or mentioned in the literature (Ott et al. 2015), but the actual data are yet to be published.

Genus *Vacuoliviride* T. Nakayama, T. Nakamura, A. Yokoyama, T. Shiratori, I. Inouye & K.-I. Ishida 2015

Type species: *Vacuoliviride crystalliferum* T. Nakayama, T. Nakamura, A. Yokoyama, T. Shiratori, I. Inouye, and K.-I. Ishida

Vegetative cells solitary, nonmotile, spherical to ellipsoidal, 6–30 μm in diameter, and covered by smooth cell wall. Cells include refractile granules, a large vacuole, and a reddish globule, frequently with a rod- to V-shaped crystalline structure, one to several greenish chloroplasts possessing bulging pyrenoid with longitudinal slit. Cells reproduce by 2–8 autospores. So far monotypic.

Eustigmatophyceae *Incertae sedis*

Genus *Botryochloropsis* H.R. Preisig and C. Wilhelm 1989

Type species: *Botryochloropsis similis* H.R. Preisig and C. Wilhelm

Spherical cells in mucilage aggregated in irregular colonies, zoospores with two emergent flagella. Pyrenoid absent. No molecular data (and no authentic culture) are available for this genus, so its exact position within eustigmatophytes is unknown. So far monotypic.

Additional Eustigmatophytes

The actual diversity of eustigmatophytes is not restricted to the taxa listed above. The many unidentified strains that have been assigned to the Eustigmatophyceae based on their 18S rDNA (Fawley et al. 2014; Fig. 1) and *rbc*L (Prior et al. 2009) sequences illustrate the extent of the hitherto unnoticed diversity of this class. Many of these strains will probably prove to represent new taxa (species and even genera), but it is possible that others can eventually be identified as previously described species after a detailed scrutiny is carried out. Indeed, several algal taxa, traditionally classified in Xanthophyceae, have been occasionally considered as candidate members of Eustigmatophytes. For example, Hibberd (1981) admitted a possibility that *Pleurochloris commutata*, the type species of the genus *Pleurochloris*, may be a eustigmatophyte based on certain morphological features of vegetative cells and zoospores. Interestingly, most of the currently known eustigmatophytes were previously classified as members of the xanthophyte family Pleurochloridaceae comprising a large number of genera and species that have not been studied by modern methods. It is very likely that many additional members of the Pleurochloridaceae will eventually be reclassified to Eustigmatophyceae.

One of the taxa of Pleurochloridaceae with possible eustigmatophyte affinities is the genus *Chloridella* Pascher. 18S rRNA gene sequences were obtained from two strains nominally representing two species, *Chloridella neglecta* (the type species of the genus) and *Chloridella simplex*, showing that both algae belong to the tight *Vischeria/Eustigmatos* cluster (Fawley et al. 2014; Fig. 1). This led Ott et al. (2015) to classify *Chloridella* as a eustigmatophyte genus. However, neither of the two strains is authentic, and their morphology has not yet been properly studied to check the identification as provided in the respective culture collections. Whereas *C. simplex* indeed resembles *Eustigmatos* species (reportedly differing by the lack of zoospores), *C. neglecta* is more reminiscent of *Pleurochloris meiringensis*, a confirmed member of Xanthophyceae (Andreoli et al. 1999b). Thus, classifying *Chloridella* as a eustigmatophyte is premature, and critical revision of this genus is needed to clarify its circumscription and phylogenetic position. A few more genera (e.g., *Gloeobotrys*, *Gloeoskene*, or *Merismogloea*) were listed as candidate

eustigmatophytes by Ott et al. (2015) based on the fact that they had been proposed to be synonymous with established eustigmatophytes or that some of their members (but not type species themselves) had been demonstrated to be eustigmatophytes.

Evidence for additional eustigmatophytes was informally presented at conferences, but bona fide publication of the data is still missing. Specifically, ultrastructural and molecular data were obtained from several strains from the ACOI collection identified as different species of the genus *Characiopsis*, indicating their eustigmatophyte nature (Santos and Santos 2001; Amaral et al. 2011, 2015). Indeed, *Characiopsis* was listed as a genus of eustigmatophytes by Ott et al. (2015), but this was based on an assumption that the alga known as *Pseudocharaciopsis minuta* (and belonging to Eustigmatophyceae; Fig. 1) is in fact the type species of *Characiopsis* Borzì. However, as discussed in detail by Hibberd (1981), the type species of the genus may actually be *Characiopsis borziana* Lemmermann, whose phylogenetic position remains unknown. Dashiell and Bailey (2009) announced a new eustigmatophyte genus ("*Microtalis*") with two new species and strains labeled "*Microtalis aquatica* Bailey,JC" and "*Microtalis reticulata* Bailey,JC" that are available from the National Center for Marine Algae and Microbiota (CCMP3153 and CCMP31547, respectively). Sequences of several genes from the former strain were published by Yang et al. (2012) and indicate that "*Microtalis aquatica*" is closely related to *Trachydiscus minutus* and several unidentified strains (Fig. 1). As mentioned above, *T. minutus* morphologically differs significantly from the type species of the genus *Trachydiscus*, so treating the clade including *T. minutus* and *M. aquatica* as a new genus may prove substantiated when characterization of the strains CCMP3153 and CCMP31547 is eventually published.

A few taxa have been assigned to the Eustigmatophyceae in error. *Ophiocytium maius* (strain CCAP 855/1) was suggested to be a eustigmatophyte based on its *coxI* sequence (Ehara et al. 1997). However, it has proven to be a misidentified member of the *Vischeria/Eustigmatos* cluster (Fig. 1); the genuine *O. maius* (strain SAG 855-1) is undoubtedly a xanthophyte (Maistro et al. 2009). Ott and Oldham-Ott (2003) included the genus *Ellipsoidion* in the Eustigmatophyceae, apparently because early reports on eustigmatophytes featured an alga (strain CCAP 822/1) then identified as *Ellipsoidion acuminatum* (Hibberd and Leedale 1970, 1971, 1972). However, Hibberd (1981) reexamined the strain and eventually identified it as *Characiopsis ovalis*, basing his taxonomic revision of the species name to *Pseudocharaciopsis ovalis* (Chodat) Hibberd. Thus, there is at present no evidence that *E. acuminatum* or the type species of the genus *Ellipsoidion*, *E. anulatum* Pascher, are eustigmatophytes; both species and the whole genus thus formally remain in the Xanthophyceae. Molecular data that were published for a single confidently identified *Ellipsoidion* species, the authentic strain of *Ellipsoidion parvum*, showed that this strain is a green alga conspecific with *Neocystis brevis* (Eliáš et al. 2013). Hence, the actual identity and phylogenetic position of the genus *Ellipsoidion* remain highly uncertain.

Maintenance and Cultivation

Eustigmatophytes presently maintained in culture collections were originally isolated using a wide variety of techniques. Single-cell isolation is possible for all the larger forms. Terrestrial and some freshwater species grow well on nutrient agar, and plating may also be used (Prior et al. 2010; Fawley et al. 2014). Agar plate techniques have been used to isolate the many new stains of freshwater Eustigmatophyceae that are presented in Fig. 1. For the minute forms, particularly when occurring in blooms, dilution techniques work well.

Cultures of freshwater and terrestrial species generally grow well in a wide variety of mineral media or in biphasic soil/water cultures where they may survive for many months, even years. Clonal cultures of most strains are available and stocks are most conveniently maintained on nutrient agar slants containing dilute (e.g., Chu No. 10) or rich (e.g., Bold's Basal Medium) media (Nichols 1973). Two of the authors have had success isolating and maintaining Eustigmatophyceae on the high-nutrient medium, WH+ (Fawley et al. 1990; Fawley et al. 2014), and the low-nutrient medium originally designed for chrysophytes, DYIV (Andersen et al. 1997). The ACOI Collection of Algae holds ca. 80 strains of eustigmatophytes (Santos and Santos 2004) that have been kept for 15 years in liquid Desmidiacean medium M7 (for chemical composition, see Schlösser 1994), with a controlled pH of 6.4–6.6. This is a suitable medium for all strains, but relatively slow growth is observed for sensitive genera, namely, *Pseudostaurastrum*, *Tetraëdriella*, *Chlorobotrys*, and *Goniochloris*. A new medium composed of a one tenth dilution of WH+ with 0.1 g^{-1} MES buffer at pH 5.5 (Karen and Marvin Fawley, unpublished) is proving effective for isolating Eustigmatophyceae from acid environments. Marine forms grow easily in standard seawater media such as Erdschreiber or ASP2 (Provasoli et al. 1957), either as standing liquid batch cultures or on agar slants for stock cultures. These forms tolerate a wide range of salinity and a half-normal salinity or even a freshwater medium is usually more convenient for maintenance of stocks. Cryopreservation has been successfully tested for several eustigmatophyte species (Osório et al. 2004; Gwo et al. 2005).

Evolutionary History

There is no fossil record known for eustigmatophytes; hence, reconstruction of their evolutionary origin and diversification has relied solely on comparative analyses of morphological, biochemical, and molecular characters. All these characters firmly place eustigmatophytes into a broader group of ochrophyte (or heterokontophyte) algae, which in turn form a prominent clade within stramenopiles (or heterokonts) (Santos and Leedale 1991; Andersen et al. 1998; Andersen 2004). Phylogenetic analyses of multigene matrices generally indicate that Eustigmatophyceae are a sister group of a clade comprising Chrysophyceae (incl. Synurophyceae) and

Synchromophyceae, altogether forming the group Limnista (Yang et al. 2012; Ševčíková et al. 2015). However, the recent analysis of stramenopile phylogeny based on a 245-protein dataset and including sequences from *Nannochloropsis gaditana* as a representative eustigmatophyte placed this organism closer to Raphidophyceae and the PX clade (Phaeophyceae plus Xanthophyceae), although with unconvincing statistical support (Noguchi et al. 2016). The phylogenetic position of eustigmatophytes among ochrophytes thus needs to be further tested.

Phylogenetic relationships within eustigmatophytes have been investigated primarily with the aid of 18S rRNA gene sequences, which confirmed eustigmatophyte monophyly (Andersen et al. 1998) and revealed the existence of two principal deeply separated subgroups, *Goniochloridales* and Eustigmatales (Fig. 1; Přibyl et al. 2012; Fawley et al. 2014). Relationships within the *Goniochloridales* are not yet clear; however, four clades within this lineage are supported by analysis of the 18S rRNA gene sequence data (Fig. 1). Within the latter subgroup, three major lineages can be recognized (their names here follow the nomenclature introduced by Fawley et al. 2014): Eustigmataceae group, Monodopsidaceae, and *Pseudoellipsoidion* group. Each group is well supported by analyses of 18S rRNA gene sequences, but their relative branching order needs to be established using a higher number of molecular markers. The phylogenetic position of *Botryochloropsis similis* is unknown given the absence of molecular data. However, a characteristic combination of morphological features documented for this species by Preisig and Wilhelm (1989), specifically the presence of an eyespot, zoospores with two flagella, and plastids with no pyrenoid, suggests that *B. similis* possibly belongs to the *Pseudellipsoidion* group.

Even though incomplete, the phylogenetic tree reconstructed for eustigmatophytes enables some inferences about evolutionary trends in this group. First, eustigmatophytes apparently emerged in a freshwater or terrestrial habitat and frequent transitions between these two habitat types seem to have occurred during their evolution, whereas the *Nannochloropsis* lineage secondarily moved to the sea, from which the species *N. limnetica* came back to the freshwater. Second, since an eyespot is altogether absent in all species of the *Goniochloridales* clade investigated so far (Schnepf et al. 1996; Přibyl et al. 2012) as well as in *Pseudotetraëdriella kamillae* (Hegewald et al. 2007), it is actually possible that the characteristic extraplastidial eyespot, regarded as one of the defining features of the whole eustigmatophyte class, arose only after some eustigmatophyte lineages had diverged. Third, zoospores were presumably lost independently in the lineages leading to *Nannochloropsis* and to *Monodopsis*, since they have been retained by *Pseudotetraëdriella kamillae* (Hegewald et al. 2007). Fourth, up to three independent losses of the continuity between the plastid ER and the nuclear envelope can be inferred to have occurred (in the *Goniochloridales*, in the Eustigmatophyceae group, and in the *Pseudellipsoidion* group). Fifth, species with zoospores with a single emergent flagellum (*Vischeria/Eustigmatos* cluster, *Pseudotetraëdriella kamillae*, members of the *Goniochloridales* with zoospore morphology investigated in detail, and potentially also *Pseudellipsoidion edaphicum*) do not form a monophyletic grouping, which indicates multiple independent losses of the posterior flagellum. Altogether, the evolutionary history of eustigmatophytes appears complex and heavily

influenced by homoplasy. A more detailed reconstruction remains a task for the future, with the very real possibility of a greatly expanded number of taxa included in the class.

Abstract

The Xanthophyceae is a clade of stramenopilan photoautotrophs containing about 118 genera and 600 species. Morphology ranges from free-living or attached unicells to colonies and unbranched or branched filaments and siphons. A large majority are found in freshwater and soil, while some occur in brackish and marine habitats. Although abundant growth of a few species can occur in nature, none are known to be of practical importance. They are characterized by possession of chlorophylls *a*, c_1, and c_2 and a range of xanthophylls, but not fucoxanthin, in generally yellowish-green, discoidal, parietal chloroplasts. Thylakoids are in groups of three, and most species investigated have a single thylakoid forming a girdle band around the periphery of the chloroplast. Chloroplasts are surrounded by chloroplast endoplasmic reticulum. Pyrenoids, when present, are typically semi-immersed and are not associated with granules of storage products. A cell wall consisting of two overlapping parts occurs in some coccoid and filamentous species. Reproduction is generally asexual but some, e.g., *Vaucheria*, exhibit sexual reproduction. The taxonomic status of a significant number of species is uncertain, especially those that are rarely observed, e.g., species of Chloramoebales, Heterogloeales, and Rhizochloridales. Transfer of species to the Eustigmatophyceae and other groups is likely. There are molecular phylogenetic data for fewer than 20% of species. Four major clades are recognized. Two

of these contain both coccoid and filamentous species. Many traditional orders, families, and genera are paraphyletic or polyphyletic. It is presently convenient to retain the traditional classification of seven orders based on morphology until these difficulties are resolved following the inclusion of more species in phylogenetic analyses.

Introduction

General Characteristics

Xanthophyceae are photoautotrophic, stramenopilan protoctists possessing green parietal chloroplasts. They are distinguished from members of the Chlorophyta by the absence of chlorophyll *b*, the presence of small amounts of chlorophylls c_1 and c_2, and the lack of starch as a storage carbohydrate. Their color is usually of a more yellow shade than is typical for the Chlorophyta due to the presence of β-carotene and xanthophylls (e.g., violaxanthin, heteroxanthin, and vaucherioxanthin) and the absence of fucoxanthin, a brown pigment present in most other photosynthetic stramenopiles. This has led to their common name of yellow-green algae. Motile cells are typically of the heterokont type, with unequal-length flagella. The longer bears hairs and is directed anteriorly during swimming, while the shorter is smooth and held posterolaterally. About 600 species have so far been described, belonging to over 90 genera.

Occurrence

Xanthophyceans occur from the tropics to the polar regions. The great majority live in freshwater as phytoplankton and periphyton in lakes, ponds, streams, and rivers. Most taxa are seen only rarely but some commonly form visible growths, especially filaments of *Vaucheria* and *Tribonema* in flowing waters. Xanthophyceans often comprise a significant part of the soil microflora (Ettl and Gärtner 1995). Species of *Vaucheria* can form thick velvety mats that help bind sediment in salt marshes, damp soil, and rarely in the coastal marine environment. Members of this clade are represented in all the major algal culture collections.

Literature and History of Knowledge

The taxon has been reviewed by Hibberd (1980, 1990) and Ott (1982). The group was monographed by Pascher (1937–1939), whose account was revised by Ettl (1978). Silva (1979) dealt with many problems of nomenclature. Descriptions of xanthophyceans in the terrestrial ecosystem are provided by Ettl and Gartner (1995). Phylogenetic relationships and taxonomic status of many taxa are under continuing scrutiny using molecular techniques that are deeply changing the perception of diversity and classification of xanthophyceans (see below).

The distinguishing characters of the Xanthophyceae remained unrecognized until the latter part of the nineteenth century, and prior to 1899, the few known species were included in the Chlorophyta. The studies of Braun (1855) and Borzi (1889, 1895) led to the recognition within the green algae of a group, the Confervales, which included species previously scattered among the various families of green

algae. The Confervales were characterized by the possession of numerous discoid yellow-green chloroplasts apparently lacking pyrenoids; fat or oil and not starch as the assimilatory storage product; and zoospores typically containing two lateral discoid chloroplasts and bearing, as it was then believed, only a single flagellum. Unicellular, filamentous, and siphonous forms possessing these characters were all known at this time. An important cytological study of the group was published by Bohlin (1897a), who extended its classification by dividing the Confervales into three families. He also described the amoeboid mastigote *Chloramoeba* (Bohlin 1897a, b) which, although placed in the mastigote group Chloromonadina, was regarded as a possible progenitor of the Confervales.

A palmelloid form (*Chlorosaccus*) belonging to this complex was described by Luther (1899) which in several features was intermediate between "flagellate" and "algal" organization. *Chlorosaccus* would have been included with *Chloramoeba* in the mastigote group Chloromonadina had its palmelloid state not been predominant. The zoospores of *Chlorosaccus* were similar to those of the Confervales except that they had a second short flagellum, and Luther, attempting to confirm the unimastigote condition of the motile cells in the Confervales, made the important discovery that the zoospores of both *Tribonema* and *Botrydiopsis* possessed a second flagellum much shorter than the first. *Chlorosaccus* could thus be regarded as a form intermediate between the Chloromonadina and Confervales.

In the absence of any significant features distinguishing these two groups, and because of the important differences between the Confervales and the remainder of the Chlorophyceae, an entirely new class, the Heterokontae, was erected to include both the Chloromonadina and the Confervales. Luther's view of the Heterokontae as an isolated and well-defined evolutionary series of algae was quickly adopted by most phycologists. The alternative name for the class, Xanthophyceae, was proposed by Allorge (1930) and first validly published by Fritsch (1935). However, Fritsch (1935) still placed *Vaucheria* and three other siphonous, filamentous genera within the Siphonales, Chlorophyceae but expressed uncertainty in this.

A very large part of the increase in knowledge of the systematics and cytology of the Xanthophyceae following these early studies is due to the work of a single investigator, Adolf Pascher. Several decades of study led to his final monumental treatment of the group (Pascher 1937–1939), *Heterokontae*, Volume II in the second edition of Rabenhorst's *Kryptogamen Flora*, in which Pascher himself authored approximately two-thirds of the included genera.

Other than those already mentioned, there were few cytological studies of xanthophyceans prior to the advent of electron microscopy The classic work of Vlk (1931, 1938) demonstrated that the long flagellum of zoospores is a "flimmergeissel," bearing lateral "flimmer" (now known to be tubular, tripartite stiff hairs), and that the short flagellum is a "peitschengeissel" (whiplash flagellum) not bearing hairs but with a thick basal part and a thinner distal part. Koch (1951) and Manton et al. (1952) provided further information of the external morphology of the flagella, the latter authors using electron microscopy for the first time on a Xanthophycean.

The next use of electron microscopy was with observations by Greenwood et al. (1957) and Greenwood (1959) on the compound zoospore of *Vaucheria.* These were followed by several investigations of chloroplast structure in the early 1960s.

Modern electron microscopy studies dealt mainly with the siphonous genera *Vaucheria* and *Botrydium* and with *Tribonema* (Lokhorst 2003; Lokhorst and Star 2003a, b; Ott 1982). Only a handful of more than 400 coccoid species have been investigated (Begum and Broady 2001; Andreoli et al. 1999).

Finally, modern phylogenetic approaches, based on analyses of genes, are dramatically changing concepts of the boundaries of this group as well as the understanding of the relationships among various xanthophycean clades (see below).

Practical Importance

The Xanthophyceae have no known practical importance except for *Vaucheria* having a role in stabilization of sediments. They have yet to be thoroughly investigated for production of biochemicals of potential biotechnological use.

Habitats and Ecology

Xanthophyceae occur predominantly in freshwater habitats. Most taxa are seen only rarely and many have never been seen again since they were originally described, probably because they mostly occur only in small numbers. Also, the inclusion of several taxa within Xanthophyceae requires confirmation by molecular analyses (Maistro et al. 2009). Most unattached forms occur in still waters among other algae or submerged vegetation, particularly in low pH habitats that are also often rich in iron. Coccoid xanthophyceans are relatively well represented in the algal biota of soils (Ettl and Gärtner 1995; Vischer 1945), although several soil algae originally attributed to the Xanthophyceae have now been shown to be Eustigmatophyceans. Species of filamentous *Tribonema* are common among floating mats in still water, particularly in late winter. Coccoid and filamentous species have been isolated from terrestrial habitats in Antarctica (Andreoli et al. 1999; Broady 1976; Maistro et al. 2007; Negrisolo et al. 2004; Rybalka et al. 2009 – and other citations therein). The most conspicuous forms in nature are species of the siphonous genera *Botrydium* and *Vaucheria.* The former occur as large green vesicles up to several mm in diameter, often in very large numbers on the surface of drying mud, while *Vaucheria* is widespread in freshwater, brackish, and marine habitats in still or running water and on soil. Many species are among the dominant autotrophs in salt marshes. Functional chloroplasts of *Vaucheria litorea* are sequestered within cells of the gut by the marine sacoglossan mollusk *Elysia chlorotica* (Pierce et al. 2009). *Heterococcus* occurs as a photobiont in species of the crustose lichen *Verrucaria* (Tschermak-Woess 1988).

Characterization and Recognition

Most xanthophycean species exist vegetatively as green to yellow-green coccoid unicells, though the relatively small number of filamentous and siphonous species are usually more abundant and more commonly found. A few monadoid, rhizopodial, and palmelloid forms have also been described, but doubt must be cast on whether many of these truly belong to this taxon. It is important that these are reinvestigated using modern methods. Their heterokont motile cells most easily distinguish xanthophyceans from chlorophytes. In the absence of these, a negative reaction with dilute iodine in potassium iodide is still a useful means of distinguishing them from chlorophytes as xanthophyceans never store starch; however, the test is often inconclusive on very small cells. In these cases data on pigment composition is necessary combined with a multigene molecular phylogenetic analysis, the only way to unambiguously assign a heterokont species to the Xanthophyceae (Maistro et al. 2009).

Pigment Composition

Chlorophylls *a* and *c* (both c_1 and c_2) are found in xanthophyceans. The *c* chlorophylls are present in extremely low concentrations and are likely to be missed unless specifically sought. Chlorophyll *e* has also been reported once but it has never been found again and so its existence seems unlikely. The presence of chlorophyll *b* in any presumed xanthophycean is an *a priori* reason for its transference to one of the classes of green algae. Presence or absence of chlorophyll *b* is the most reliable taxonomic criterion when the gross assignment of very small planktonic species is in question; when chlorophyll *b* is lacking, xanthophyceans may be distinguished from Eustigmatophyceans by their distinctive xanthophyll composition (Whittle 1976; Whittle and Casselton 1975).

The yellow-green color of xanthophyceans is partly due to the masking of the green color of chlorophyll *a* by carotenoid pigments, but is probably due primarily to the absence of fucoxanthin, the pigment responsible for the overall brown color of Chrysophyceans, Haptophyta (Prymnesiophyceans), diatoms, and the brown seaweeds. Carotenoids typically present in the Xanthophyceae include β-carotene and the xanthophylls diatoxanthin, which is dominant, diadinoxanthin, heteroxanthin, and vaucheriaxanthin ester (Rowan 1989; Stransky and Hager 1970; Whittle 1976; Whittle and Casselton 1975). Minor xanthophylls include neoxanthin and cryptoxanthin monoepoxide and several others have been identified less commonly. A blue-green color, produced by some species when treated with concentrated hydrochloric acid, thought to be caused by a reaction with xanthophyll pigments, is sometimes said to be a test for the group, but it is unreliable as some species produce no color change, some turn a shade other than blue green, and others give a variety of colors.

Vegetative Cell Structure

Xanthophyceans usually contain several discoid parietal chloroplasts (Fig. 1a, b) which show little variation in form. Absence of pyrenoids from xanthophycean chloroplasts was once considered to be characteristic but detailed light microscope investigation and electron microscopy has shown that many species do, in fact, possess pyrenoids (Broady et al. 1997; Hibberd and Leedale 1971; Massalski and Leedale 1969).

The chloroplast lamellae usually comprise three thylakoids which show varying degrees of coherence depending on species. In the majority of investigated forms a single lamella, the girdle band, encircles the others around the edge of the chloroplast, enclosing between itself and the ends of the parallel lamellae a region of less dense matrix (Falk and Kleinig 1968; Hibberd and Leedale 1971; Massalski and Leedale 1969; Fig. 1e, f), almost certainly the location of the chloroplast DNA. The absence of a girdle band in *Bumilleria sicula* (Massalski and Leedale 1969), *Bumilleriopsis filiformis* (Böger and Kiermayer 1974; Hibberd and Leedale 1971), and *Pseudobumilleriopsis pyrenoidosa* (Deason 1971a) is probably due to secondary loss, since these three species are relatively advanced filamentous forms and seem closely related.

The chloroplasts in both vegetative cells and zoospores are bounded by the usual chloroplast envelope of two membranes and also by a two-membrane layer of chloroplast endoplasmic reticulum (PER), the outermost membrane of which is continuous with the outermost membrane of the nuclear envelope (Fig. 2). The region between the chloroplast envelope and the PER, the periplastidial compartment, contains a membranous reticulum, the periplastidial network. This network is best developed where the nuclear envelope and PER are confluent and appears either tubular or vesicular in transverse section (Hibberd and Leedale 1971; Massalski and Leedale 1969; Fig. 2). It shows occasional connection with the inner membrane of the PER (Falk and Kleinig 1968), and clusters of 3–6 spherules with dense walls can commonly be seen in tangential sections (Hibberd and Leedale 1971; Massalski and Leedale 1969). The composition of the spherules and their exact relationship with the periplastidial network has not yet been established.

Pyrenoids are typically of a semi-immersed type, forming a bulge on the inner face of the chloroplast (Deason 1971a; Falk 1967; Hibberd and Leedale 1971; Massalski and Leedale 1969). They are traversed by normal three-thylakoid lamellae but these are more widely spaced than in the remainder of the chloroplast and may also show discontinuities (Massalski and Leedale 1969). Thylakoid-free outpushings of the chloroplast in *Tribonema viride* (Falk and Kleinig 1968), the germlings of *Vaucheria woroniniana* (Marchant 1972), and three strains of *Xanthonema* (Broady et al. 1997) have been described as projecting pyrenoids, but these attributions must remain in doubt pending more thorough investigation. No storage material or capping vesicle has been found to be associated with pyrenoids in the Xanthophyceae but lipid droplets (plastoglobuli) (Fig. 1c), which are normally

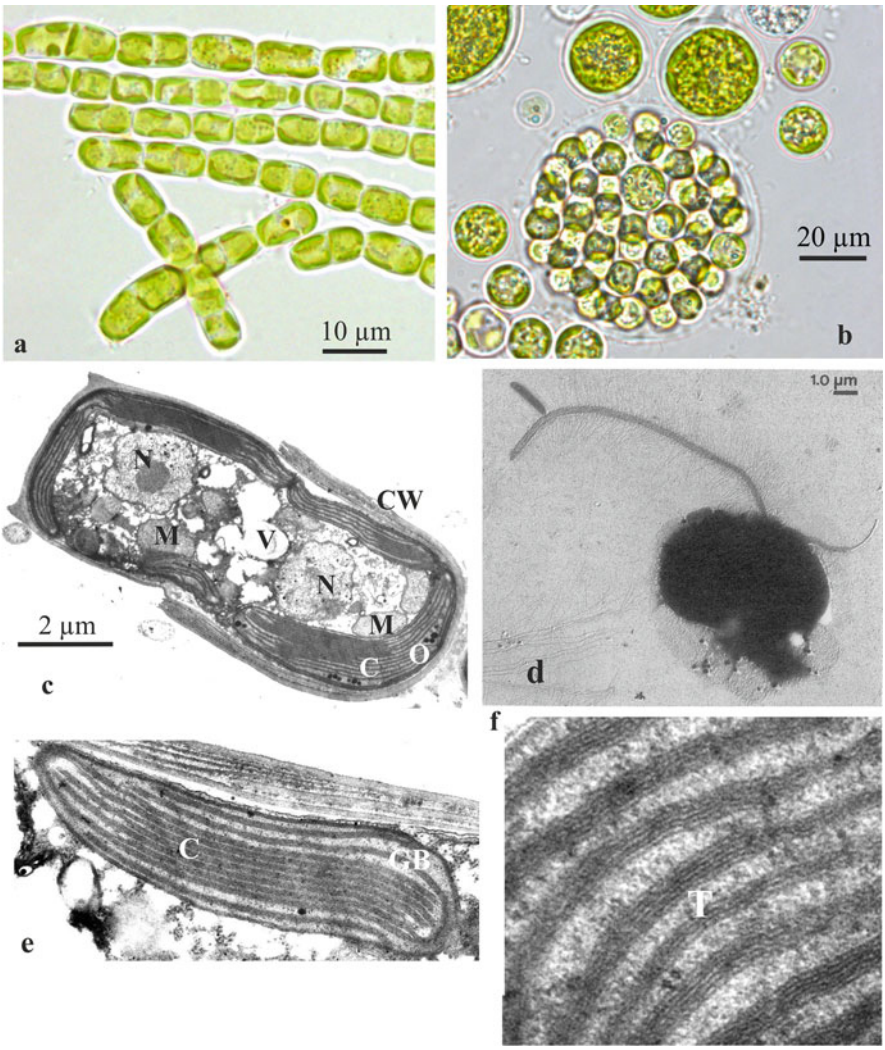

Fig. 1 Cell structure in the Xanthophyceae. distributed randomly in the chloroplast matrix, are often seen to be concentrated at the periphery of the pyrenoid (Deason 1971a; Falk 1967; Hibberd and Leedale 1971; Massalski and Leedale 1969).

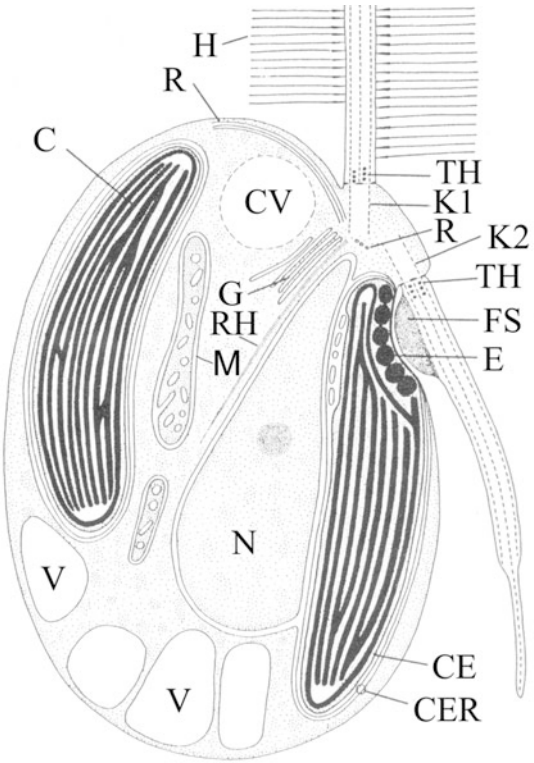

Fig. 2 Schematic representation of a xanthophyte zoospore (C = chloroplast, CE = chloroplast envelope, CER = chloroplast ER, CV = contractile vacuole, E = eyespot, FS = flagellar swelling, G = Golgi body, H = flagellar hairs, K1 = kinetosome long flagellum, K2 = kinetosome short flagellum, M = mitochondrion, N = nucleus, R = microtubular flagellal roots, RH = microfibrillar flagellal root (rhizoplast), TH = transitional helix, V = empty vacuole)

The nucleus in vegetative cells is more or less regular in shape (Fig. 1c), although part of the envelope has been seen to extend toward a pair of centrioles (Deason 1971a; Hibberd and Leedale 1971); this may be the general rule. The outer membrane of the nuclear envelope is confluent with the outer membrane of the PER although the area of contact is not usually extensive. Mitosis has been studied at the ultrastructural level in only one species of *Vaucheria* (Ott and Brown 1972) and *Tribonema regulare* (Lokhorst and Star 2003b). The most noteworthy feature of nuclear division is that the nuclear envelope remains completely intact at all stages, and it is not penetrated at the poles by gaps or fenestrae as commonly found in other examples of "closed" division. Following migration to opposite poles of each pair of centrioles normally associated with each nucleus, a spindle consisting of both continuous and noncontinuous microtubules forms within the nuclear envelope. The nucleolus fragments by metaphase and the centrioles duplicate by early anaphase. Anaphase is characterized by the formation of an extremely long interzonal spindle, probably by extension of the continuous spindle microtubules. By early telophase the spindle is very narrow and consists of only about 24 microtubules. Each nucleus is then cut off from the spindle by invagination of the nuclear envelope and the nucleolus reforms. Even if this type of closed division is found to be typical of the Xanthophyceae as a whole, it is likely that the very long interzonal spindle is confined to *Vaucheria* and perhaps the other siphonous forms.

Conventional chromosome cytology of the Xanthophyceae is extremely difficult owing to the generally small cell and nuclear size, but counts of 17 chromosomes have been published for four species of *Tribonema* (Iorya 1974).

Golgi bodies in the Xanthophyceae are typically small, consisting of 3–7 cisternae (Falk 1967; Falk and Kleinig 1968; Hibberd and Leedale 1971; Massalski and Leedale 1969). Each Golgi body lies against a flattened or concave face in the nuclear envelope, with one edge close to the centriole pair; the same positional relationship exists in the zoospores between the nucleus, Golgi body, and kinetosomes (Fig. 2). Species of *Vaucheria* are unusual in that each of the numerous Golgi bodies in the siphonous filaments is associated with an ER cisterna and a mitochondrion (Greenwood 1959; Ott and Brown 1974).

Mitochondria in the Xanthophyceae have tubular invaginations of the inner mitochondrial membrane into the matrix.

Cell Wall Structure and Composition

The cell wall of many xanthophyceans is delicately sculptured and in others, particularly the filamentous and large coccoid species, the wall consists of two overlapping halves (Bohlin 1897a; Ettl 1978; Pascher 1937–1939). In most cases the bipartite nature is not obvious, becoming apparent only after staining or swelling with alkalis or when the two halves separate for some reason such as zoospore release. It must be stressed that a bipartite wall is present in by no means all, perhaps not even a majority of, species. In species with a bipartite wall, the parts may be more or less equal in size or very unequal, but in all cases studied in detail (Deason 1971a; Hibberd and Leedale 1971; Falk and Kleinig 1968), the gradually tapering edges overlap widely. In the case of filamentous species, the walls are formed of interlocking H-shaped pieces (Bohlin 1897a; Ettl 1978; Pascher 1937–1939; Fig. 1c). Treatment with dilute KOH or NaOH characteristically swells the wall and reveals a complex lamellate construction (Bohlin 1897a), the walls appearing to be composed of closely stacked, deeply U-shaped elements. Electron microscopy of sectioned material shows that the cell walls of the species investigated have a distinctly layered structure and that the tapering edges of the overlapping walls are held together by a separate layer of cementing material (Falk and Kleinig 1968; Hibberd and Leedale 1971). Bipartite cell walls also stain strongly with dilute basic dyes, such as methylene blue and Congo red, and are very resistant to strong acids; for all these reasons the walls have often been described as being composed predominantly of an acid pectic compound. However, cellulose has been identified by a variety of techniques as a major constituent of the continuous tubular wall of *Vaucheria* (Mizuta et al. 1989; Tomaselli 2004). Although *Vaucheria* may not typify the whole group in this respect, its cell wall resembles that of most xanthophycean species in giving a strong positive reaction with Schiff's reagent *without* prior acid hydrolysis. This neglected and poorly understood reaction is largely confined to the Xanthophyceae (Prat 1947) and forms a further useful diagnostic character. However, since all species do not react, a negative reaction is inconclusive.

Motile Cells

While the vegetative cells of many coccoid xanthophyceans may be difficult to distinguish from green algae or Eustigmatophyceans, their motile stages (mainly zoospores) are characteristic (Ettl 1978; Hibberd and Leedale 1971; Lokhorst and Star 2003a; Massalski and Leedale 1969; Pascher 1937–1939; Fig. 2). Xanthophycean motile cells, with the exception of the spermatozoids (motile gametes that fertilize larger nonmotile gametes) and extremely large compound zoospores (synzoospores) of *Vaucheria*, are remarkably constant in structure. They are mostly ovoid or pyriform in shape, vary from about 5–20 μm in length, and are completely naked, bounded only by a plasmalemma. A degree of plasticity of shape and ameboid movement are therefore also common characteristics of these cells. The zoospores bear two flagella of unequal length and are bilaterally symmetrical with an obliquely truncate anterior end into which the flagella are inserted in the median plane of symmetry. The long flagellum is usually about the same length as the body of the zoospore while the second is from half to one-quarter this length. The long flagellum beats in an approximate sine wave, propagated at the tip of the flagellum, "pulling" the cells through the water. The cells rotate about their axis and describe a somewhat helical path. This may be due to the action of the short flagellum, which is difficult to see during life but appears to beat laterally. Electron microscopy shows that the long flagellum bears lateral hairs (Fig. 1d) as does the shorter anterior flagellum of the two relatively long flagella of *Vaucheria* spermatozoids (Koch 1951; Moestrup 1970). The hairs are straight and stiff, vary in length between 1 and 2 μm depending on species, and are about 20 nm thick with a short tapering basal part attached to the flagellar membrane at the narrow end, a tubular shaft, and two long fine terminal filaments of equal or unequal length. Appendages of this kind are referred to either as tubular mastigonemes (Bouck 1972) or tripartite tubular hairs (Moestrup 1982). The short flagellum of xanthophycean zoospores and the long posterior flagellum of *Vaucheria* spermatozoids are always free of appendages but may terminate in a hair point (Fig. 1d). The very large synzoospores of *Vaucheria* are exceptional in that both members of the numerous pairs of subequal flagella are smooth (Greenwood et al. 1957; Koch 1951; Ott and Brown 1974).

The two flagella of a typical zoospore are inserted at an obtuse angle to each other into a raised dome of cytoplasm on the anterior truncate face of the cell (Fig. 2). The long flagellum emerges freely but the proximal 1 μm of the short flagellum bears an asymmetrically wedge-shaped swelling with electron-dense contents at its proximal end. The swelling lies in a shallow depression in the cell immediately over the eyespot (Fig. 2).

The kinetosomes are constructed of the usual 9 triplet microtubules, but the transition region between the kinetosome and the axoneme has a characteristic structure shared with the Chrysophyceae and Eustigmatophyceae (Hibberd 1980). Thus, the lumen of the axoneme is traversed by a partition with a central axosomal thickening that always occurs exactly at the level at which the flagellum enters the cell body. Close to this and surrounding the proximal few nm of the central pair of axonemal tubules is a dense helix usually with 3–4 gyres, called the transitional helix

(Hibberd 1979, 1980; Fig. 2). This helix has also been called a "coiled fiber" (Bouck 1971) and a "Spiralkorper" (Casper 1972) in members of the Chrysophyceae.

A detailed three-dimensional description of the flagellar apparatus including the kinetosomes has been done solely for the zoospore of *Tribonema* by Lokhorst and Star (2003a). Conversely for other xanthophycean motile cells, the analysis of the kinetid is not complete, but it appears that two types of root originate near the kinetosomes: a single narrow cross-banded fibrous root (rhizoplast) that runs closely against the inner surface of the anterior prolongation of the nucleus and at least three microtubular roots extending in various directions through the cytoplasm (Hibberd 1980; Fig. 2). There are three or four component microtubules in each of these roots near the kinetosomes. The spermatozoids of *Vaucheria* are unusual in having an anterior "proboscis," similar to that in the spermatozoids of the brown alga *Fucus*, which contains a band of eight or nine microtubules originating near the kinetosomes (Moestrup 1970).

There are one to several but most commonly two chloroplasts in each zoospore, the number being species specific. One, usually designated as occupying a ventral position, always terminates immediately below the truncate face of the cell, while the dorsal chloroplast extends into the anterior end (Fig. 2). In species where pyrenoids occur in the chloroplasts of the vegetative cells, they are always present in the chloroplasts of the zoospore. When there is only a single chloroplast in each zoospore, this occupies the ventral position. Zoospores of most species possess a reddish refractile eyespot (stigma) at the anterior end of the ventral chloroplast. This consists of a single layer of densely osmiophilic globules immediately within the chloroplast envelope and directly beneath the swelling on the short flagellum (Figs. 1d and 2). The presence of eyespots has been reported by Van den Hoek et al. (1995) and observed in *Tribonema regulare* during the germination stage (Lokhorst and Star 2003a). In *Vaucheria*, however, their absence is genuine; the spermatozoids lack chloroplasts (Moestrup 1970) and the synzoospores have chloroplasts without eyespots (Ott and Brown 1974).

The nucleus in xanthophycean zoospores is pyriform and occupies a characteristic position, lying against the inner face of the ventral chloroplast with its tip close to the kinetosomes; the outer membrane of the nuclear envelope is confluent with the outer membrane of the chloroplast ER over a wide area (Fig. 2). In the compound zoospores of *Vaucheria*, one nucleus is attached to each pair of kinetosomes, but there is no association with the chloroplasts (Greenwood et al. 1957; Ott and Brown 1974). *Bumilleria sicula* is unusual in having patches of a delicate network with 15 nm openings occurring in the perinuclear space (Massalski and Leedale 1969). A further unusual feature in this species is that endoplasmic reticulum has been found organized parallel to areas of the nuclear envelope with circular fenestrations exactly opposed to the nuclear pores.

Zoospores generally contain only a single Golgi body, which lies with its forming face close against the nuclear envelope and with one edge near the kinetosomes (Fig. 2). When more than one Golgi body is present, all of them lie against the anterior prolongation of the nucleus (Massalski and Leedale 1969). The contractile vacuoles occur in the anterior region of the cell adjacent to the Golgi body and

kinetids (Fig. 2). They show no particularly noteworthy structural features, but coated vesicles may often be found in close proximity. Zoospores of some species contain several characteristic types of vesicles and inclusions. Most commonly seen are small peripheral vesicles containing a single spherical densely osmiophilic body (Deason 1971a; Hibberd and Leedale 1971; Massalski and Leedale 1969), possibly produced in the Golgi body (Deason 1971b). Others, with less dense, spirally wound fibrous contents, occur at the posterior end of the zoospores of *Ophiocytium majus* (Hibberd and Leedale 1971) and appear to contain the adhesive material by which the zoospore attaches itself during settling (Hibberd 1980). Peculiar fibrous discoid vesicles apparently produced in the perinuclear space have been found in the zoospore of more than one species (Deason 1971a; Massalski and Leedale 1969) and possibly give rise to the cell wall material as the cells settle. Irregularly shaped droplets, probably of lipoidal material, are generally distributed in the cell, and large, apparently empty vacuoles regularly occur in the posterior ends of zoospores (Fig. 2).

Reproduction and Life Cycles

The majority of xanthophyceans reproduce asexually in a variety of ways, the method being dependent on the basic cell form. The few monadoid or rhizopodial forms uncertainly attributed to this clade divide bilaterally and also appear to produce endogenous cysts similar but not identical to those characteristic of the Chrysophyceae. The palmelloid forms can reproduce by division but also produce zoospores or their non-mastigote equivalent, "hemiautospores" (Ettl 1978) or "aplanospores." The majority of species, the coccoid forms, reproduce primarily by the production of autospores, small replicas of the parent cells (Fig. 1b). Zoospore formation is also common among the coccoid species, although in culture large numbers are normally produced only after a change to fresh medium or some other stimulation. The most usual number of both aplanospores and zoospores produced by each parent cell is two to four, but many more may be found in multinucleate species showing a marked increase in vegetative cell size. Synzoospores probably result from incomplete cleavage. They occur in siphonous, filamentous, and some multinucleate coccoid forms; species producing them usually also have normal bimastigote zoospores. Filamentous forms reproduce either by cell division, leading to filament growth and subsequent fragmentation, or by zoospores. As in the coccoid forms, zoospores are common but are produced in large numbers in culture only following some environmental shock.

Little information is yet available on the fine structure of zoosporogenesis, but a similar pattern of events apparently occurs (Deason 1971b; Falk 1967; Hibberd 1980). The chloroplasts move away from the walls of the cell to take up a more internal position, one or two coming to lie against each nucleus. An eyespot appears in the chloroplast or in one of the chloroplast pair relatively late in the formation process. The pair of centrioles normally associated with each nucleus comes to lie at one end of the chloroplasts and each pair produces two flagella in a vesicle. The

Golgi body maintains its position relative to the centrioles and nuclear envelope. Flagellar hairs are formed in the perinuclear compartment and are then transported to the cell surface in vesicles of the endoplasmic reticulum. Zoospore cleavage occurs by the formation and coalescence of vesicles which separate the nuclei and associated chloroplasts. Zoospore release occurs by rupture or gelatinization of part of the mother cell wall or, in species with bipartite walls, by separation of the two sections of the wall.

Asexual reproduction in *Vaucheria* is by means of very large compound zoospores (synzoospores) bearing numerous pairs of slightly unequal flagella or by means of multinucleate aplanospores (Van den Hoek et al. 1995). A sporangium is formed by septation of the tip of a filament. Organelles accumulate before separation of the zoosporangium by a septum (Ott and Brown 1974). The normal association between the mitochondria and Golgi bodies disappears and flagella form in internal vesicles from the pair of centrioles accompanying each nucleus. These vesicles eventually coalesce to produce large internal flagellar pools that then migrate to the surface of the maturing zoospore and evaginate so that the flagella become situated on the zoospore surface. Septation of the zoospore from the vegetative filament occurs during this stage. The compound nature of the zoospore is revealed by the production of an incipient cleavage furrow which "attempts" to cut off the chloroplasts from the remainder of the zoospore.

Published information on zoospore settling is so far available only for *Vaucheria* (Ott and Brown 1975) and *Ophiocytium* (Hibberd 1980). In the latter, the body of the zoospore gradually rounds up and the flagella are withdrawn. The posterior end of the cell then rapidly elongates and narrows forming the stipe of the new vegetative cell. The distal end of this stipe becomes surrounded by finely fibrillar adhesive material, apparently released from dense vesicles with fibrillar contents present in the swimming zoospores. Later in settling, the axonemes disintegrate and the eyespot disappears. The bipartite nature of the cell wall is established from the earliest stage of wall formation. The first-formed wall material is very dense and composed of two overlapping parts; this is also apparently formed from vesicles normally present in the zoospore. As this wall forms, the chloroplasts come to lie closely against the wall, the nucleus regains its more or less spherical shape, and a normal lamellate and less dense wall is laid down.

In *Vaucheria*, the flagella are retracted into the body of the zoospore, and the peripheral layer of cytoplasm, which contains only nuclei and vesicles, alters in appearance. The nuclei sink into the cytoplasm and the vesicles disappear, probably giving rise to the cell wall, and are replaced by chloroplasts and other organelles. The withdrawn axonemes disintegrate and a bulge forms at one end of the settled cell. The various organelles and vesicles then become arranged as in the vegetative cells and a large central vacuole forms.

Sexuality in the Xanthophyceae has rarely been observed except in the siphonous genera *Botrydium* and *Vaucheria.* In *Botrydium* sexual reproduction is by means of bimastigote isogametes. Sexual reproduction in *Vaucheria* is oogamous. Antheridia and oogonia are formed either on special lateral branches of the main filament or are

sessile. They are separated from the main filament by a cross-wall. The antheridium produces a large number of colorless spermatozoids that are structurally different in a number of ways from xanthophycean zoospores, as already described. The mature oogonium is uninucleate, containing a single oosphere, and fertilization through a special pore produces a thick-walled resting zygote (oospore). Meiosis occurs at germination, yielding a new siphonous filament.

With the exception of the oospores of *Vaucheria*, resting stages are seen only rarely. Endogenously produced cysts with a bipartite wall appear to be confined to the few monadoid or rhizopodial forms. The most common resting stage in coccoid and filamentous forms is the akinete, a single-celled spore in which the wall is formed by a thickening of the parent cell wall. A particular type of aplanospore with a bipartite cell wall of quite different shape from that of the parent cell has also been described for some coccoid and filamentous forms, including *Tribonema.* Nagao et al. (1999) studied the process of akinete formation in relation to the acquirement of freezing tolerance in the freshwater *Tribonema bombycinum.* Both akinetes and this type of aplanospore produce zoospores or hemiautospores on germination.

Traditional Classification

The clade is named Xanthophyceae. An alternative and nomenclaturally typified name for this class, Tribophyceae, based on the generic name *Tribonema*, has been published (Hibberd 1981). This proposal resulted from changes in the International Code of Botanical Nomenclature, which allows names of taxa above the rank of family (to which the principles of typification and priority do not necessarily apply) to be considered as automatically typified when they are ultimately based on generic names. A class name based on *Tribonema* has not yet been validly published. The name Xanthophyceae is based on the generic name *Xanthonema* established by Silva (1979).

Current formal classification of Xanthophyceae does not reflect results obtained by modern molecular phylogenetic studies. Indeed, the latter approach has revealed that many orders, families, and genera currently defined by morphological characters (Ettl 1978) are paraphyletic or even polyphyletic and do not form clades (Andersen et al. 1998; Bailey and Andersen 1998; Maistro et al. 2007, 2009; Negrisolo et al. 2004; Potter et al. 1997; Rybalka et al. 2009; Zuccarello and Lokhorst 2005). A modern biological classification must be based on a rigorous phylogenetic approach and every taxonomic unit should be a monophyletic group. The provision here of new formal names would be premature as several key taxa have not yet been analyzed within a phylogenetic framework (Maistro et al. 2009). Below, we follow a pragmatic approach and retain the formal classification of seven orders provided by Ettl (1978) based largely on morphology of vegetative stages with, in some cases, additional information from reproductive characteristics. Taxa marked with an asterisk (*) are those found to be para-/polyphyletic in molecular phylogenetic analyses.

The unicellular flagellates are placed in the order Chloramoebales, while the ameboid forms belong to Rhizochloridales. The palmelloid and coccoid species are contained respectively in Heterogloeales and Mischococcales. Filamentous taxa form the Tribonematales, while siphonous taxa are assigned to Botrydiales or Vaucheriales. In the previous version of this chapter (Hibberd 1990), all siphonous forms were placed in Vaucheriales, but there is now overwhelming phylogenetic evidence that siphonous forms do not constitute a monophyletic group. Adl et al. (2005) revised the classification of Xanthophyceae and assigned all taxa to Tribonematales except for *Vaucheria* that was assigned to Vaucheriales. This classification is also strongly contradicted by phylogenetic analyses (Maistro et al. 2007, 2009; Negrisolo et al. 2004).

Chloramoebales, Rhizochloridales, and Heterogloeales contain few species that in many cases are known only from original descriptions and have yet to be rediscovered (Ettl 1978; Hibberd 1990; Pascher 1937–1939). Their inclusion within Xanthophyceae requires corroboration through rigorous phylogenetic analyses (Maistro et al. 2009). The remaining four orders encompass the majority of species with Mischococcales containing the most.

In the traditional classification, features defining each family include: habit (free-living or attached; solitary, colonial, or filamentous), whether cells are coenocytic or uninucleate, and presence or absence of surrounding mucilage and of branching. Classification into genera and species is based mainly on cell shape and size, cell envelope characters (lorica or cell wall, wall smooth or thickened in various ways), and to a lesser extent on cell contents (chloroplast number, presence or absence of a pyrenoid). However, several of these features result from convergent evolution and are poor indicators of phylogenetic relatedness (Maistro et al. 2007, 2009; Negrisolo et al. 2004).

Order Chloramoebales

The cells are solitary, free-swimming, naked, and more or less constant in shape or ameboid, with two unequal flagella or rarely only one flagellum, one to several chloroplasts, one or two anterior contractile vacuoles, and sometimes an eyespot. Reproduction is by longitudinal fission. Palmelloid stages and bipartite cysts are known. Species are usually freshwater, but are also found in marine and brackish waters. The order includes one family, Chloramoebaceae, with 11 genera and 14 species.

Family Chloramoebaceae

A poorly-known, certainly unnatural family; several species may belong in other phyla. Ettl (1978) recognizes the separate family Bothrochloridaceae for forms in which the flagella are inserted into a gullet-like depression.

Order Rhizochloridales

The cells are naked and ameboid, with pseudopodia or filopodia, but lack flagella. They are solitary or colonial, free-living or attached, and sometimes loricate. They

contain one to several chloroplasts, sometimes with an eyespot. Reproduction is by fission or by the production of zoospores that bear two unequal flagella. Endogenously produced resting stages with a bipartite wall are found in some forms. Species are freshwater, marine, or brackish.

Family Rhizochloridaceae
The cells are always free-living solitary amebas without a lorica. Relatively few (2–16) chloroplasts are present. The family comprises one genus, *Rhizochloris*, found in freshwater.

Family Stipitococcaceae
The cells produce a delicate hyaline vase-shaped lorica borne on a mostly filiform stipe. The lorica has one or more pores through which the filopodia extend. One to several chloroplasts are present, and some species possess an eyespot and contractile vacuole. Reproduction is by division into two zoospores. Freshwater species are epiphytic on filamentous algae. The family includes three genera, *Stipitococcus*, *Stipitoporos*, and *Rhizolekane*, with 10 species.

Family Myxochloridaceae (Chlamydomyxaceae)
The cells are large ameboid plasmodia containing numerous nuclei and chloroplasts and several contractile vacuoles. Reproduction, where known, is by division into smaller plasmodia, into zoospores bearing two flagella of unequal length, into small uninucleate amebas, or into endogenous uninucleate cysts with a bipartite silicified wall. Freshwater forms usually live in the hyaline cells of the leaves of the moss *Sphagnum*. There are two monospecific genera, *Myxochloris* and *Chlamydomyxa*.

Order Heterogloeales
The cells are palmelloid in organization, i.e., nonmotile, possessing neither flagella nor pseudopodia, but, in some species, containing permanent contractile vacuoles and an eyespot. They are solitary or colonial, free-living or attached, and surrounded by mucilage or not. Species are freshwater, marine, or brackish.

Family Heterogloeaceae
The cells are spherical or ellipsoidal, embedded in structureless mucilage forming free-floating or attached gelatinous masses. Reproduction is by simple division or production of zoospores with one or two unequal-length flagella. The family includes three genera, *Heterogloea*, *Gloeochloris*, and *Helminthogloea*, with seven species.

Family Mallodendraceae
The cells are naked, attached by a thick gelatinous stipe that can branch at division giving rise to arbusculate colonies. Reproduction is by longitudinal fission and by zoospores. Species are freshwater or brackish. There is only one genus, *Mallodendron*, with two species.

Family Pleurochloridellaceae
The cells are solitary, spherical, and unattached with a cell wall but no surrounding mucilage. Reproduction is by zoospores or autospores. There is one genus, *Pleurochloridella*, with two freshwater species. The placement of this family within Xanthophyceae is very doubtful and requires molecular corroboration. Indeed *Pleurochloridella botrydiopsis*, the only species so far analyzed using a molecular approach, was not included within Xanthophyceae (Maistro et al. 2009).

Family Characidiopsidaceae
The cells are solitary with a distinct cell wall, growing attached by means of a stipe and gelatinous disc. There is no surrounding mucilage. Reproduction is by zoospores. There is one genus, *Characidiopsis*, with four freshwater species.

Order Mischococcales*
The cells are coccoid in organization, i.e., having a distinct cell wall and lacking flagella, contractile vacuoles, and eyespot in the vegetative state. They contain one to several chloroplasts and nuclei (usually one nucleus and two chloroplasts). The cell wall is in one or two pieces and is either smooth or sculptured. Reproduction is by autospores, zoospores, or hemiautospores. Bipartite cysts are known for some species. The majority of species of Xanthophyceae are classified in this order.

Family Pleurochloridaceae*
The cells are solitary, free-living, and mostly uninucleate. Classification is based mainly on cell shape and cell wall features. Their shape varies from spherical through ellipsoidal to fusiform or polygonal. The cell wall is smooth and featureless or ornamented in a variety of ways and is in one or two pieces. Reproduction is by means of autospores or zoospores. The family comprises 38 genera with 190 species, freshwater or marine.

Several species formerly classified here have been transferred to the Eustigmatophyceae and many more probably belong there.

Family Botrydiopsidaceae*
The cells are characterized by their capacity for prolonged growth without division, producing large multinucleate cells with numerous chloroplasts. They can be solitary, free-living, or attached. They are spherical to irregular in shape, with the cell wall in one piece and unsculptured. Reproduction is by zoospores, aplanospores or autospores. There are four genera with seven freshwater species. The genus *Botrydiopsis** is polyphyletic.

Family Botryochloridaceae*
The cells remain attached after autosporulation, forming regular to irregular colonies which may or may not be embedded in mucilage. Cell shape varies from spherical to

fusiform. Reproduction is by zoospores or autospores. There are eight genera with 48 freshwater species. *Chlorellidium** is polyphyletic.

Family Gloeobotrydaceae
Species in this family are colonial forms in which the cells are not mutually attached but embedded in a common mucilage. Colonies are attached or free-floating. The cells are mostly spherical or ellipsoidal. Reproduction is by zoospores or autospores. There are eight genera with 27 freshwater species (14 in *Gloeobotrys*).

Family Gloeopodiaceae
The cells secrete a mostly stratified mucilaginous stipe by which they are attached to the substratum. They are unicellular or form small arbusculate colonies. There is one genus, *Gloeopodium*, with six freshwater or brackish species.

Family Mischococcaceae
The cells are united in arbusculate, di-, or tetrachotomous colonies. These colonies are borne on mucilaginous stipes, the cells in twos or fours at the ends of the ultimate branches. Stipes are produced by swelling of the inner layers of the mother cell wall during autospore formation. There is one genus, *Mischococcus*, with six freshwater species.

Family Characiopsidaceae
The cells are solitary or in groups of two or four, always attached to the substratum either directly, by means of a mucilaginous pad, or by a stipitate extension of the cell wall. The cell wall is in one or two parts, smooth or sculptured. Reproduction is mostly by zoospores, rarely by autospores. There are eight genera with 98 freshwater, brackish, and marine species, including 65 species of *Characiopsis*.

Family Chloropediaceae
The cells are arranged in flat tabular colonies, attached directly to the substratum. Reproduction is by zoospores or autospores. There is one genus, *Chloropedia*, with two freshwater species.

Family Trypanochloridaceae
The cells are irregularly rounded to stellate with a single parietal chloroplast and a central nucleus. Reproduction is by large numbers of autospores produced from the central cytoplasm only. There is only a single species, *Trypanochloris clausiliae*, occurring in the outermost layers of the shells of *Clausilia*, a genus of small terrestrial gastropods.

Family Centritractaceae*
The cells are solitary, uninucleate, free-living, prominently elongate, and with a cell wall in two pieces. Reproduction is by zoospores and aplanospores. There are three

genera, *Bumilleriopsis**, *Pseudobumilleriopsis* (Maistro et al. 2009), and *Centritractus*, with 19 species.

Family Ophiocytaceae (Sciadiaceae)
The cells are elongate-cylindrical with a cell wall in two unequal parts, always with two nuclei or multinucleate with two to many chloroplasts. They are solitary or colonial, free-living, or stipitate. Reproduction is by zoospores. There is one genus, *Ophiocytium*, with 14 freshwater species.

Order Tribonematales*
The order includes all Xanthophyceae with filamentous organization in which cells are mainly uninucleate with one to several chloroplasts. Classification into families is based mainly on the degree of differentiation of the filaments. Reproduction is by cell division, zoospores, and aplanospores. Species are freshwater and marine.

Family Neonemataceae
Uniseriate to mostly multiseriate filaments with exterior layers of mucilage; the individual cells are separated from each other. Reproduction is by cell division, zoospores, and aplanospores. There are two genera, *Neonema* and *Chadefaudiothrix*, with four freshwater species.

Family Tribonemataceae*
Species in this family are unbranched uniseriate filaments without exterior layers of mucilage and can be either attached or free-floating. The cell wall is usually clearly differentiated into two parts, the half-walls from adjacent cells forming H-shaped pieces. Reproduction is by zoospores and aplanospores. Thick-walled resting stages (akinetes) are also produced. There are six genera: *Brachynema*, *Heterotrichella*, *Xanthonema**, *Heterothrix*, *Bumilleria*, and *Tribonema**, with 49 freshwater and marine species (Maistro et al. 2009). Some possible polyphyletic species have been identified within *Tribonema* using the *rbcL* gene (Zuccarello and Lokhorst 2005).

Family Heterodendraceae
Species in this family are branched, uniseriate filaments, forming small arbusculate growths attached by an enlarged basal cell. Reproduction is by zoospores. There is only one genus, *Heterodendron*, with two freshwater species.

Family Heteropediaceae
Species in this family form branched uni- to multiseriate filaments, differentiated into pseudoparenchymatous basal and erect filamentous parts. The cell wall is not differentiated into H-shaped pieces. Reproduction is by cell division and zoospores. Zoospores are formed either in all cells or in separate zoosporangia. Palmelloid stages are known. The family comprises six genera with 50 freshwater species (45 in *Heterococcus*).

Order Botrydiales
There is just a single family and genus in this order with the characteristics as described below.

Family Botrydiaceae
These consist of a macroscopic aerial globular part up to several mm in diameter, containing a large number of nuclei and chloroplasts, and subterranean colorless branched rhizoids. Asexual reproduction is mainly by means of zoospores and autospores. Sexual reproduction is by fusion of iso- or anisogametes giving rise to a zygote. Gametes are formed in undifferentiated vegetative cells. Members are terrestrial, often found on drying mud in freshwater environments. There is one genus, *Botrydium*, with eight species.

Order Vaucheriales*
The order Vaucheriales comprises xanthophyceans with siphonous organization (nuclear division taking place without cell wall formation during vegetative growth).

Family Vaucheriaceae*
Species in this family consist of branched siphonous filaments with unlimited apical growth, forming a thallus usually several cm in extent, the filaments containing large numbers of chloroplasts and nuclei in a peripheral cytoplasmic layer surrounding a central vacuole. Cross-walls are formed only during reproduction. Sexual and asexual reproduction in *Vaucheria* is described above. Reproduction in *Asterosiphon* is asexual only, by aplanospores. In *Asterosiphon*, the filaments are regularly branched, forming rosettes up to 1 cm diameter on moist soil. Species of *Vaucheria* commonly form extensive growths on moist soil or grow submerged; many species amphibious. Species occur in freshwater, marine, and brackish habitats. *Asterosiphon* is monospecific; *Vaucheria* includes over 70 species.

Molecular Phylogenetics

Molecular phylogenetic data exist for approximately one-sixth of known xanthophycean species (Andersen and Bailey 2002; Bailey and Andersen 1998; Maistro et al. 2007; Negrisolo et al. 2004; Rybalka et al. 2009, 2013; Zuccarello and Lokorst 2005). Each of these can be firmly placed in one of the four major clades into which the class can be divided. These clades have been designated as the Botrydiopsalean, the Chlorellidialean, the Tribonematalean, and the Vaucherialean (Maistro et al. 2009). The Botrydiopsalean clade contains only coccoid forms and may contain most of the species currently included in Mischococcales but this requires phylogenetic confirmation. The Chlorellidialean clade includes strains with a wide range of morphological expression ranging from coccoid unicells to branched filaments of *Heterococcus* (currently in Tribonematales). There are no

unique features of morphology visible by light microscopy that define this group, although the clade receives very strong molecular support (Maistro et al. 2009). The Tribonematalean clade contains filamentous unbranched species of *Bumilleria*, *Tribonema* and *Xanthonema*, *Heterothrix*, as well as new genera awaiting formal description. Also included are coccoid species of *Bumilleriopsis*, *Pseudobumilleriopsis* and *Ophiocytium*, and siphonous *Botrydium*.

All species except those of *Botrydium* have a bipartite cell wall (Hibberd 1990) that could constitute a synapomorphic feature for this clade. The siphonous thallus of *Botrydium* would then have been acquired by secondary loss of this feature (Maistro et al. 2007). However, the position of *Botrydium* is not fully resolved although tests for alternative phylogenies did not reject the phylogenetic position of *Botrydium* as sister group of other taxa present in the Tribonematalean clade. If further studies show this to be so, then the *Botrydium* clade could be regarded as the traditional order Botrydiales as defined by Ettl (1978). The Vaucherialean clade contains siphonous species of *Vaucheria* and conforms with earlier concepts of order Vaucheriales (Ettl and Gärtner 1995; Adl et al. 2005).

Siphonous *Asterosiphon dichotomus* has been placed as sister species of the Tribonematalean clade, but alternative topology tests did not reject its position as sister species of *Vaucheria* (Maistro et al. 2009). If this latter phylogenetic hypothesis is preferred, then *Vaucheria* + *Asterosiphon* would represent the Vaucheriales sensu Ettl (1978) and Rieth (1980). However, current evidence suggests that *A. dichotomus* should be placed outside the Vaucherialean clade and its unusual morphology of a rosette-shaped, dichotomously branched thallus (Ettl and Gärtner 1995) supports this contention.

Some coccoid species remain outside major clades in poorly resolved positions. Molecular data are unavailable for other coccoid and filamentous taxa as well as for all Chloramoebales, Heterogloeales, and Rhizochloridales.

Maintenance and Cultivation

For the great majority of species that occur in nature as walled unicells, single cell isolation is probably the best isolation technique, especially as most species are usually found only in small numbers. Plating or dilution may be tried when numbers are sufficient. Biphasic soil/water media usually offer the best chance of growth, although since most species multiply relatively slowly it may take several weeks for any growth to become apparent. Biphasic cultures may also be used for long-term maintenance. Agnotoxenic cultures also generally grow well in a wide variety of defined mineral media (listed by Nichols 1973). Axenic cultures may be obtained by repeated washing of single cells or by plating where the species grow well on agar. They are usually maintained on slopes containing proteose peptone, 0.1%; KNO_3, 0.02%; K_2HPO_4, 0.002%; and $MgSO_4$ $7H_2O$, 0.002%.

Species of *Vaucheria* mostly grow well in biphasic soil/water media. They are isolated from thalli that are reproducing sexually by inoculating media with washed oospores, which then germinate to produce a clean vegetative thallus. Zoospores

may also be used as an inoculum in the few species producing them. A simple but effective method for producing axenic cultures of *Vaucheria* has been devised by Åberg and Fries (1976).

Evolutionary History

The Xanthophyceae constitutes one of the major phyletic lines that emerged within the photosynthetic Stramenopiles (e.g., Cavalier-Smith and Chao 2006). Fossil xanthophyceans are extremely rare (e.g., Butterfield 2004) and totally insufficient to trace the evolution of the clade and to establish the evolutionary relationships with other stramenopilans. Before the advent of molecular techniques, the placement of Xanthophyceae and other stramenopileans algae was assessed using biochemical and structural data. These showed evolutionary relationships with other stramenopilean taxa: e.g., Xanthophyceae, Phaeophyceae, and Chrysophyceae share cell wall structure and growth, the form of the resting spore, part of pigments, storage products, and the flagella of motile cells (Pascher 1937–1939). Ultrastructural characteristics, particularly of motile cells, of the Xanthophyceae, Chrysophyceae, Phaeophyceae, and Bacillariophyceae, added support for a common ancestry of these four groups (Hibberd 1976, 1979; Hibberd and Leedale 1971, 1972; Massalski and Leedale 1969).

The main features of motile cell structure common to the Chrysophyceae, Xanthophyceae, and Phaeophyceae include: (1) a long anterior flagellum bearing two opposite rows of tubular hairs and a smooth posteriorly directed flagellum, which, except in the spermatozoids of the xanthophycean *Vaucheria* and some brown algae, is shorter than the anterior flagellum; (2) a swelling at the proximal end of the short flagellum closely associated with the cell membrane it overlies; and (3) an eyespot consisting of a single layer of pigment droplets within one of the chloroplasts. Other features of cell structure common to these three phyla but not confined to them include: (1) bilateral symmetry; (2) chloroplast ER; (3) a chloroplast girdle band; (4) a transitional helix; (5) a pyriform nucleus positioned close to the kinetosomes, which in the Chrysophyceae and Xanthophyceae and probably Phaeophyceae is attached to them by means of (6) a fibrillar root (rhizoplast); and (7) a constant positional relationship between the Golgi body, nucleus, and kinetosomes. The Bacillariophyceae share several features of ultrastructure with these three phyla, including possession of tubular hairs by the single flagellum of the male gametes of some centric forms, and a girdle band.

In addition to these four lineages, the Raphidophyceae also possess heterokont flagella and chloroplasts with a girdle band, and on this basis have been considered to be allied with them.

Biochemical characters, mainly pigment composition, when considered in isolation, are less helpful than structural characters in indicating the possible relationships of the Xanthophyceae. Indeed different distributions of various pigments suggest different relationships with various protist lineages belonging to the Chromalveolata (Adl et al. 2005). Thus, the absence of chlorophyll *b* and the synthesis of

c chlorophylls in the Prymnesiophyceae, Dinophyceae, and Cryptophyceae as well as in the Xanthophyceae, Chrysophyceae, Phaeophyceae, and Bacillariophyceae, provides reasonably strong evidence for the common ancestry of the chlorophyll *c*-related genes in all these groups (Ragan and Chapman 1978). However, distribution of a number of major pathways of carotenoid biosynthesis, particularly that leading to fucoxanthin, suggests that Chrysophyceae, Bacillariophyceae, Phaeophyceae, and Prymnesiophyceae have a common phylogenic heritage. Other pathways indicated that the Xanthophyceae and Raphidophyceae appear to be phylogenetically close to this line and to each other, but the absence of the fucoxanthin pathway and its replacement in these two phyla and the Eustigmatophyceae by the vaucheriaxanthin pathway indicates affinity, although the Eustigmatophyceae also shows some significant differences from the Xanthophyceae, supporting its separation as a distinct clade.

Molecular phylogeny has revolutionized the perception of Xanthophyceae placement in the tree of life. There is robust molecular evidence that Xanthophyceae are one of the phyla of photosynthetic protists included in the Stramenopiles (e.g., Cavalier-Smith and Chao 2006; Riisberg et al. 2009; Yang et al. 2012). Furthermore all photosynthetic heterokonts form a monophyletic group that is supported by various types of molecular evidence (e.g., Cavalier-Smith and Chao 2006; Riisberg et al. 2009; Yang et al. 2012). Relationships among the 16 photosynthetic heterokont algal classes are not yet fully understood but molecular analyses are rapidly filling the gap (e.g., Cavalier-Smith and Chao 2006; Kai et al. 2008; Riisberg et al. 2009; Yang et al. 2012). Multiple gene phylogenies show that the Xanthophyceae together with Chrysomerophyceae, Aurearenophyceae, Phaeothamniophyceae, Phaeophyceae, and Schizocladiophyceae form a well-defined group named clade PX (Cavalier-Smith and Chao 2006; Kai et al. 2008; Riisberg et al. 2009; Yang et al. 2012). This clade derived its name from the two most species-rich classes, Xanthophyceae (X) and Phaeophyceae (P) (Kai et al. 2008). Within clade PX the phylogenetic relationships are not yet fully resolved and further analyses are necessary to properly identify the position of Xanthophyceae. The clade PX together with Raphidophyceae form a clade named SI that constitutes one of the three major phyletic lines that emerged during the evolution of photosynthetic Heterokonta (Yang et al. 2012).

Acknowledgments This revised version of the chapter is indebted to the original written by David J. Hibberd (1990). We have left unchanged large parts of his sections on morphology, biochemical characteristics, and life history. However, his treatment of taxonomy and phylogeny has been largely rewritten as understanding has advanced dramatically.

Hyphochytriomycota and Oomycota

13

Gordon W. Beakes and Marco Thines

Abstract

The anteriorally uniflagellate Hyphochytriomycota and biflagellate Oomycota are in the Kingdom Straminipila (commonly referred to as stramenopiles) which are part of the SAR superkingdom. Both appear to be basal to the large assemblage of golden-brown algae, the Ochrophyta. Both feature osmotrophic nutrition and have traditionally been considered as zoosporic "fungi," but are unrelated to organisms in the monophyletic kingdom Mycota. The Hyphochytriomycota is a small group encompassing around half a dozen genera, which have simple nonmycelial, holocarpic thalli, traditionally encompassing three families: the endobiotic Anisolpidiaceae, the polycentric Hyphochytriaceae, and the monocentric Rhizidiomycetaceae. Recently the former have been shown to be placed among the early diverging Oomycota, leaving just the latter two families in the monophyletic Hyphochytriomycota clade. Hyphochytriomycota are widespread in occurrence, and most are saprotrophs or parasites, infecting the resting spores of Oomycota and Glomeromycota. In contrast, the Oomycota are a large and diverse assemblage, consisting of two major (class level) clades, the Saprolegniomycetes and Peronosporomycetes, and several early diverging classes most of which are simple holocarpic organisms that lack mycelial organisation. Many of these early-diverging clades are as yet poorly resolved because of sparse taxon

sampling. The early-diverging orders include the Eurychasmales and Olpidiopsidales, both of which are marine seaweed parasites, the nematode infecting Haptoglossales and crustacean infecting Haliphthorales. The Saprolegniomycetes mostly have fungal-like mycelial thalli and include the orders Atkinsiellales s.lat., Leptomitales, and Saprolegniales, which are mostly saprophytes or parasites of invertebrates and, occasionally, vertebrates such as fish and amphibians. A few species in the Saprolegniales are root infecting parasites of plants. The Peronosporomycetes are the second major fungal-like class, and include the largely saprotrophic Rhipidiales, the facultively parasitic Pythiales s.lat., which can infect both animals and plants and the predominantly plant pathogenic Albuginales and Peronosporales sensu lato. Indeed, the Oomycota are significant parasites of both animals and plants, impacting both natural ecosystems and causing significant economic losses in both aquacultural and agricultural systems. The molecular systematics of the Oomycota is still in a state of flux, and in this account a relatively conservative approach has been taken. It is apparent that most of the early-diverging genera are almost exclusively marine and that the Peronosporales represents the main terrestrial and plant pathogenic lineage. Most early-diverging genera lack the oogamous sexual reproduction that characterizes this group and suggests that the oogenesis evolved around the time of emmergence from the sea to the land and freshwater ecosystems. It is also clear that obligate biotrophy in the white blister rusts (Albuginales) and downy mildews (Peronosporales s.str.) has evolved independently.

Where s. lat. is used after a name, there are significant subclades which suggests this taxon will require splitting, although at present the low statistical support, or incomplete taxon sampling means it cannot be done with confidence.
Where names are placed between " " means names have not been formally published.
~Before the name means this Order, Family or genus appears to be para- or polyphyletic and will require taxonomic revision.
[a]Indicates Family or species has not been sequenced, so taxonomic position not confirmed by molecular data.
[b]Recent multigene trees, suggest this clade may merit a new order and family rank (Paralagenidiales, Paralagenidiaceae) (Spies et al. 2016).
[c]This family's Order placement still not fully resolved.
[d]Recent multigene trees, suggest this clade may merit order rank (Pythiales), but may also require further splitting (Spies et al. 2016).
[e]Recent multigene trees, suggest this clade may merit order rank as Peronosporales s. str. (Spies et al. 2016).

Introduction

General Characteristics

Historically, the zoosporic fungi studied by mycologists encompassed chytrids, hyphochytrids, labyrinthulids, thraustochytrids, oomycetes, and plasmodiophorids. All generally had walled thalli that fed by osmotrophic absorption, although many had small holocarpic thalli rather than a typical mycelium. These organisms are a polyphyletic assemblage with only the Chytridiomycota now included in the kingdom Fungi (Fig. 1a; Adl et al. 2012). The Plasmodiophorids are now placed in the Cercozoa, a sister clade to Rhizaria (Heuhauser et al. 2010), which together with all other biflagellate fungal-like groups fall within the recently defined "SAR" (Straminipila, Alveolata, Rhizaria) superkingdom (Fig. 1a; Burki et al. 2007, 2008; Burki and Keeling 2014). Molecular studies confirm that both the anteriorly uniflagellate Hyphochytriomycota and the biflagellate Oomycota (Fig. 1b; Tsui et al. 2009; Van der Auwera et al. 1995) are part of the same lineage as the chlorophyll c containing Ochrophyta (Cavalier-Smith and Chao 2006), which together form the sister clade to the Labyrinthulomycota and Opalinids (Tsui et al. 2009). Dick (2001)

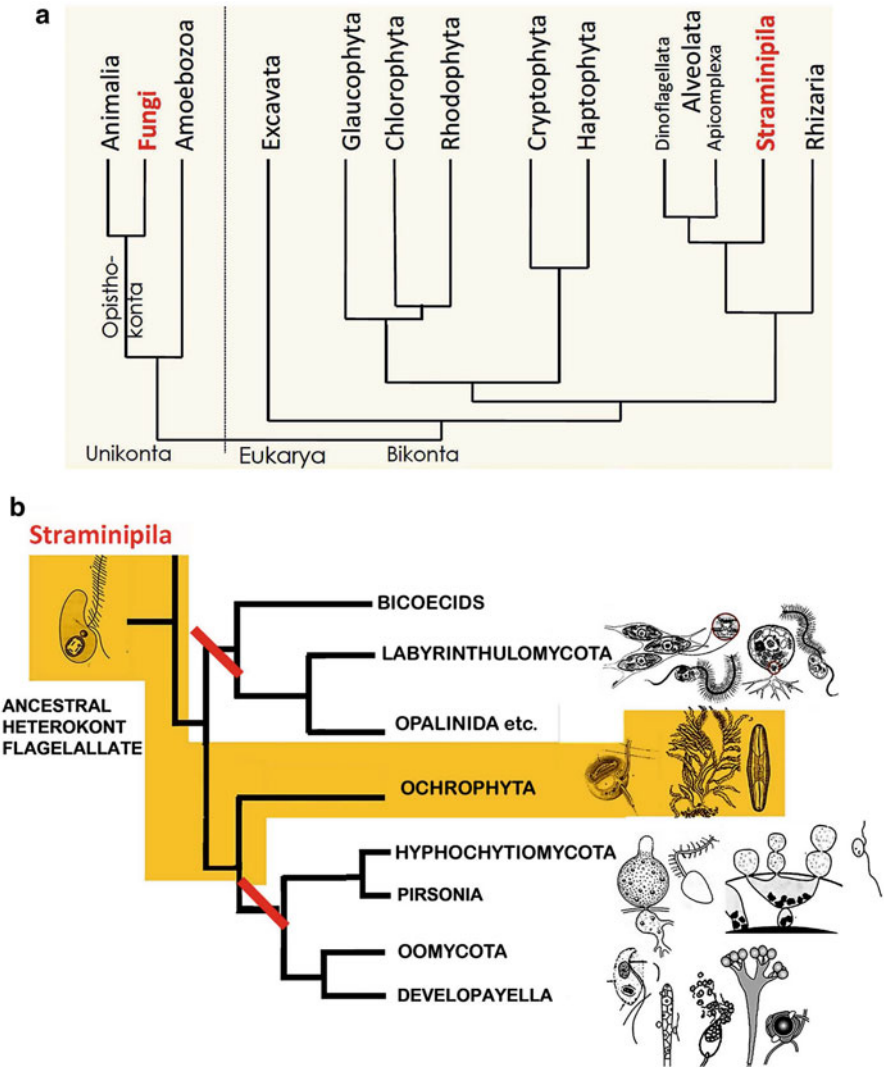

Fig. 1 General phylogeny. (**a**) Overview summary tree of main Eukaryote supergroup clades, showing relative phylogenetic postions of the Fungi and Straminipila, which is part of the Straminipila, Alveolata, Rhizaria (SAR) superclade (Based on Burki et al. 2008). (**b**) Schematic tree of the Straminipila clade, showing probable relationships between the Hyphochytriomycota and Oomycota, with respect to other members of the clade. The *red bars* represent possible plastid loss events as proposed by Tsui et al. (2009) on which Figure is based. However, not all data supports multiple plastid losses, others have proposed multiple plastid acquisitions rather than losses (see Beakes et al. 2014a) (Adapted from Beakes et al. (2011) from *Protoplasma* with permission)

placed all of these mastigonate fungal-like groups in his revised Kingdom Straminipila, while Cavalier-Smith and Chao (2006) placed the Hyphochytriomycota and Oomycota in the phylum Pseudofungi, together with a number of protists, including the bacteriotrophic flagellate *Developayella* (Leipe et al. 1994) and the parasitoid *Pirsonia* (Kühn et al. 2004).

Members of the Hyphochytriomycota are characterized by their small holocarpic, chytrid-like thalli and zoospores with a single, anteriorly-directed flagellum (Figs. 2a and 7a). At the end of a motile period, the zoospores encyst, germinate, and grow to form simple epi- or endobiontic chytrid-like thalli (Fig. 2a–e). Hyphochytriomycota is a small phylum/subphylum consisting of a single order (Hyphochytriales) containing only four or five described genera encompassing around two dozen species. These were grouped by Karling (1942, 1977) into three families: the Anisolpidiaceae, Rhizidiomycetaceae, and Hyphochytriaceae. Molecular sequencing studies of *Hyphochytrium catenoides* (Van der Auwera et al. 1995) and *Rhizidomyces inflatus* (Hausner et al. 2000) confirmed that the Hyphochytriomycota form a well-defined clade sister to the Oomycota (Fig. 1b). However, recent sequence data for the marine phaeophyte parasite *Anisolpidium ectocarpi* have revealed that the Anisolpidiaceae fall within the basal Oomycota, close to *Olpidiopsis spp.* (Gachon et al. 2015), and thus, are excluded from the Hyphochytriomycota (Table 1).

In contrast, the Oomycota is a large and diverse phylum/subphylum containing mostly fungal-like organisms (Fig. 2q, r–u; Money 1998; Richards et al. 2006). There are around 1500 or more species grouped into about a 100 genera, the majority of which, however, contain fewer than five species (Table 1; Dick 2001). They typically produce biflagellate zoospores (Fig. 7b–e) and many saprolegniomycete genera produce two generations of zoospores (diplanetic; Fig. 7b, d) or aplanospores and zoospores. The anterior flagellum is mastigonate (Fig. 7e), while the posterior flagellum is smooth with a terminal acroneme (Fig. 7c; Vlk 1939; Manton et al. 1951; Fig. 2). Characteristics that separate Oomycota from true Fungi include having a diploid rather than haploid vegetative thallus (Win-Tin and Dick 1975), cell wall microfibrils composed of cellulose and glucans rather than chitin (Bartnick-Garcia 1970), and a different biochemical pathway for lysine biosynthesis (Vogel 1960). In addition, they store β1–3 mycolaminarins rather than glycogen as their main carbohydrate reserve (Wang and Bartnicki-Garcia 1974). Molecular phylogeny based on ribosomal subunit genes confirmed that the Oomycota share the same common ancestor as the Ochrophyte algae (Fig. 1b: Adl et al. 2012; Cavalier-Smith and Chao 2006; Förster et al. 1990; Gunderson et al. 1987; Leipe et al. 1994; Rilsberg et al. 2009).

Occurrence

The Hyphochytriomycota are found in both soil and water in freshwater, marine, and terrestrial environments and are cosmopolitan in distribution (Fuller 1990, 2001; Gleason et al. 2009). There are both saprotrophs and low-impact parasites, particularly of other chromistans (Oomycota and Phaeophyta) and possibly of crustacea. Although relatively small numbers of species have been described, environmental

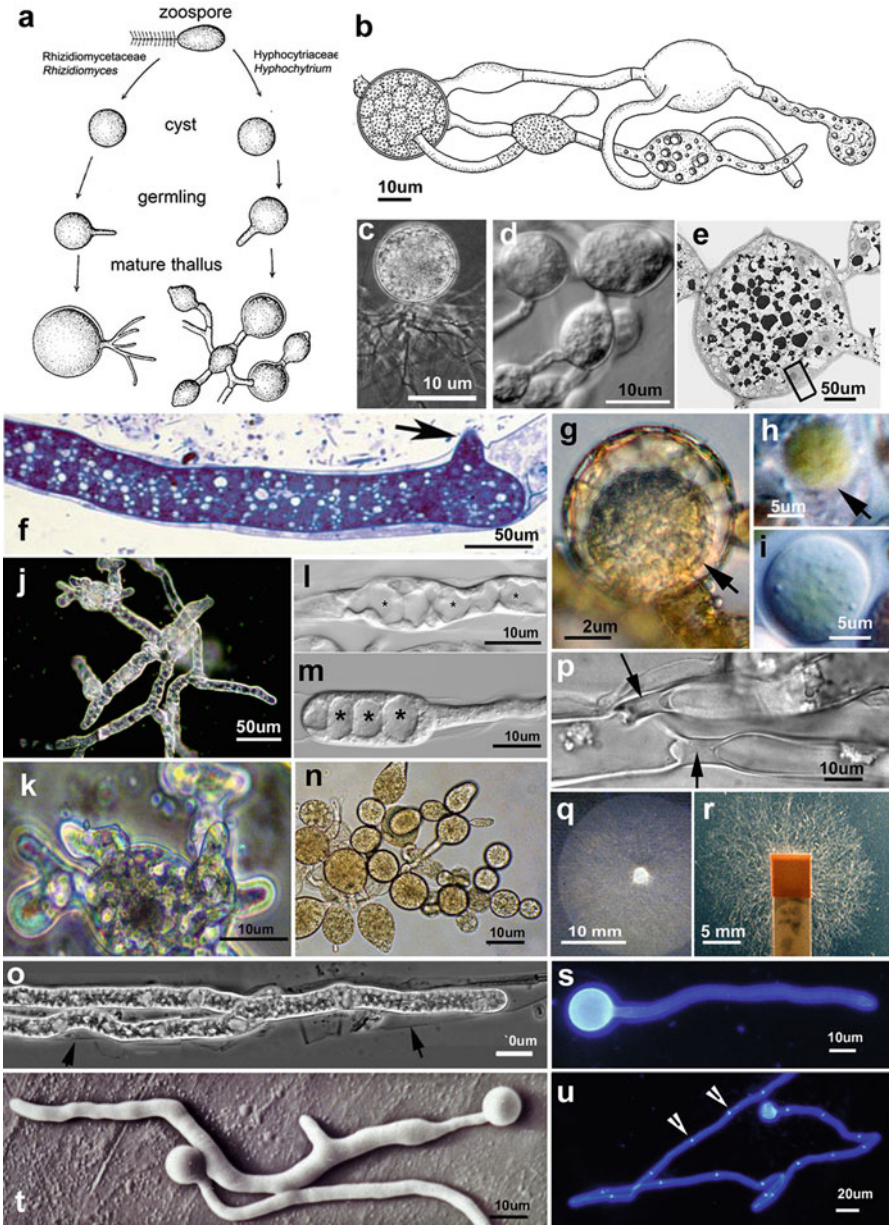

Fig. 2 The vegetative thallus. (**a**) Schematic hyphochytridiomycete life style diagram showing monocentric thallus development in *Rhizidiomyces* and polycentric development in *Hyphochytrium* (Adapted from Fuller 1990, with permission*) (**b**) Diagram of the polycentric thallus of *Hyphochytrium catenoides* showing swollen thalli, interconnectd by short hyphal-like segments (From Karling (1977), with permission of Charles Lubrecht) **(c)** Light micrograph of *Rhizidiomyces apophysatus*, showing spherical thallus, with basal rhizoids (From Fuller and Jaworkski (1987) with

sequencing from both marine (Diéz et al. 2001; Massana and Pedró-Alió 2008; Massana et al. 2002, 2004, 2006) and freshwater (Richards et al. 2012) environments has revealed many unknowns that fall within the hyphochytrid clade, suggesting that as a group they are both more diverse and widespread than generally appreciated. Hyphochytrid cultures are not widely available although both *H. catenoides* and *R. inflatus* are listed in the American Type Culture Collection (ATCC).

Oomycetes are also ubiquitous in marine, freshwater, and terrestrial ecoystems, where they occur as widespread saprotrophs infesting decaying plant and animal detritus (Dick 1990, 2001; Hulvey et al. 2010; Newell and Fell 1995; Riethmüller and Langer 2004) or as necrotrophic and biotrophic pathogens of a wide range of animals (Fig. 3a–k: Karling 1981; Phillips et al. 2008) and plants (Fig. 4a–v: Constantinescu 1991; Dick 2001; Thines 2014; Voglmayr 2008). Plant pathogenic species (Fig. 4a–v) show the greatest diversity, and recent molecular studies have explored the phylogenetic relationships between these pathogens and their hosts (Choi and Thines 2015; Göker et al. 2007; Thines et al. 2008, 2009a; Voglmayr 2003, 2008). Many oomycete plant pathogens, notably *Albugo* and *Hyaloperonospora* infecting

Kingdom: Straminipila	Superphylum: Pseudofungi
3c: Downy mildews with coloured conidia (DMCC)	***Pseudoperonospora, Peronospora***
3d: Downy mildews with pyriform haustoria (DMPH)	***Basidiophora, Benua, Bremia, Novotelnova Paraperonospora, Plasmopara, Plasmoverna, Protobremia,***

Those genera that are not emboldened have not been included in molecular phylogenies until the end of 2016
Those prefixed by a ~ appear to be paraphyletic or polyphyletic and are in need of revision
Families prefixed with a ? are in Dick (2001) and although reflected by clades, but it is uncertain whether all will eventually be given family level designation. These subclades are mostly based on a recent unpublished study of Spies et al. (2014, 2016)
Those Orders and Families in quotation marks " ", have not been formally published
[a]The phylogenetic position of this family/genus still not fully resolved. Some analyses have it as sister clade to *Halophytophthora* in the Peronsporaceae s. lat. clade

Arabidopsis, have provided model systems for exploring the molecular interactions between biotrophic pathogens and their hosts (Jiang and Tyler 2012; Kemen and Jones 2012; Thines and Kamoun 2010; Thines et al. 2009c). The occurrence and diversity of marine oomycetes have been greatly underestimated (Hulvey et al. 2010; Nigrelli and Thines 2013), and many recent studies on marine picoplankton samples have revealed many unknown stramenopiles within the Oomycota clade (Diéz et al. 2001; Massana and Pedró-Alió 2008; Massana et al. 2002, 2004, 2006; Richards et al. 2012).

Culture collection holdings of oomycetes are largely confined to the saprophytic and facultatively parasitic species with the largest collections held in the major culture collections such as the American Type Culture Collection (ATCC), Maryland; the Commonweath Agricultural Bureau International fungal collection (CABI), Egham; the Centraalbureau voor Schimmelcultures (CBS), Baarn, and the National Biological Resource Centre (NBRC), Chiba. Some academic institutions hold specialist collections, mainly of *Phytophthora* and *Pythium* isolates, such as the World Oomycete Genetic Resource Collection at the University of California, Riverside; the Department of Agriculture Mycology Culture Collection Ottawa; and a collection of *Aphanomyces* and fish-pathogenic *Saprolegnia* isolates in the Oomycete Culture Collection, Real Jardin Botanico (CSIC), Madrid. The Culture Collection for Algae and Protozoa (CCAP) in Oban has recently established a small collection of dual clonal cultures of marine oomycetes on their seaweed hosts (Strittmatter et al. 2013).

Literature and History of Knowledge

While there have been no dedicated monographs on the Hyphochytriomycota, they were included by Karling (1977) in his richly illustrated monograph of the chytrids sensu *lato*. In this he illustrates over half of the 23 accepted species and gives the

Fig. 3 **Animal pathogenic Oomycota**. (**a**–**d**) Achelminth pathogens. important references for their study. Other reviews of this phylum include those by Fuller (1990, 2001), Dick (2001), and Beakes et al. (2014a). The first observations of zoosporic fungi possessing a single anterior flagellum were first made in the late nineteenth century (Zopf 1884), although the hyphochytrids were not formally separated from the posteriorly flagellate chytrids until later (Karling 1939, 1943).

The most recent comprehensive monograph of the Oomycota is the scholarly overview by Dick (2001) which lists much of the extensive taxonomic and general biological literature up to end of the millennium. Two important plant pathogenic genera, *Pythium* and *Phytophthora*, have been previously monographed, respectively, by Plaats-Niterink (1981) and Waterhouse (1970). The former is currently being comprehensively updated (previewed by de Cock et al. 2012). Recent literature sources for the plant pathogenic downy mildews can be found in Thines and Choi (2016), Lebeda and Spencer-Phillips (2007), Thines (2014), Thines et al. (2009a, b), and Voglmayr (2008). A review of the updated taxonomy of the Albuginaceae is given in Choi et al. (2006, 2008) and Thines and Voglmayr (2009). The three principal genera in the Saprolegniales (*Achlya*, *Aphanomyces* and *Saprolegnia*) have been monographed, respectively, by Johnson (1956), Scott (1961), and Johnson et al. (2002 updated from Seymour 1970). For other taxa, particularly the holocarpic species, reference should be made to Dick (2001), Karling (1981), and Sparrow (1960).

Detailed accounts of the extensive historical studies on the Oomycota have been given by both Dick (2001) and Johnson et al. (2002) and only highlights will be covered here. During the late eighteenth century, there were a number of reports of what we now recognize to be *Saprolegnia* infections of fish (reviewed by Hughes 1994). Similarly the first documented plant pathogenic oomycete was by Persoon who described the white blister rust *Aecidium candidum*, which was subsequently transferred by de Roussel in 1806 to the genus *Albugo* (Choi et al. 2007), although at that time it was still not recognized as an oomycete (Dick 2001). Much of the early documentation of the Oomycota stems from the pioneering researches of Pringsheim, de Bary, Regel, and Tulasne among others (Dick 2001). The higher oomycete taxa were recognized almost as soon as sufficient species had been described to put them into groups. De Bary separated the "Peronsporei" from the mucoraceous phycomycetes and shortly after proposed the "saprolegnieen" and "peronosporeen" family

Fig. 4 (continued) upper leaf showing dark fleck-like oospores within tissue. (**l**) Mature oospore of *W. bliti* showing reticulate oospore ornamentation. (**m**) Blister-like leaf lesion of *Albugo "armoraciae"*. (**n**–**p**) Graminicolousdowny mildews – *Sclerospora graminicola*. (**n**–**o**) Infected plants of *Setaria viridis* and details of leaf surface showing white conidiophores. Detail of orange-pigmented thick-walled angular oospores, typical of these mildews. (**q**–**v**) Downy mildews of herbaceous angiospermae. (**q**–**u**) *Cerastium* sp. infected with *Peronospora* sp. (**q**) plants (unifected *left*, infected *right*) showing stunting and chlorosis. (**r**) Detail of lower surface of a leaf, showing darker regions in areas where oospores have formed. (**s**) Branched sporangiophores (darkfield), with terminal disarticulating conidiosporangia. **t**. Mature reticulate oospores within infected leaf tissue. (**u**) Cotyledons of *Microthlaspi erraticum*, showing abundant condiophores of *Hyaloperonospora thlaspeos-perfoliat*ion both upper and lower surfaces. (**v**) SEM micrographof conidiophore of *Plasmopara nivea*, showing branchlets that bore the now-detached conidiosporangia

concepts (de Bary 1881). *Albugo* was eventually recognized as an oomycete when its sexual stages were described by Léveillé (1847) and subsequently placed in the "peronosporeen group" by de Bary (1881). The first attributable oomycete parasites of aquatic plants, protozoa and invertebrate animals were described by Schenk (1858), Cornu (1872), and Zopf (1884). The first plant pathogenic member of the oomycetes to be described was *Albugo candida* (Persoon, in Gmelin 1792). By the mid nineteenth century, there had also been descriptions of the first three downy mildew genera: *Peronospora* (Corda 1837), *Bremia* (Regel 1843), and *Basidiophora* (Roze and Cornu 1869). However, it was not until the end of the century that Schröter (1893) placed these plant pathogenic species into their own separate family, the Peronosporaceae.

In the latter half of the twentieth century, the taxonomic synthesis of the Oomycota was forged by three outstanding scholars of zoosporic fungi: Dick (1973a, b; 2001), Karling (1981), and Sparrow (1960, 1976). In the second edition of "*Aquatic Phycomycetes,*" Sparrow (1960) listed four major oomycete orders, the Saprolegniales, Leptomitales, Lagenidiales, and Peronosporales. In his final synthesis, Sparrow (1976) proposed splitting of the oomycetes into two 'galaxies', which Dick (2001) later formalized into the subclasses Saprolegniomycetidae and Peronosporomycetidae and also introduced a new order the Eurychasmales, in which he placed a number of little known marine taxa. He considered this new order to be part of the "saprolegnian galaxy" together with the Leptomitales and Saprolegniales. His "peronosporalean galaxy" included the orders Peronosporales, which encompassed most important plant pathogens, and Lagenidiales, which encompassed most of the holocarpic parasites of invertebrates and algae. Dick had continued to refine the classification of the Oomycota (Dick 1976a, b, 1997, 1998; Dick et al. 1984) culminating in his final synthesis which he outlined in his encyclopaedic treatise, "*Straminipilous Fungi*" in which he expanded the number of orders to around a dozen (Dick 2001). However, as a result of subsequent molecular studies, a substantial revision of Dick's (2001) scheme has recently been proposed (Beakes et al. 2014a).

Economic and Practical Importance

No hyphochytrid (i.e., excluding *Anisolpidium*) is known to cause any economically significant disease of plants or animals. Artemchuk and Zelezinskaya (1969) described a species (*Hyphochytrium peniliae*) that caused a severe mycosis of a freshwater crawfish, but there have been no subsequent reports of this disease, and Dick (2001) questioned whether this organism was even a hyphochytrid. Both *Rhizidiomyces* spp. and *Hyphochytrium catenoides* are known to parasitize oospores of plant pathogenic oomycetes (Ayers and Lumsden 1977; Sneh et al. 1977; Wynn and Epton 1979), and *Rhizidiomycopsis stomatosa* (Sparrow 1977) infects the resting spores of the endomycorrhizal fungus *Gigaspora margarita* (Schenck and Nicolson 1977; Sparrow 1977). Hyphochytrids may, therefore, adversely affect populations of both potentially harmful oomycetes and beneficial mycorrhizal fungi in soil ecosystems (Sneh et al. 1977). The closely related parasitoids belonging to the genus *Pirsonia* infect centric diatoms and bring about a decline in planktonic

blooms (Kühn 1997; Schnepf et al. 1990). Members of the genus *Anisolpidium* infect both freshwater algae (Canter 1950) and filamentous phaeophyte seaweeds (Karling 1943; Küpper and Müller 1999); however, this genus is now thought to be an oomycete (Gachon et al. 2015).

In contrast, the economic importance of the Oomycota is well known. Many are devastating and economically important plant pathogens (Fig. 4a–v), with even threatening natural ecoystems such as the Jarrah forest in Australia (Fig. 4e). In the mid-nineteenth century, de Bary and Berkeley established that the species we now know as *Phytophthora infestans* (Fig. 4a, b) was the causal agent of the devastating potato blight epidemic responsible for the great Irish famine (Berkeley 1846; de Bary 1876; Yoshida et al. 2013). Other species cause serious losses to wild and farmed fish (Fig. 3i, k) and crustaceans (Fig. 3e, g), and there are a few species that can opportunistically infect mammals, including humans (Bruno et al. 2011; de Grooters et al. 2013; Mendoza 2005; Phillips et al. 2008; Schurko et al. 2004; Van West 2006). Economically important genera include the obligate biotrophic white blister rusts (*Albugo*; Fig. 4f–l) and the downy mildews (e.g., *Bremia*, *Peronospora*, *Sclerospora* etc.; Fig. 4n–v) and facultatively parasitic genera such as *Aphanomyces, Phytophthora* (Fig. 4a–e)*, Pythium* and *Saprolegnia*. White blister rusts (Fig. 4f–l) and downy mildews (Fig. 4n–v) infect plants, the latter often causing stunting (Fig. 4f, q) and may result in significant yield losses to many economically important crop plants (Constantinescu 1991; Thines and Choi 2016; Van Wyk et al. 1995). The graminicolous downy mildews (GDM; Fig. 4n, o) in particular pose a serious threat to agriculture in the semi-arid tropics (Bock et al. 2000; Kenneth 1981; Telle et al. 2012; Vilgoen et al. 1997). Many *Phytophthora* species cause economically and ecologically devastating dieback diseases of trees and scrubs, such as sudden oak death caused by *Phytophthora ramorum* (Davidson et al. 2003) and jarrah forest dieback (Fig. 4e) caused by *Phytophthora cinnamomii* (Newhook and Podger 1972; Podger 1972). *Aphanomyces euteiches* causes serious economic losses by infecting the roots of leguminous crops such as peas and beans (Gaulin et al. 2007). Comprehensive catalogues of oomycete diseases of crop plants have been given by, among others, Dick (2001) and Constantinescu (1991).

Both *Nematophthora,* which infects nematode eggs (Dick 2001), and *Lagenidium giganteum,* which infects mosquito larvae (Kerwin 2007), have been explored as potential biocontrol agents. Marine species such as *Atkinsiella*, *Haliphthoros* (Fig. 2l, m)*, Halodaphnea* (Fig. 2j, k), and *Salilagenidium* spp. can cause serious economic losses to cultured crustaceans (crabs and prawns etc.) in coastal aquaculture systems (Hatai 2012; Hatai et al. 1980). *Aphanomyces astaci* (Fig. 3e–g), which was introduced to Europe around a century ago on imported signal crayfish (*Pacifastacus leniusculus*) from north America, now threatens to wipe out the native European white-clawed crayfish (*Astacus astacus*) which has no innate resistance to this pathogen (Cerenius et al. 1988; Edgerton et al. 2004).

Saprolegnia infections of fish and their eggs have been extensively documented and are responsible for significant losses to salmonids worldwide (Bruno et al. 2011; Van West 2006). Epizotoic ulcerative syndrome (EUS) caused by *Aphanomyces invadans* (syn *A. piscida*) is an emerging disease of farmed fish in warmer countries,

from the Indian subcontinent eastwards (Johnson et al. 2004; Lilley et al. 1998). Equine phycomycosis is an opportunistic pathogen of mammals caused by *Pythium insidiosum* (Krajaejum et al. 2011; Schurko et al. 2004), which, although largely affecting domesticated livestock in tropical countries, can cause potentially fatal infections to humans (Mendoza 2005). A newly recognized holocarpic lagenidiaceous species (*Paralagenidium karlingii*) has recently been shown to be the cause of fatal mycoses in dogs (de Grooters et al. 2013). In contrast to their importance as pathogens, no hyphochytrid or oomycete is known as a source for any economically important product, although, as with other heterokonts, they are able to synthesize valuable fatty acids (Domergue et al. 2005), but have not so far been commercially exploited.

Habitats And Ecology

Hyphochytriomycota, in common with the Chytridiomycota and Oomycota, are likely to be encountered in soil and water samples from any area of the world (Gleason et al. 2009; Thines 2014). Soil samples baited with pollen and boiled grasses commonly yield isolates of *Rhizidiomyces* (Figs. 2c, 6a–b) and *Hyphochytrium* (Fig. 2b, d). Gleason et al. (2009) demonstrated that *H. catenoides* is capable of surviving extreme environmental conditions. Viable colonies were recovered after subjecting dried material to extremes of pH (2.8–11.2), hypersalinity and freezing temperatures. Species belonging to the genera *Hyphochytrium, Latrostium,* and *Rhizidiomyces* have all been reported to infect algal thalli (Canter 1950). *Hyphochytrium infestans* was isolated from the decaying ascocarps of ascomycetous fungi, while both *Hyphochytrium* and *Rhizidiomyces* spp. infect oogonia of *Saprolegnia* and *Pythium* spp. and the resting spores of endomycorrhizal fungi (Fuller 2001; Schenck and Nicolson 1977; Sparrow 1977).

The Oomycota are likewise ubiquitous in marine, terrestrial, and aquatic ecosystems worldwide. Water moulds in the Saprolegniales have been recovered from almost every freshwater ecosystem but appear most abundant at the margins of lakes and ponds (Dick 1976; Johnson et al. 2002; Willoughby 1962; Wood and Willoughby 1986). In general population levels of saprolegniaceous water molds appear higher in cooler and wetter seasons, often showing peaks in spring and autumn (Ali-Shtayeh et al. 1986; Dick and Ali-Shtayeh 1986). Stagnant water and anaerobic environments also have their own distinctive communities of oomycetes, in which members of the Leptomitales and Rhipidiales (such as *Sapromyces*, Fig. 2p) predominate, and these fungi are often referred to as sewage fungi (Emerson and Natvig 1981; Riethmüller and Langer 2004). In coastal ecosystems, genera such as *Halophytophthora* and *Salisapilia* are now known to play a major role in the initial colonization, degradation and recycling of organic substrates, such as cord grass and mangrove leaves (Hulvey et al. 2010; Nakagiri et al. 1994; Newell and Fell 1995; Nigrelli and Thines 2013). Oomycota also infect a wide range of invertebrate animals such as crustaceans (Fig. 3e–g; Duffey et al. 2015; Hatai et al. 1980, 1992), insects (Frances et al. 1989; Kerwin 2007; Martin 1977), nematodes

(Figs. 2f, o; 3a–c; Dick 2001; Glockling and Beakes 2000a; Karling 1981), and rotifers (Fig. 3d; Molloy et al. 2014).

Oomycota play significant roles in terrestrial ecosystems. In soils, saprotrophic or facultatively pathogenic genera such as *Aphanomyces, Phytophthora*, and *Pythium* spp. predominate (Ali-Shtayeh et al. 1986; Arcate et al. 2006; Duncan 1990; Gaulin et al. 2007). Many oomycetes are obligate plant pathogens infecting annual or perennial herbs (Fig. 4f, q) and grasses (Fig. 4n). The white blister rusts (Fig. 4f–l) are found almost exclusively on herbaceous angiosperm hosts (Dick 2001; Choi et al. 2008; Constantinescu and Fetehi 2002; Spencer 1981; Spencer and Dick 2001; Thines 2009; Thines and Voglmayr 2009; Volgmayr and Riethmüller 2006; Van Wyk et al. 1995) with genera that appear to be restricted to specific host lineages (e.g., *Albugo* s.str. to the Rosidae, *Albugo* s.lat. to the Solanales, *Pustula* to the Asteridae, and *Wilsoniana* to the Caryphyllidae; Thines and Voglmayr 2009). Recent molecular phylogenetic studies have revealed downy mildew and white blister rust species that are restricted to a single host species (Choi and Thines 2015; Choi et al. 2007, 2008; García-Blázquez et al. 2008; Göker et al. 2004; Ploch et al. 2010; Thines et al. 2009b; Voglmayr 2003; Voglmayr et al. 2004). In contrast, some downy mildew genera such as *Peronospora* and *Plasmopara* have a very wide host ranges (Voglmayr and Constantinescu 2008; Voglmayr et al. 2004). While a few species of downy mildews are known to be parasitic to trees (e.g., *Plasmopara cercidis*, *Pseudoperonospora celtidis*), shrubs, and lianae (e.g., *Plasmopara viburni*, *Plasmopara viticola*, *Plasmopara australis*, *Pseudoperonospora humuli*, *Peronospora sparsa*), it is the hemibiotrophic genus *Phytophthora* that is more commonly encountered as pathogens of woody plants (Fig. 4e; Davidson et al. 2003; Newhook and Podger 1972).

Characterization and Recognition

Thallus Organization

Spore germination in monocenric hyphochytrids such as *Rhizidiomyces* results in the formation of a primary rhizoid from which the basal rhizoidal system develops, while the spore body expands to form the main vegetative thallus (Fig. 2a, c; Karling 1971; Sparrow 1960). In the polycentric *Hyphochytrium*, a much broader germ tube emerges, into which a nucleus moves and divides, and develops into a rhizomycelium of interconnected thalli (Fig. 2a, b, d; Wells 1982; Karling 1977). Young thalli of *Hyphochytrium* contain many small vacuoles with electron-dense inclusion bodies (Fig. 2e; Clay et al. 1991). Hyphochytriomyota are characterized by the presence of both chitin and cellulose in their cell walls (Bartnick-Garcia 1970; Clay et al. 1991; Fuller 1960). Immunogold labeling reveals the vegetative thallus walls are predominantly composed of cellulose, while chitin is principally located in the septa and the sporangial discharge tubes and restraining vesicle (Clay et al. 1991).

Many early-diverging Oomycota also have simple endobiotic holocarpic thalli, which directly differentiate into sporangia on maturity (Figs. 5b, c, f; 6a, b). Many

(**c**) Mature thallus of *Eurychasma dicksonii* infecting *Ectocarpus* filament, showing characteristic peripheral net of primary cysts from which zoospores have been released and escaped. (**d**) TEM section of a young thallus of *E. dicksonii* in an expanded vacuolated host cell. Note close proximity of host nucleus (HN) and unwalled nature of the

holocarpic oomycetes, such as the parasities of algae *Ectrogella* (Ragukumar 1980), *Eurychasma* (Sekimoto et al. 2008a), and *Olpidiopsis* (Sekimoto et al. 2008b), have naked plasmodia stages during the earliest stages of infection (Fig. 5d). Taxa that have more extensive lobed, branched or segmented thalli (Fig. 2j, k, n) include the marine crustacean parasites, such as *Atkinsiella* (Karling 1981), *Haliphthoros, Halodaphnea* (Sekimoto et al. 2007), and algal parasites, such as *Lagenisma* (Schnepf et al. 1977, 1978a, b, c; Thines et al. 2015a) and *Petersenia* (Molina 1981; Pueschel and van der Meer 1985) as well as terrestrial genera such as *Chlamydomyzium* (Beakes et al. 2014b; Glockling and Beakes 2006b) and *Cornumyces* (Inaba and Hariyama 2006). Although none of these species produce typical hyphal-like thalli, most can be cultured on solid artificial media, where they form slow-growing irregular colonies (Glockling and Beakes 2006b; Sekimoto et al. 2007). Most thalli in the Rhipidiales (Fig. 2p) and Leptomitales form more typical fungal-like colonies on solid media, although they still have segmented thalli with regular constrictions. It appears that as in the Hyphochytriomycota, the Oomycota also have the capacity to synthesize chitin or chitin-like analogues, as evidenced by the widespread presence of chitin synthase genes within the phylum (Badreddine et al. 2008). In the Leptomitales, the pores in the constricted regions are plugged with refractile chitin-containing cellulin granules (Huizar and Aronson 1986).

The majority saprolegniomycete and peronosporomycete species have branched filamentous mycelial thalli that grow as fungus-like colonies on agar media (Fig. 2q, r). The hyphal tips contain accumulations of vesicles although they lack a well-defined Spitzenkörper analog found in most Fungi (Bartnicki-Garcia 1996). Hyphae vary in diameter from around 2 μm in genera such as *Pythiogeton* and *Verrucalvus* to nearly 150 μm in many genera in the Saprolegniaceae (Dick 2001). Hyphal vacuoles contain soluble β1–3 glucans (mycolaminarins), which are a major storage reserve in the Oomycota (Bartnicki-Garcia and Wang 1983; Wang and Bartnicki-Garcia 1974) as in the Ochrophyta. Most obligate biotrophic plant pathogens produce extensive intercellular hyphae in the infected leaf tissues from which haustoria intrude into the surrounding host cells (Hickey and Coffey 1977, 1978). The hyphae of the relatively

early diverging white-blister rusts, such as *Albugo*, form small stalked globose haustoria (Coffey 1975; Mims and Richardson 2002; Soylu et al. 2003), whereas *Phytophthora* (Coffey and Wilson 1983) and the downy mildews form generally larger digit-like to globose saccoid haustoria (Göker et al. 2003; Voglmayr et al. 2004).

Sporogenesis

In the Hyphochytriomycota, the expanded thallus is directly converted into simple zoosporangia. The cytoplasm then differentiates into uninucleate and uniflagellate zoospores during the zoosporogenesis phase of development (Karling 1977). In *Rhizidiomyces*, the sporangial cytoplasm flows into an external vesicle (Fig. 6a) where the completion of zoospore differentiation takes place (Fig. 6b; Clay et al. 1991; Fuller and Jaworksi 1987). In *Hyphochytrium*, the zoospores form within the sporangium and are released via open discharge tubes (Karling 1977).

Asexual reproductive structures provide many of the morphological characters which have been traditionally used to define genera (Dick 2001; Coker 1923; Johnson et al. 2002; Sparrow 1960), although recent molecular studies have revealed the inherent unreliability of many of these traditional morphological characters (Thines 2006). In early diverging Oomycota genera with plasmodial thalli, the thallus becomes walled prior to spore differentiation (Fig. 5f; Molina 1981; Raghukumar 1980; Schnepf et al. 1978b; Sekimoto et al. 2008a, b). Holocarpic endobiotic species usually form one or more elongate exit tubes (Figs. 2f, 3a, 5g, f, j) to facilitate the release of their spores from their hosts (Glockling and Beakes 2000a; Karling 1981). In species such as *Haliphthoros milfordensis*, these discharge tubes may be very long and hyphal-like in appearance (Fig. 5j). In *Aphanomyces*, primary aplanospores differentiate within what appear to be undifferentiated hyphae (Hoch and Mitchell 1972, Johnson et al. 2002). However, most species with eucarpic thalli form septum-delimited sporangia with a characteristic morphology (Fig. 6f–j) that are typically formed terminally (Johnson et al. 2002; Sparrow 1960). In the

(**l**) Video sequence showing vesiculate discharge of zoospores in *Hp. vesicula*. (**m**) Video sequqence showing discharge of spore mass into vesicle in a lagenidiaceous *Myzocytiopsis* sp. It takes about 10 min before the zoospores become fully motile and the vesicle ruptures. (**n**–**q**) Electron micrographs of the dense-body (DB)/finger-print (FP) vesicles associated with sporogenesis (all Beakes unpublished). (**n**) Densebody vesicle from primary cyst of *Achlya* (Saprolegniaceae), showing cap of lamellate material associated with the dense vesicle inclusion body. (**o**) High magnification detail of regular lamellate arrays from a oosphere DBV in Saprolegniaceaeshowing a periodicity of ca. 15 nm. (**p**) A finger-print vesicle from zoospore of *Pythium* Pythiaceae) showing reticulate array of lamellate material. (**q**) High magnification detail of regular lamellate arrays from a cyst of *Phytophthora* (Peronosporaceae) showing a periodicity of ca. 15 nm

Saprolegniales, sporangia are delimited by a double-walled septum (Gay and Greenwood 1966), whereas in the Peronosporales they are separated by a callose plug (Fig. 6i, j; Hohl and Hammamoto 1967). There are a significant number of taxa that produce nonmotile primary aplanospores (e.g., *Achlya*: Fig. 6h; *Aphanomyces*: Figs. 3f, 6c; *Calyptralegnia*: Fig. 6d, *Eurychasma*: Fig. 5c, *Protascus*: Fig. 7n, and *Thraustotheca* Fig. 6e). Many downy mildew genera in the Peronosporaceae such as *Bremia*, *Hyaloperonospora* (Fig. 4u) and *Peronospora* (Fig. 4s) form condiosporangia that germinate directly by means of germ tubes.

Zoospores or aplanospores are released (Fig. 6g, h, l) following the dissolution of the apical papillum wall (Beakes 1987; Gay and Greenwood 1966). In the Peronosporales, the papillum usually contains a plug (Fig. 6k, m), which often gives rise to extra-sporangial vesicles into which partially differentiated cytoplasm (Fig. 6m) or fully differentiated zoospores (Fig. 6l) are released (Beakes 1987; Glockling and Beakes 2006b; Lunney and Bland 1976). In the hyphochytrid *Rhizidiomyces* (Fig. 6a, b; Fuller and Reichle 1965) and some Peronosporomycete genera, such as ~*Lagenidium* (Gotelli 1974), *Myzocytiopsis* (Fig. 6m; Glockling and Beakes 2006a), and *Pythium* (Lunney and Bland 1976), the final stages of zoospore differentiation take place within the extra-sporangial vesicle, outside of the thallus. In other Peronosporomycete genera, such as *Phytophthora* and *Halophytophthora* (Fig. 6l), fully motile zoospores form within the sporangium and are also released into a transient restraining vesicle (Hyde et al. 1991a), while in downy mildew species such as *Plasmopara* spp. and *Pseudoperonospora* spp., zoospores are directly released from the sporangium (Thines 2006). In most downy mildews, the sporangia are formed on determinate sporangiophores of distinctive branched morphology (Fig. 4s, v). In most leaf-borne plant pathogens, the mature reproductive structures are disseminated by disarticulation (Fig. 4s) and dispersed by wind and rain splash (Dick 2001, Thines 2006). In the white blister rusts, basipetally maturing chains of conidia/sporangia are produced subepidermally by sporogenous hyphae (Fig. 4g, h), remiscent to true rusts, and again disseminated by disarticulation after lysis of the plant epiermis (Fig. 4j; Heller and Thines 2009; Kemen and Jones 2012; Mims and Richardson 2002).

In the genus *Saprolegnia*, two morphologically distinct types of zoospore are produced, traditionally referred to as primary and secondary zoospores (Beakes 1987; Coker 1923; Holloway and Heath 1977a; Sparrow 1960). Primary zoospores simply serve to disperse the spores from the immediate vicinity of the parent sporangium and are generally weak swimmers. They are usually pip or pear shaped and have apically inserted flagella (Fig. 7b)) which are retracted upon encystment (Holloway and Heath 1977a). The resulting primary cysts (Fig. 7o) typically release the stronger swimming dispersive secondary zoospores (Fig. 7d) which are typically reniform in shape and have laterally inserted flagella (Fig. 7d, g, i) that are shed upon encystment (Holloway and Heath 1977a). This ability to produce two generations of zoospore appears to have been lost in many Saprolegniomycete genera (Beakes et al. 2014a; Johnson et al. 2002), such as where the primary spore initials encyst at the mouth of the exit tube as in *Aphanomyces* (Fig. 3f, 6c) and *Achlya* (Fig. 6h) or within the sporangium as in *Dictyuchus* and *Thraustotheca* (Fig. 6d).

(**f**) Schematic diagram of TEM longitudinal profile of a zoospore of *Hyphochytrium catenoides*. From Fuller 1990. From Cooney et al. (1985) *Can. J. Bot*. with permission. (**g**) Longitudinal LS section of a secondary zoospore of *S. parasitica*, showing central

The ability to produce both primary zoospores (Fig. 7b) and cysts (Fig. 7o) has been entirely lost in Peronosporomycetes, which only form secondary type zoospores and cysts (Fig. 7i, n–r; Beakes 1987; Dick 2001; Hohl and Hammamoto 1967; Lunney and Bland 1976; Sparrow 1960). In the downy mildews, the complete loss of zoospore production has taken place independently in several genera (e.g., *Bremia*, *Hyaloperonospora*, *Paraperonospora*, *Peronosclerpospora*, and *Peronospora*; Göker et al. 2007; Thines 2006; Thines et al. 2009a; Voglmayr et al. 2004). The recent finding of a complete absence of genes associated with flagellum formation and function in the genome of *Hyaloperonospora* indicates that, in some downy mildews at least, this is an irreversible loss (Baxter et al. 2010).

In order to maximize zoospore production, sporangium proliferation frequently occurs throughout the Oomycota following zoospore discharge. Regrowth may take place through the basal septum (internal renewal), or from a lateral branch (cymose renewal) or by outgrowth of the sporangiophore from sites where sporangia were discharged as in some *Phytophthora* species and the grass parasite *Viennotia* (Thines et al. 2007; Thines 2009). In the Albuginales, sporangia are produced in basipetal sequence by the sporogenous hyphae as occurs in true rust fungi (Fig. 4g, h; Heller and Thines 2009; Kemen and Jones 2012; Mims and Richardson 2002).

Encysted zoospores in Oomycota (cysts; Fig. 7o–r) are typically spherical, although in some nematode infecting species, such as *Protoascus* (Fig. 7n), may be elongate and spindle-shaped. They are typically uninucleate and thin walled and contain abundant lipid and vacuolar dense-body/fingerprint vesicles (Fig. 7n–r). Most secondary cysts germinate directly by means of a vegetative germ tube, thus completing the asexual life cycle (Fig. 2s–u). However, the encysted zoospores of the nematode-infecting genus *Haptoglossa* (Beakes and Glockling 1998, 2000, 2002) germinate to produce specialized infection structures known as gun cells

Fig. 7 (continued) nucleus (N) and electron-dense kinetosome-associated bodies (K2) adjacent to the ventral groove. (**h**) TEM detail of a kinetosome associated K-body from *Achlya flagellata* (Saprolegniaceae). (**i**) Near median LS through zoospore of *Phytophthora palmivora*, showing disposition of fingerprint vesicles and lipid around the nucleus. (**g**–**i**) From Beakes (1989), Oxford Clarendon Press, with permission. (**j**) Fixed zoospore of *Phytophthora cinnamomi*, stained with FITC labeled monoclonal antibody (vsv-1) which labels the ventral vesicle fraction. (**k**) Kinetosomes associated with spore of *Haptoglossa erumpens*, showing both anterior (AK) and posterior (PK) kinetosomes and intervening striate fan structure. (**j**, **k**) Beakes unpublished. (**l**–**m**) Schematic diagrams showing basal bodies and rootlet system associated with secondary zoospores of *Hyphochytrium catenoides* (**l**) and *Phytophthora* (**m**). From Barr and Allen (1985) *Can. J. Bot.* with permission). (**n**) Elongate cyst of nematode parasite *Protascus subuliforme*, showing apical vesicles (asterisk), basal cluster of dense body vesicles (DB) and central nucleus (N). Courtesy Sally Glockling. (**o**) Section of a primary cyst of *Achlya flagellata*, showing nucleus and dispersed lipid bodies and mitochondria. (**p**) Cyst of Sapromyces elongatus that had encysted with sporangium. Note single nucleus and basal vacuoles (V) derived from coalesced dense body vesicles (Beakes unpublished). (**q**) Infection gun cell of *Haptoglossa erumpens*, showing basal vacuole (V) and inverted injection tube (asterisked). From Beakes and Glockling (2002), *Fung. Genet and Biol.* with permission). (**r**) Cyst of *Phytophthora palmivora*, showing nucleus (N) and array of finger-print vesicles (FPV). Beakes unpublished.

(Fig. 7q; Robb and Barron 1982). These cells contain a needle-like structure within an inverted tube (Beakes and Glocklng 1998, 2000, 2002). Upon contact with a suitable host, the tube everts and the needle ruptures the host cuticle, resulting in the injection of a minute infective sporidium into the body cavity of the nematode (Glockling and Beakes 2000b).

Most Oomycota also produce vegetative resting structures, variously referred to as chlamydospores in the Peronosporomycetes (Hemmes 1983) and gemmae in Saprolegniomycetes (Dick 2001; Johnson et al. 2002). These structures are delimited by similar septa to sporangia but are thicker-walled. They typically contain abundant storage reserves, particularly lipid (Beakes 1994; Hemmes 1983). When environmental conditions become favorable, they either germinate by producing germ tubes or convert into zoosporangia.

Sexual Reproduction

Sexuality has never been documented in the Hyphochytriomycota sensu stricto (i.e., excluding Anisolpidiaceae; Karling 1977), although structures that have been described as resistant sporangia have been reported in *Rhizidiomyces* spp. and *H. catenoides* (Karling 1977) which might explain why these species appears to be able to survive extreme environmental conditions (Gleason et al. 2009).

Most early diverging Oomycota (Table 1) are usually stated to lack a sexual stage (Sparrow 1976; Karling 1981). However, as Sparrow (1976) points out it seems improbable that all such species are genuinely asexual and suggested that they must have some form of cryptic (i.e., non oogamous) sexual reproduction. The best documented evidence supporting this comes from *Lagenisma coscinodisci*, which has recently been established to be an early diverging member of the Saprolegniomycetes closely related to *Atkinsiella* (Thines et al. 2015a). This species produces zoomeiospores which form cysts that conjugate to form the diploid resting zygote (Schnepf et al. 1977). Recent unpublished observations suggest that this might also be the form of sexual reproduction in *Eurychasma,* although this has only been observed on certain host seaweeds (Gachon, personal communication). Further support that conjugative, nonoogamous, sexual reproduction is prevalent in early diverging Oomycota also comes from *Anisolpidium ectocarpii* (Johnson 1957; Karling 1943, 1981). This species has recently been shown to be an early diverging member of the Oomycota closely related to marine *Olpidiopsis* spp. (Gachon et al. 2015) and reproduces by the fusion of adjacent protoplasts, derived from different cysts (Johnson 1957). Plasmogamy is immediately followed by nuclear fusion (karyogamy). The resulting zygote nucleus divides repeatedly as the cell enlarges and the wall thickens (Johnson 1957). All of these recent observations suggest that oogamy might have evolved at around the time of the Peronosporomycete divergence (Fig. 9a, b) and may even have arisen independently in saprolegniomycete and peronosporomycete lines (Thines et al. 2015a). However, the paraphyletic/polyphyletic genus *Olpidiopsis* needs further investigation in this respect, as

oogenesis has been reported in freshwater species such as *Olpidiopsis varians* (Martin and Miller 1986c) but not in any of the marine species (Sekimoto et al. 2008b, 2009).

In holocarpic Peronosporomycete species, such as *Lagenidium* and *Myzocytiopsis* adjacent thallus segments differentiate into male and female gametangia which have been interpreted as antheridial and oogonial segments, and give rise to a typical oosporic zygote (Dick 1995; Glockling and Beakes 2006a; Karling 1981; Martin and Miller 1986c). In the holocarpic, basal saprolegniomycete genus *Chlam ydomyzium* thick-walled oospore-like structures are formed, but without the apparent involvement of antheridial segments (Beakes et al. 2014b; Glockling and Beakes 2006b). Unfortunately, no information is available regarding nuclear changes that take place during resting spore formation in this genus to confirm whether this is a genuine sexual process, such as described in *Saprolegnia* species that lack antheridia (Beakes 1980b).

Oomycota as a group were named after their distinctive oogamous sexual reproduction present in the vast majority of species, involving the production of spherical to ovoid female oogonia, containing one (Fig. 8i) to several (Fig. 8a, f) large eggs (oospheres), and the associated male antheridia (Fig. 8f, i). In the diploid Oomycota gametangial meiosis preceeds gamete formation (Beakes and Gay 1977; Dick and Win-Tin 1973; Howard and Moore 1970). The female oosphere nuclei and male antheridial nuclei are the only haploid stages in the life cycle (Howard and Moore 1970; Beakes 1980b). The diploid state is restored by the fusion of the gamete nuclei, which normally takes place before the oospores (zygotes) have reached maturity (Beakes 1980b; Beakes and Gay 1977; Howard and Moore 1970). The morphology of gametangia (Fig. 8a, f, i) and oospores (Fig. 8g, h, k–p) have been widely used as key taxonomic characters (Dick 1969, 1990, 2001; Sparrow 1960). In the genus *Saprolegnia*, but also in the Albuginales, species identification is almost entirely dependent upon sexual characters (Choi et al. 2007, 2008; Coker 1923; Johnson et al. 2002; Ploch et al. 2010; Thines et al. 2009c; Voglmayr and Riethmüller 2006). It seems likely that in the Oomycota gametangium differentiation is regulated and coordinated by diffusible steroid hormones (antheridiols and oogoniols), whose functions have been well documented particularly in *Achlya bisexualis* (McMorris and Barksdale 1967; Raper 1939) and certain *Phytophthora* spp. (Ko 1988). In contrast to Saprolegniomycetes, several Peronosporomycetes were reported not to be able to synthesise their own sterols and require these as supplements in order to reproduce sexually (Jee and Ko 1997; Kerwin and Washino 1983). The male antheridia typically are formed on either subtending branches (monoclinous; Fig. 8a) or hyphal compartments (hypogynous) or from separate hyphae produced either on the same thallus (diclinous; Fig. 8f) or in the case of heterothallic species from separate thalli (Dick 1972, 1995, 2001). Many *Phytophthora* species show a unique type of amphigynous antheridium-oogonium association, where the oogonium penetrates the young antheridium which then forms a collar around the base of the oogonium (Fig. 8i; Hemmes and Bartnick-García 1975; Beakes et al. 1998).

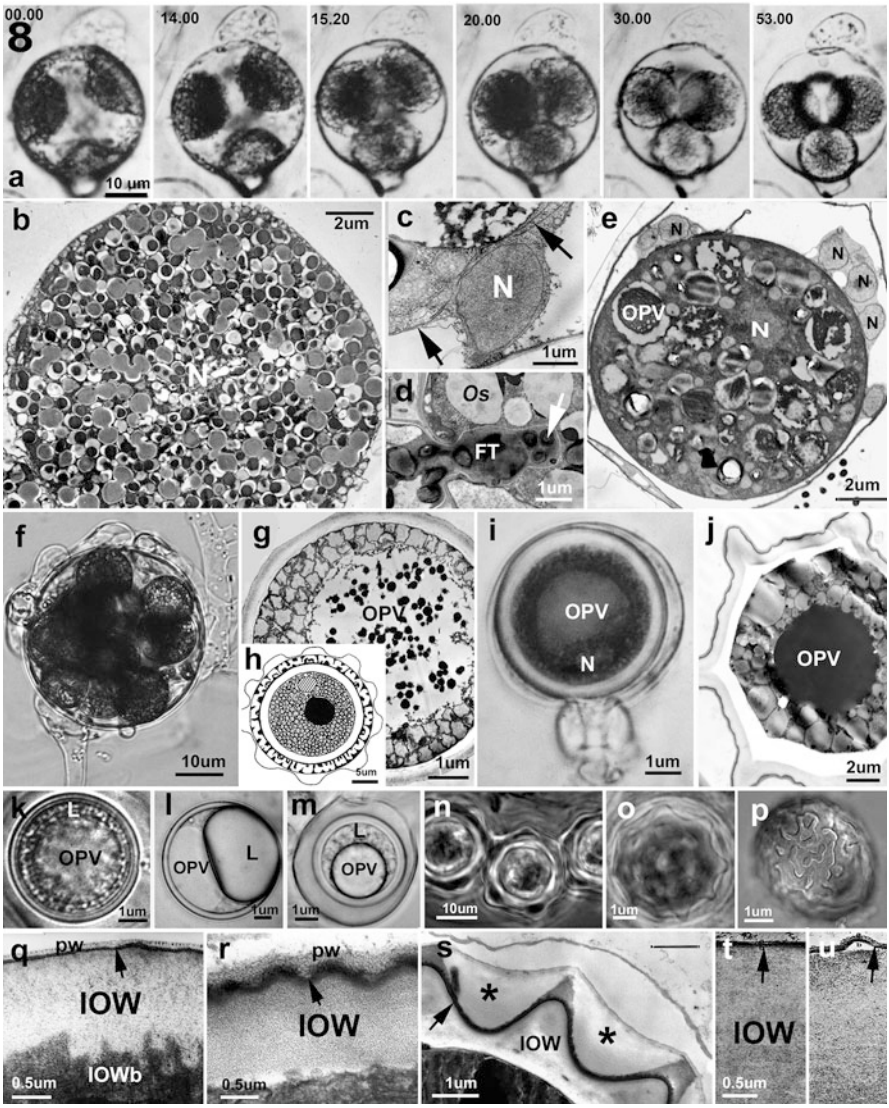

Fig. 8 Sexual reproduction. (**a**–**b**) Differentiating oospheres in *Saprolegnia furcata* (Saprolegniales). (**a**) Timelapse sequence over 53 min showing oosphere formation resulting from the fusion of the tonoplast with the plasma membranes, resulting in naked (unwalled) oospheres that initially swell (<20 min). As the oosphere primary wall forms, the oospheres achieve their final volume (around 30 min) and this is followed by fertilization tube formation from the attached antheridium (53 min). (**b**) TEM section through a newly formed, naked oosphere of S. furcata, showing interspersed lipid and densebody vesicles and central nucleus. (**a**–**b**) From Beakes and Gay (1977),*Trans. Br. Mycol. Soc.* with permission. (**c**–**e**) Differentiationg oospheres in *Myzocytiopsis spp.* (Peronosporales). Detail of a periplasmic nucleus (N) and part of a differentiated oosphere, separated by a double membraned envelope (*arrow*). (**d**) TEM of a developing fertilization tube (FT) extending into the oosphere (Os). The fertilization tube is bounded by a thin wall

In the Saprolegniomycetes, egg (oosphere) differentiation occurs as a result of the fusion of the central tonoplast membrane with the plasma membrane (Fig. 8a) resulting in naked oospheres (Fig. 8b), which within 30 minutes acquire an outer primary oosphere wall (Fig. 8a; Beakes and Gay 1978b). Following fertilization (Fig. 8a, d) thick inner oospore wall layers are accreted below a thin intervening electron-dense layer. In contrast in all Peronosporomycetes, a uninucleate oosphere (Fig. 8e) is cleaved from the cytoplasmic mass, surrounded by an outer periplasmic layer containing supernumerary nuclei (Fig. 8c; Beakes 1981; Hemmes and Bartnicki-Garcia 1975; Stevens 1901), which also contributes to the oospore formation by the the formation of an outer wall of the oospore.

Fig. 8 (continued) (*white arrow*). **e**. TEM of fully differentiated oosphere surrounded by a multinucleate (N) periplasm, typical of all Peronosporomycetes. The central nucleus (N) is surrounded by lipid and coalescing ooplast vesicles (OPV). All from Glockling and Beakes (2006a) *Mycol. Res.* with permission. (**f**) Light micrograph a mature oogonium of *Saprolegnia australis*, showing multiple oospores and diclinously attached antheridia. Beakes and Dieguez-Uribeondo unpublished. (**g**) TEM section through a mature oospore of *S. furcata*, showing central ooplast vacuole (OPV) containing densebody granules, surrounded by a lipid rich peripheral cytoplasm (From Beakes and Gay (1978a) *Trans Br. Mycol. Soc.* with permission) (**h**) Diagram of a mature oospore of *Albugo candida*(Albuginales) showing complex mutli-layered verrucose wall, and rather small ooplast vacuole surrounded by lipid-rich cytoplasm (adapted from Beakes (1981)) (**i**) Mature oogonium of *Phytophthora megasperma* (Peronosporales), showing amphigynous antheridium forming a collar around the the oogonium stalk and single oospore with a homogenous large central ooplast vacuole (OPV) and single zygotic nucleus (N). Beakes unpublished. (**j**) Near media profile of a mature oospore of *Myzocytiopsis venatrix,* showing lipid packed cytoplasm surrounding the homogenous central ooplast vacuole (OPV). Beakes and Glockling unpublished. (**k**) Light micrograph of a near mature centric oospore of *S. furcata* showing ooplast vacuole (OPV) is still homogeneous, but will eventually appear granular due to the dense body granules undergoing Brownian motion. (**l**) Mature eccentric oospore of *Leptomitus* (Leptomitales) showing transleucent ooplast vacuole and single large lipid globule. m. Sub eccentric oospore of *Apodachlya* (Leptomitales) showing homogenous ooplast vacuole (OPV) surrounded by a layer of fairly large lipid droplets (L). (**k**–**m**) Beakes unpublished. (**n**) Chain of stellate oospores of *Chlamydomyzium dictyuchoides* (Atkinsiellales s. lat.), showing punctate thick walls (From Beakes et al. (2014b) *Fung. Biol.* with permission) (**o**) Phase contrast LM of mature oospore of *M. vermicola* (Pythiaceae), showing punctate wall. Glockling and Beakes (2006a), *Mycol. Soc.* with permission. (**p**) DIC light micrograph of mature oospore of *Albugo* "*armoraciae*" (Albuginales), showing complex ornamentation that varies from species to species. Thines unpublished. (**q**) Oospore wall of *Saprolegnia furcata* (Saprolegniales) showing outer exospore wall layer (pw), electron-dense epispore layer (*arrow*) and thick inner endospore wall (IOW), which in this genus has an irregular electron dense inner zone (IOWb). Beakes and Gay (1978b) *Trans. Br. Mycol. Soc*. with permission. (**r**) Mature oospore wall of *Cornumyces* (Saprolegniomycetes), which shows similar layers to above, except for the absence of the inner electron dense zone to the endospore wall. Beakes unpublished. **s**. TEM through mature oospore wall of *Myzocytiopsis vermicola*(Peronosporomycetes) showing that punctate spines are the result of the uneven thickening (*asterisked*) of the endospore layer. The outer electron leucent exospore layer is laid down early in oospore maturation before the formation of the electron dense epispore layer (From Glockling and Beakes (2006a) *Mycol. Res*., with permission) (**t**–**u**) TEM through mature oospore walls of *Ph. megasperma*, fixed with glutaraldehyde and osmium (**t**) and additianlly stained with permanganate (**u**) showing outer electron-dense epispore (*arrowed*) and homogeneous, but finely fibrillar endospore wall (IOW) (From Beakes and Bartnicki-Garcia (1989). *Mycol. Res.*with permission)

Ultrastructure

Mitosis in the Hyphochytiomycota has only been described at the ultrastructural level in *Rhizidiomyces* (Barstow et al. 1989). During prophase the centrioles of unequal length divide and migrate to the poles of the nucleus. During metaphase small polar fenestrae (gaps) develop in the nuclear envelope, allowing the spindle microtubules to span the nucleus. By metaphase the chromosomes are grouped equatorially and vesicles appear and fuse with each other on the poleward side of chromosomes (Barstow et al. 1989). At metaphase the nucleolus is located in a pocket to the side of the chromosomes, after which it disperses completely. During anaphase the intranuclear cisternae migrate ahead of the advancing chromosomes. A perinuclear endoplasmic reticulum and microbodies surround dividing nuclei during anaphase and telophase. During telophase, offspring nuclei are formed by the addition of new envelope to existing membranes and the mid-region of the original nucleus is excluded (Barstow et al. 1989).

This contrasts with the completely closed mitosis described in most Oomycota (Beakes 1980c). Mitosis has been documented at the ultrastructural level in *Albugo* (Khan 1976), *Lagenisma* (Schnepf et al. 1978a), *Olpidiopsis* (Martin and Miller 1986a), *Phytophthora* (Hemmes and Hohl 1973) and *Saprolegnia* (Beakes 1980b, c; Heath and Greenwood 1970a). In most, the nuclear membrane persists throughout mitosis and an intranuclear spindle forms between pairs of polar or sub-polar centrioles, which are usually oriented at 180° (end to end) to each other. Only in *Olpidiopsis varians* are small polar fenestrae reported to form during prophase (Martin and Miller 1986a).

The vegetative thallus in both the Hyphochytriomycota and Oomycota is filled with large somatic vacuoles, which contain osmiophilic inclusion bodies of unknown composition that are often associated with the tonoplast membrane (Figs 2e, 5a, h). Nuclei and other cytoplasmic organelles are distributed throughout the peripheral cytoplasm (Fig. 5a, f, h). In both groups mitochondria have prominent tubular cristae (Fig. 5i), which are a characteristic feature of the chromalveolate lineage (Cavalier-Smith and Chao 2006). In vegetative hyphae and young sporangia in the Saprolegniales, the Golgi dictyosomes are associated with mitochondria and an intervening cisternum of endoplasmic reticulum (ER), a feature shared with many diatoms (Beakes 1989).

During sporangium differentiation in both the Saprolegniales and Peronosporales vacuolar dense body/fingerprint vesicles (DBV/FPV) increase (Beakes 1980a, 1994; Gay and Greenwood 1966; Glockling and Beakes 2006a) and their osmiophilic inclusion bodies become associated with lamellate material of regular periodicity (Fig. 6n–q). In *Phytophthora* phosphorylated glucan derivatives (phospho-mycolaminarin) have been shown to co-localize with isolated FPV (Powell and Bracker 1977). However, no lamellate DBV have been observed in early diverging genera (Beakes and Glockling 2000; Sekimoto 2008; Sekimoto et al. 2008a, b, 2009), which may indicate phosphorylated mycolaminarins are not synthesised by these species, although this needs experimental confirmation.

In most species spore formation involves the division (cleavage) of the multinucleate protoplast into uninucleate spore initials each with a defined complement of organelles. In early diverging genera such as *Eurychasma* (Sekimoto et al. 2008a), *Haliphthoros* (Fig. 5i), *Haptoglossa* (Fig. 5b; Beakes and Glockling 2000), *Olpidiopsis* (Martin and Miller 1986b; Sekimoto et al. 2008b, 2009) and *Petersenia* (Molina 1981) there is a tight association mitochondria around nuclei prior to cytoplasmic cleavage. Cytoplasmic cleavage in the Oomycota follows one of two general patterns (Beakes 1994; Dick 2001). The first, usually referred to as centrifugal cleavage (Beakes 1989, 1994) is found in most early diverging genera (Sekimoto 2008) and Saprolegniomycetes (Beakes et al. 2014a). A central vacuole expands delimiting a peripheral layer of uninucleate initials (Fig. 5h) and spore initial formation is effected by the fusion of the tonoplast with the plasma membrane (Gay and Greenwood 1966; Sekimoto et al. 2008b, 2009), as occurs in oosphere differentiation illustrated in Fig. 8a. In most Saprolegniomycetes flagellum formation occurs after the zoospore initials have differentiated (Beakes 1987; Gay and Greenwood 1966; Glockling and Beakes 2006b).

The second pattern, described as centripetal cleavage (Beakes 1994), predominantly occurs in the Peronosporomycetes (and probably Hyphochytriomycota). The uninucleate zoospore initials are delimited by the progressive disposition of a system of narrow Golgi-derived cleavage vesicles/cisternae, occasionally with additional infurrowing of the plasma membrane as occurs in *Albugo* (Khan 1976, 1977), *Phytophthora* (Hemmes 1983; Hohl and Hammamoto 1967; Hyde et al. 1991a, b) and *Pythium* (Lunney and Bland 1976). This leads to the concurrent, rather than sequential, formation of zoospore initials and flagella (Hohl and Hammamoto 1967; Hyde et al. 1991a, b; Lunney and Bland 1976). As a consequence beating flagella can often be observed in differentiating sporangia or extrasporangial vesicles even before the formation of individual zoospores.

Zoospore Ultrastructure

The ultrastructure of motile cells has traditionally been widely used to provide taxonomically and phylogenetically informative characters in protists and is still important in helping to define clades of chytrid fungi (Powell and Letcher 2014). In the Hyphochytriomycota and Oomycota, zoospores are also a rich source of phylogenetically informative characters (reviewed by Beakes 1987, 1989). Hyphochytriomycota zoospore ultrastructure has been documented for both *R. apophysatus* (Fuller and Reichle 1965) and *H. catenoides* (Barr and Désaulniers 1989; Cooney et al. 1985; Lange and Olson 1979: see Fig. 7f). In common with other members of the stramenopile lineage (Cavalier-Smith and Chao 2006) there is a helically coiled double transitional helix (TH) located just above the basal plate of the flagellum (Fig. 7f). In the Hyphochytriomycota the anterior flagellum is associated with two microtubular rootlets consisting of single (AR1) and doublet (AR2) type, both of which have rib-like microtubules extending from them, providing a cytoskeletal framework for the zoospore (Fig. 7l; Barr and Désaulniers 1989; Beakes et al. 2014a; Dick 2001). In addition, there is a third doublet rootlet (designated as multistranded

root, MS), which originates between the two basal bodies and extends to the spore posterior (Fig. 7l; Barr and Désaulniers 1989).

In the Hyphochytriomycota, the ribosomes in the zoospores are aggregated around the posterior region of the nucleus and are surrounded by a zone of mitochondria (Fig. 7f; Cooney et al. 1985; Fuller 1966; Fuller and Reichle 1965; Lange and Olson 1979). Lipid bodies and microbodies and assorted vesicles, including those containing mastigoneme tubules, are also scattered throughout peripheral zoospore cytoplasm (Fig. 7f). When Hyphochytriomycota zoospores encyst, the axoneme of the flagellum is retracted into the body of the cyst (Fuller and Reichle 1965; Wells 1982). The outer cyst coat is derived from the discharge of structured peripheral vesicles (Fuller 1966) which are similar to the encystment vesicles described in the Oomycota (Beakes 1987, 1989).

The structure and orientation of the four microtubular flagellar rootlets in Oomycota zoospores has been meticulously documented from serial section reconstructions in *Saprolegnia* (Fig. 7m; Barr and Allan 1985; Barr and Désaulniers 1987, 1989; Holloway and Heath 1977b) and *Phytophthora* (Barr and Allan 1985; Hardham 1987) and appears broadly similar to other biflagellate stramenopiles (Anderson et al. 1991; Barr 1981). Most Oomycota zoospores have the expected double TH in the flagellum base (Beakes et al. 2014a; Barr 1981; Dick 2001) although in *Olpidiopsis saprolegniae* it has only a single gyre (Bortnick et al. 1985), and it is apparantly absent in a few species, including the Peronosporomycete *Lagena radicola* (Barr and Désaulniers 1989). Zoospores contain an array of peripheral vesicles (Fig. 7g–j), which upon encystment are discharged to form both a ventral pad of adhesive and the outermost cyst coat layers (Beakes 1983, 1989, 1994; Gubler and Hardham 1988; Lehnen and Powell 1989). In Saprolegniomycetes, this system includes the larger kinetosome-associated (K-bodies) vesicles (Fig. 7h; Beakes 1989; Holloway and Heath 1977b; Randolph and Powell 1992) which upon encystment discharge to form a ventral pad of adhesive material (Burr and Beakes 1994; Lehnen and Powell 1989). In Peronosporomycetes the homologous vesicles are smaller and generally located along the rim of the ventral zoospore groove rather than immediately adjacent to the kinetosomes (Fig. 7j Gubler et al. 1990), and are often morphologically indistinguishable from the dorsal vesicle fraction. Saprolegniomycete genera also contain a second vesicle fraction, which in *Saprolegnia ferax* were called bar-bodies (Heath and Greenwood 1970b), although in other genera such as *Apodachlya* are spherical in profile (Randolph and Powell 1992). Upon discharge the peripheral component of these vesicles give rise to the thin outer electron-dense primary cyst coat (Beakes 1983, 1989; Randolph and Powell 1992). The corresponding vesicles in secondary zoospores of genera such as *Dictyuchus* and *Saprolegnia* contain, respectively, conspicuous tapered spines or boathook spines (Beakes 1983; Burr and Beakes 1994; Heath and Greenwood 1970b) that on release decorate the secondary cyst coat (Fig. 3j). In other genera such as *Apodachlya*, *Aphanomyces*, and *Achlya* the equivalent vesicles are spherical or ovoid in shape and have granular contents rather than tubules or spines and form only the thin outer electron-dense layer to the cyst wall (Beakes 1989). Morphologically similar encystment vesicles also occur in the zoospores of many of

the early diverging oomycetes, including *Eurychasma* (Sekimoto et al. 2008a), *Lagenisma* (Schnepf et al. 1978c), *Haliphthoros* (Overton et al. 1983; Sekimoto 2008), *Haptoglossa* (Beakes and Glockling 2000), *Olpidiopsis spp.* (Sekimoto et al. 2008b, 2009), and *Petersenia* (Pueschel and van der Meer 1985). In contrast, in Peronosporomycetes, the homologous vesicle fraction are the so-called dorsal small vesicles (dsv), which are often morphologically indisguishable from the ventral vesicle fraction, and upon encystment form a structurally diffuse sticky glycoprotein coat (Gubler and Hardham 1988; Gubler et al. 1990).

Mature Oospore Ultrastructure

Following nuclear transfer and fusion (karyogamy) the fertilized oosphere matures into the thick-walled resting zygote, the oospore (Fig. 8g–p; Beakes 1980a; Beakes and Gay 1978a; Hemmes and Bartnicki-Garcia 1975; Tewari and Skoropad 1977). Following fertilisation a thick electron-dense wall layer is layed down (Fig. 8q–u), to which further wall layers may be added both internally from egg cytoplasm and externally from the periplasm (Fig. 8q–u; reviewed by Beakes 1981). This "epispore" layer appears to represent the transition from oosphere to oospore, and after its formation, the mature eggs are much more recalcitrant to TEM fixation (Fig. 8g, j). The overall organization of the cytoplasmic components in mature oospores was described by Dick (1969) and has proven to be a useful taxonomic character. In all species the oospore protoplasm contains a prominent ooplast vacuole (Dick 1969; Fig. 8g–m) derived from the fusion and expansion of the oosphere DBV system (Beakes 1980a; Beakes and Gay 1978a; Beakes et al. 1986; Hemmes and Bartnicki-Garcia 1975; Howard and Moore 1970). This vacuole is usually surrounded by the peripheral cytoplasm containing oil reserves, which may be organized into many small droplets (in centric, subcentric or plerotic oospores; Fig. 8g, h, j) or these may coalesce into a small number of large droplets (as in the eccentric oospores of *Leptomitus*; Fig. 8l). In the genus *Saprolegnia* the mature ooplast vacuole contains small granules which are in constant Brownian motion (granular ooplast; Fig. 8g, k) whereas in the Leptomitales (Fig. 8l; Dick 1969, 1973a) and Peronosporomycete species the ooplast vacuole usually has a uniform refractile appearance (Fig. 8i; Beakes et al. 1986) and appears as a homogenously electron-dense matrix in the transmission electron-microscope (Fig. 8j; Beakes 1981; Beakes et al. 1986).

Oospores are mostly not shed from the oogonium wall which provides an additional protective outer layer to the zygote. It is often thick and multilayered (Beakes and Bartnicki-Garcia 1989; Hemmes and Bartnicki-Garcia 1975) and in many genera can be papillate (e.g in *Chlamydomyzium dictyuchoides*: Fig. 8n; *Sclerospora stellatus*: Fig. 8o) or ornamented (e.g., Fig. 8p; *Albugo ipomoeae-panduratae*; Voglmayr and Riethmüller 2006). In *Saprolegnia* there are often thinner-walled pit regions through which the germ tube hyphae escape. Mature oospore walls are also thick multi-layered structures and contain a large amount of storage carbohydrates (and probably lipids) that are mobilized upon germination (Beakes and Bartnicki-Garcia 1989; Bartnicki-Garcia and Wang 1983). The thick (2–3 μm) innermost endospore wall layer may be multilayered as in the genus *Saprolegnia* (Fig. 8q Beakes and Gay 1978b) or relatively homogeneous as in

Cornumyces (Fig. 8r) and most Peronosporomycete species (Fig. 8t, u; Beakes 1981; Beakes and Bartnicki-Garcia 1989; Hemmes and Bartnicki-Garcia 1975). In the Peronosporomycetes, the outermost oospore wall layer (the exospore layer; Beakes 1981) may at least be partially derived from the residual periplasm (Fig. 8s) and is particularly thick and complex in the Albuginales (Fig. 8h; Stevens 1901; Tewari and Skoropad 1977). In the Albuginales and many Peronosporales species (such as *Peronospora tomentosa*, Fig. 4l and *Myzocytiopsis vermicola*, Fig. 8o; Glockling and Beakes 2006a) the exospore is unevenly thickened, which gives the oospores their ornamented appearance (Fig. 8n–p).

The onset of germination is indicated by the rapid digestion and reabsorption of the thick inner endospore wall (Beakes 1980b; Beakes and Bartnicki-Garcia 1989) followed by the breakdown of the electron-dense ooplast globule material as the central vacuole expands. The broad germ tube hypha is often terminated by a zoosporangium (Ruben and Stangellini 1978). In *Albugo* also the swollen oospore may be converted directly into a zoosporangium, as depicted by Schröter (1893).

Genomic Studies

So far, there are no genome sequences for any Hyphochytriomycota in the public domain, although *Hyphochytrium catenoides* is being sequenced by Tom Richards, University of Exeter, and as part of the ATCC 18717 genome project. Some prelimary data for this organism has been included in publications, exploring horizontal gene transfer into the Oomycota (Richards et al. 2011; Savory et al. 2015). The top ten Oomycota pathogens, which genomes have been sequenced (even though some have not been released to the public domain so far) and which have been extensively studied in molecular plant pathology have recently been reviewed by Kamoun et al. (2015). Six are *Phytophthora* species, with the potato blight pathogen, *Ph. infestans* coming top of the list. The remaining places, were taken by two downy mildews (*Hyaloperonospora arabidopsis* and *Plasmopara viticola*), and a single *Albugo* and *Pythium* (Kamoun et al. 2015). The downy mildew *Hyaloperonospora arabidopsidis* and white blister rust *Albugo laibachii* both infect the model plant *Arabidopsis,* and have provided excellent systems in which to explore host pathogen interactions at the molecular level (Kemen and Jones 2012; Thines et al. 2009a). Much recent effort has been directed at unravelling the molecular basis of pathogenicity in economically important plant pathogenic oomycetes (see reviews by Jiang and Tyler 2012; Thines and Kamoun 2010). However, compared with the Fungi, genetic manipulation of stramenopiles has generally proven difficult and frustrating. With a few exceptions, such as *Phytophthora capsici*, it has been difficult to routinely transform Oomycota (Judelson and Ah-Fong 2009). Gene silencing techniques have often been the only tool available to explore gene functions (Whisson et al. 2009).

Representatives of the phytopathogenic genera *Albugo* (Kemen et al. 2011, Links et al. 2011), *Hyaloperonospora* (Baxter et al. 2010), *Peronospora* (Derevnina et al. 2015), *Plasmopara* (Sharma et al. 2015a), several *Phytophthora species* (e.g., Haas

et al. 2009; Judelson 2012; Tyler et al. 2006), *Pseudoperonospora* (Tian et al. 2011) and *Pythium ultimum* (Cheung et al. 2008; Lévesque et al. 2010) and the fish pathogen, *Saprolegnia parasitica*, have had their full or partial genome sequences released. Comparative genomics is promising to unlock many interesting secrets about these organisms (see Greville-Briggs et al. 2011; Judelson 2012; Lamour et al. 2007; Pais et al. 2013; Seidl et al. 2012; Sharma et al. 2015a, b). Features of genome evolution in the Oomycota, has revealed repeat-driven expansions, deletions, gene fusions and horizontal gene-transfer (Judelson 2012; Haas et al. 2009; Savory et al. 2015; Tyler et al. 2006). One surprising discovery appears to be the extent to which the genomes of oomycetes contain genes derived from other prokaryotes and eukaryotes, suggesting horizontal gene transfer (HGT) from bacteria, fungi and red and green algal endosymbionts (Jiang and Tyler 2012; Maruyama et al. 2009; Richards et al. 2006; Soanes et al. 2007). Genes of green algal ancestry have been discovered in oomycetes (Richards et al. 2011; Jiang and Tyler 2012). This might suggest that the single plastid acquisition-multiple loss interpretation related to evolution of non-photosynthetic organisms, such as Oomycota, from a photosynthetic ancestor needs further evaluation (Dorrell and Smith 2011; Maruyama et al. 2009; Stiller et al. 2009).

Recent genomic studies on non-biotrophic pathogens in genera such as *Aphanomyces* (Gaulin et al. 2007; Krajaejun et al. 2011), *Saprolegnia* (Torto-Alalibo et al. 2005; Wavra et al. 2012) and *Pythium* (Cheung et al. 2008; Lévesque et al. 2010) show these organisms contain a formidable array of glucanase and proteinase encoding genes, which have enabled them to so successfully exploit a wide range of plant and animal substrates (Jiang and Tyler 2012). Genomic studies have also revealed a startling array of pathogenicity factors and effector molecules, which presumably have enabled *Phytophthora* species (Judelson 2012; Lamour et al. 2007; Morgan and Kamoun 2007; Qutob et al. 2002; Sharma 2015a), downy mildew species (Baxter et al. 2010, Derevnina et al. 2015, Sharma et al. 2015a, b), and white blister rusts (Kemen et al. 2011; Links et al. 2011) to become such effective plant pathogens. The independent evolution of obligate biotrophy in the white blister rusts is also reflected by the fact that *Albugo laibachii,* the white blister rust pathogen of *Arabidopsis thaliana* (Thines et al. 2009c), has a much smaller genome compared with obligate parasites in the Peronosporales (Kemen and Jones 2012; Kemen et al. 2011) and has evolved a novel group of CHxC/CxHC effectors that are unique to this clade (Kemen et al. 2011; Links et al. 2011).

Classification

Karling (1977) presents what is probably the most realistic systematic treatment of the Hyphochytriomycota. He questioned Sparrow's (1973) classification that placed emphasis on zoospore cleavage patterns and rejected *Canteriomyces* and *Rhizidiomycopsis* as independent genera. In this account the Hyphochytriomycota have been treated as a phylum in their own right, which may also include the phagotrophic protist, *Pirsonia* (Kühn et al. 2004), which we will consider to be of *incertae sedis*.

The most recent formal systematic account of the Oomycota was by Dick (2001) and is largely based on a critical and scholarly evaluation of morphological characters. Since this account was published there have been many molecular phylogenetic studies on oomycetes (see review by Beakes et al. 2014a). Most of these have compared genes such as those encoding the small (SSU) and large ribosomal subunits (LSU) and the intervening internal transcribed spacer region (ITS), beta-tubulin, NADH and the mitochondrially-encoded cytochrome c oxidase subunit II genes (*cox*2). Some studies have concentrated on higher level taxonomic boundaries and general phylogenic relationships (e.g.; Choi et al. 2015; Dick et al. 1999; Göker et al. 2007; Hudspeth et al. 2000; Lara and Belbahri 2011; Léclerc et al. 2000; Petersen and Rosendahl 2000; Riethmüller et al. 1999; Thines et al. 2008, 2015b), whilst others have been concerned with resolving species clades within the main genera (e.g., *Albugo* Choi et al. 2007, 2008; Ploch et al. 2010; Thines et al. 2009c: *Aphanomyces* Diéguez-Uribeonodo et al. 2009; Levenfors and Fatehi 2004; Lilley et al. 2003; *Haliphthoros* Sekimoto et al. 2007; *Basidiophora* Sökücü and Thines 2014; *Hyaloperonospora* Göker et al. 2004, *Peronospora* Voglmayr 2003; *Peronosclerospora* (Telle et al. 2011), *Phytophthora* Blair et al. 2008; Cooke et al. 2000; Förster et al. 2000; Runge et al. 2011; *Pseudoperonospora* Choi et al. 2005, Runge et al. 2011; *Pythium* Lévesque and de Cock 2004; Martin 2000; *Saprolegnia* Diéguez-Uribeondo et al. 2009; Hulvey et al. 2007; Inaba and Tokumasu 2002; Léclerc et al. 2000; Sandoval-Sierra et al. 2014; Steicow et al. 2013, 2014). As a result of these studies it is now clear that many of the taxonomic changes that were introduced by Dick (1997, 2001) are not supported by molecular data and require substantial revision. It is also becoming apparent that many of the ordinal, family and generic circumscriptions in Oomycota require re-evaluation and that many traditional morphological characters used in taxonomy (such as patterns of asexual spore formation in the Saprolegniceae, patterns of antheridium attachment in *Phytophthora* and conidiophore development in the downy mildews etc.) are not reliable indicators of genetic relatedness.

A revised taxonomic framework of the Hyphochytriomycota and Oomycota based on molecular data is summarised in Table 1. We have refrained from making formal taxonomic descriptions, but will use working names, indicated by “ ” when first used for likely new classes, orders and families. Those taxa that we consider not to be monophyletic and consider are in need of revision are indicated by the ~ before them. We have assumed that the Oomycota form a phylum in their own right and consequently have raised to full class rank the sub-orders proposed by Dick (2001). The placement of the taxa (Rhipidiales, Leptomitales and “Atkinsiellales”) which lie at the cusp of the divergence of the main groups, the Saprolegniomycetes and Peronosporomycetes, have proven particularly problematic and their taxon sampling under-represented, as is the case with many of the smaller marine and holocarpic genera (Table 1).

The majority of Oomycota genera listed in Table 1 fall into one of two major clades with a high degree of statistical support (Fig. 9b). These have been assigned as separate classes the Saprolegniomycetes and Peronosporomycetes (Beakes et al. 2014a, Thines et al. 2015a), which approximate to the galaxies proposed by Sparrow

(1976) and assigned sub-class status by Dick (1997, 2001). Molecular studies have also revealed a number of early diverging basal clades, mostly encompassing marine species (Cook et al. 2001; Küpper et al. 2006; Sekimoto et al. 2007, 2008a, b). However, because of the limited or complete absence of molecular data for many genera in these early-diverging clades, we have refrained from assigning them to new classes at present and therefore they are placed under class(es) *incertae sedis* (Table 1).

Phylum Hyphochytriomycota

Class Hyphochytriomycetes

Order Hyphochytriales

Fuller (1990, 2001) considered that the Hyphochytriomycota consisted of one class (Hyphochytriomycetes), one order (Hyphochytriales), and three families (Anisolpidiaceae, Rhizidiomycetaceae, and Hyphochytriaceae). The Rhizidiomycetaceae have simple monocentric thalli and release their zoospores into a vesicle (Fig. 6b), consisting of 3 genera (Dick 2001; Fuller 2001). The Hyphochytriaceae have polycentric thalli and zoospores differentiate fully within the sporangium and are not released into a transient vesicle and at present also contains 3 genera (Dick 2001; Fuller 2001). Only two Hyphochytiomycota genera, *Hyphochytrium* and *Rhizidiomyces*, have so far been sequenced and together form a well supported clade that is well separated from the Oomycota (Fig. 1b). Recent molecular sequencing has shown that *Anisolpidium* belongs within the Oomycota (Gachon et al. 2015) and will be excluded from the Hyphochytiomycota in this account.

Phylum Oomycota Arx

Basal Class(es) – incertae sedis

Order "Eurychasmales"

The "Eurychasmales" (Table 1, Fig. 9b; Sparrow 1976) are a monotypic order of holocarpic parasites of seaweeds. Although three *Eurychasma* species have been described, most is known about *E. dicksonii* (Fig. 5c) a widespread parasite of filamentous brown seaweeds (Greville-Briggs et al. 2011; Küpper and Müller 1999). In all phylogenetic trees where it is included, *Eurychasma* is the earliest-diverging clade (Küpper et al. 2006; Sekimoto et al. 2008a; Strittmatter et al. 2013).

Order Haptoglossales M.W. Dick

The Haptoglossales (Dick 2001) forms a second early-diverging order (Table 1, Fig. 9b), which may ultimately form a new class together with the Eurychasmales as they both appear to share a common ancestor, but always with long branch separation (Beakes et al. 2006). This monotypic order and family contains a dozen or so species, all of which are parasites of bacterivorous nematodes and rotifers (Beakes and Glockling 1998, 2000, 2002; Glockling and Beakes 2000b, c; Hakariya et al.

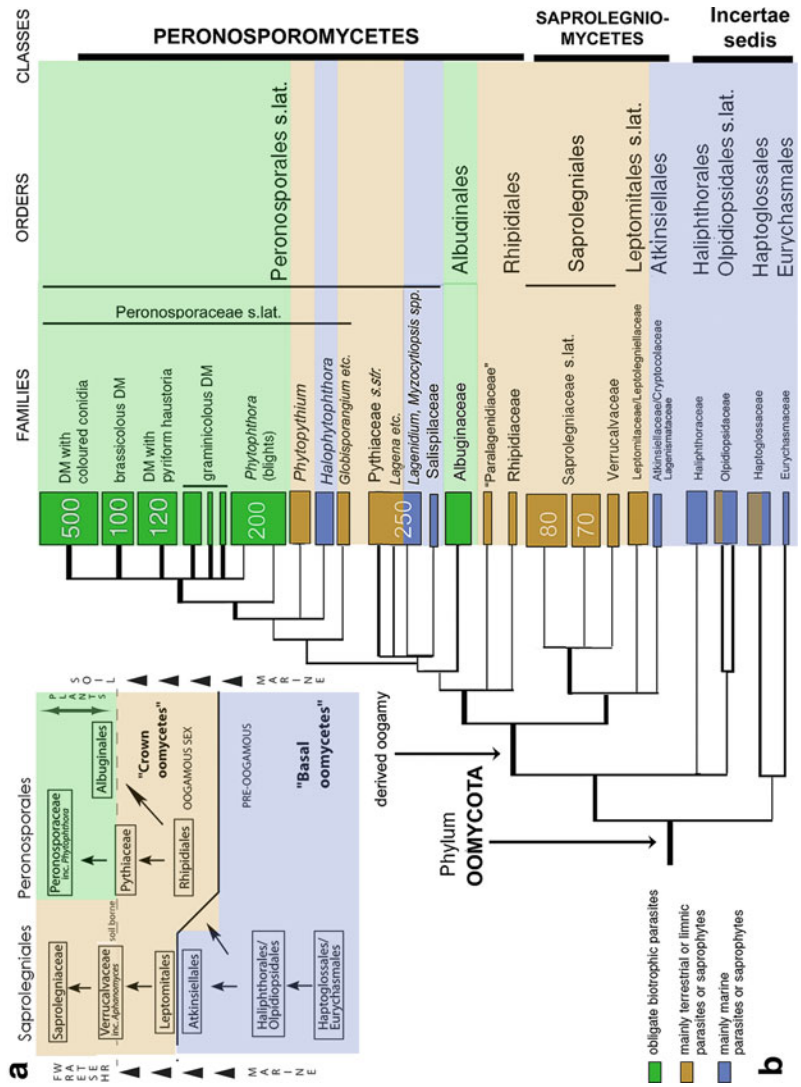

Fig. 9 Oomycete phylogeny diagrammatic summaries. (**a**) Diagram summarizing likely evolutionary path way of the Oomycota, indicating, for illustration, taxonomic clades (Adapted from Beakes et al. (2012). *Protoplasma*, with permission). (**b**) Schematic phylogenetic tree showing main taxonomic clades with an indication of taxon diversity (numbers in *boxes*) and predominant ecology of clades

2002, 2007). *Haptoglossa* (Figs. 2f, 3a, b, 5) is unusual amongst the genera in the early diverging clades of Oomycota in that it is a predominantly terrestrial genus, although *H. heterospora* has also been reported to infect marine nematodes (Newell et al. 1977). This genus produces unique infection 'gun cells' (Figs. 3b, 7q; Beakes and Glockling 1998; Robb and Barron 1982). Recent studies have revealed a number of species, such as *H. erumpens* (Beakes and Glockling 2002) and *H. heteromorpha* (Glockling and Beakes 2000c), which produce several morphological types of gun cells, which suggest they may have evolved to infect multiple hosts. Species within *Haptoglossa* clade also appear deeply diverging (Hakariya et al. 2007) and this genus will require revision.

Order ~Olpidiopsidales s. lat. M.W. Dick

The ~Olpidiopsidales (Fig. 5e–g) as currently defined is a paraphyletic or polyphyletic order of predominantly marine genera that are mostly parasites of marine algae (Fig. 5e–f). This order traditionally encompased three families, the Olpidiopsidaceae, Sirolpidiaceae and Pontismataceae (Dick 2001) but so far only representatives of the first family have been sequenced. The different species of marine *Olpidiopsis* for which sequence data have so far been published fall into two closely related clades, one with *O. porphyrae* and *O. pyropiae* (Klochclova et al. 2015; Sekimoto et al. 2008b) and the second with *O. bostrychiae* and *O. feldmanni* (Fletcher et al. 2015; Sekimoto et al. 2009) (Table 1). However, the type of the genus, *O. saprolegniae,* a freshwater endoparasite of saprolegniaceous water moulds (Bortnick et al. 1985), does not form a monophyletic clade with the marine species (Sekimoto and Inaba, unpublished sequences). This means the marine species will most likely have to be renamed. Recently, Gachon and colleagues (personal communication) have shown that two *Anisolpidium* species (*A. ectocarp, A. rosenvingei*) also forms a discrete clade nested between the marine *Olpidiopsis* spp. and the "Haliphthorales" clade. Therefore, it seems likely that as currently constituted even the genus *Olpidiopsis* is probably polyphyletic and will need significant revision, with new genera names required for the marine species.

Order "Haliphthorales"

The "Haliphthorales" (Figs. 2j–m, 5h) has not been formally described and among others contains the parasites of marine crustacea, *Haliphthoros* and *Halocrusticida* (renamed as *Halodaphnea* by Dick in 1998, but without supporting molecular data). These species can be cultured on agar media, have constricted segmented thalli (Hatai 2012; Hatai et al. 1980, 1992; Sekimoto et al. 2007), and form rather long (often >100 um) hyphal like discharge tubes (Fig. 5j). At present a single order (not as yet not formally described) and family (Haliphthoraceae) contains three or four poorly circumscribed genera (Sekimoto et al. 2007), including the recently described parasite of abalone, *Halioticida* (Maurosa et al. 2009). *Haliphthoros* as currently recognised appears to be a paraphyletic genus, with some "*Haliphthoros*-like" isolates apparently occuring within the crown Oomycota clade close to *Atkinsiella* (Sekimoto et al. 2007; Gachon, personal communication). Clearly much more research is required on this order.

It also seems possible that *Petersenia* and *Pontisma* in the Pontismataceae and *Sirolpidium* in the Sirolpidiacae will also turn out to be related to these two early-diverging marine orders or the basal lineages of the Saprolegniomycetes, currently they are placed as orders *incertae sedis* until sequence data become available (Taxonomic Summary; Table 1). The Ectrogellaceae (Dick 2001; Karling 1981) has been traditionally considered as part of the Saprolegniomycete line (Sparrow 1973, 1976) and also forms 'naked' plasmodial thalli in their diatom hosts similar to *Lagenisma* (Raghukumar 1980 – see below). However *Ectogella* has not yet been sequenced and therefore the Ectrogellaceae must also be considered as a family *incertae sedis*.

Class Saprolegniomycetes Thines et Beakes

The Saprolegniomycetes (Table 1; Fig. 9b), are characterized by the formation of two morphologically distinct generations of zoospore or aplanospore (Figs. 6c, 7a, d), a phenomenon usually referred to as diplanetism (see Dick 2001; Johnson et al. 2002). Fully differentiated zoospores or aplanospores are released directly from the sporangium (Fig. 6g, h). Both zoospores (Figs. 6f–h, 7b, d) and oospores are formed as a result of centrifugal cleavage (Fig. 8a) without the differentiation of a peripheral periplasmic layer of cytoplasm. Saprolegniomycetes are able to synthesize the sterols they require for oogenesis and generally utilize ammonium as a source of nitrogen and may also use organic sulphur (Gleason 1976). We have taken a conservative approach to their taxonomy, recognizing three orders within the class, the "Atkinsiellales", Leptomitales s. lat., and Saprolegniales (Fig. 9, Table 1).

Order "Atkinsiellales" and closely related taxa.

The order Atkinsiellales contains a handful of relatively little studied parasites of marine crustaceans and terrestrial invertebrates and contains two families as defined by Dick (1998, 2001), the Atkinsiellaceae and Crypticolaceae. *Atkinsiella dubia* forms a highly distinct clade (Fig. 16) at the base of the Saprolegniomycetes (Cook et al. 2001; Sekimoto 2008; Sekimoto et al. 2007, Thines et al. 2015a). A second species, *Atkinsiella entomophaga,* a parasite of dipteran larvae described by Martin (1977), was transferred by Dick (1998) to the previously monotypic genus *Crypticola*. The latter had been created for *C. clavulifera,* a parasite of mosquito larvae described by Frances et al. (1989). *C. clavulifera* forms a clade with *A. dubia* in *cox*2 analyses (Deborah Hudspeth, personal communication), which suggests the Crypticolaceae should also be included in this order, although family cirumscriptions require more data.

The diatom pathogen *Lagenisma coscinodisci,* which Dick (2001) placed in its own family, the Lagenismataceae, has been shown to form an early diverging Saprolegniomycete clade with some affinity to *Atkinsiella* (Thines et al. 2015a). We have therefore included this family in the Atkinsiellales (Table 1). The paraphyletic genus *Chlamydomyzium* (Dick 2001), which has both Saprolegniomycete and Peronosporomycete characteristics (Glockling and Beakes 2006b; Beakes et al. 2014), also forms clades amongst these early diverging Saprolegniomycete genera (Beakes et al. 2006; Beakes et al. 2014a). Isolates of the genus *Cornumyces* obtained

from keratin baits appears to be closely related to the nematode parasite *Chlamydomyzium* (Fig. 2o; Inaba unpublished trees) as well as to the Leptomitales clade (Inaba and Hariyama 2006). Dick (2001) also transferred *Lagenidium pygmeaum* to *Cornumyces* in absence of molecular data supporing this. He considered *Cornumyces* might belong in the Leptolegnielliaceae for which there is as yet no supporting sequence data. It is clear that much more work is required on these little studied basal Saprolegniomycetes before their formal taxonomy can be fully resolved.

Order Leptomitales Kanouse

The Leptomitales is a long-standing order that formerly included two families, the Leptomitaceae and Rhipidiacae (Dick 1973a; Sparrow 1960). These were separated into two orders by Dick (2001), and the Rhipidiales are now thought to be members of the Peronosporomycetes (Hudspeth et al. 2003; Thines et al. 2009c). The revised Leptomitales encompasses four small families, the most familiar of which are the Leptomitaceae, which are commonly known as sewage fungi. The Saprolegniomycete characteristics of *Apodachlya* and *Leptomitus* had long been been recognized (Beakes 1987) and sequence data confirms they form an early diverging clade within the class (Petersen and Rosendahl 2000). Recently the anamorphic genus *Blastulidium paedophthorum*, a parasite of freshwater cladocerans, has been confirmed to be in a clade close to *Apodachlya* and *Leptomitus* (Duffey et al. 2015), which confirms Dick's placement in the Leptomitales. To date no sequence data exists for any member of the Ducellariaceae and Letolegnielliaceae that Dick (2001) also included in the Leptomitales. These families contain a number of rarely encountered, holocarpic genera (*Aphanodictyon, Aphanomycopsis Brevilegniella, Ducellaria, Leptolegniella, and Nematophthora*) that have been mainly been documented by Karling (1981).

Order Saprolegniales E. Fisch.

The Saprolegniales is one of the largest and longest-established orders (Sparrow 1960, Dick 1973b) and forms a well-supported monophyletic clade (Dick et al. 1999; Inaba and Tokumasu 2002; Léclerc et al. 2000; Petersen and Rosendahl 2000; Riethmüller et al. 1999; Spencer et al. 2002; Steicow et al. 2014). Beakes et al. (2014a) suggested this order should be divided into three family level clades: a redefined Verrucalvaceae, the "Achlyaceae" and a re-circumscribed Saprolegniaceae sensu stricto. Dick et al. (1999) had introduced the family Leptolegniaceae which encompassed the genera *Aphanomyces, Plectospira* and *Leptolegnia*. Unfortunately, the inclusion of *Leptolegnia* with these other two genera is not well supported by most molecular studies (e.g., Arcate et al. 2006; Léclerc et al. 2000; Petersen and Rosendahl 2000; Steicow et al. 2013, 2014). Furthermore subsequent molecular studies have also shown that the grass pathogens, *Pachymetra* and *Verrucalvus*, which Dick et al. (1988) had placed in their own family, the Verrucalvaceae, also fall within the *Aphanomyces* clade (Hudspeth et al. 2003; Riethmüller et al. 2002; Telle and Thines, unpublished data). Therefore the family name Verrucalvaceae should take precedence over Leptolegniaceae. This clade is characterized by having species

with narrow hyphae and, when formed, relatively undifferentiated sporangia (Fig. 3f). Genera in this clade are predominantly soil-borne, root-infecting parasites, saprotrophs or animal parasites (Fig. 3e–g; Dick et al. 1984, 1988; Diéguez-Uribeondo et al. 2009; Johnson et al. 2002; Levenfors and Fatehi 2004; Lilley et al. 1998). The Verrucalvaceae also includes the nematode-trapping genus *Sommerstorffia* (Spies and Levesque, unpublished sequence data) as well as the recently described rotifer parasitic genus, *Aquastella* (Fig. 3d; Molloy et al. 2014). The genera *Aphanomyces* and *Plectospira* both form clusters (balls) of primary aplanospores (Fig. 6c), a feature shared with *Somerstorffia* (Johnson et al. 2002). All the genera form uni-oosporiate oogonia with more or less plerotic oospores, which in *Verrucalvus* have prominent verrucose ornamentation (similar to shown in Fig. 8n, o; Dick et al. 1988).

Although the branching order of the proposed family clades in the Saprolegniales is not well-resolved statistically, morphological and molecular evidence points to the recircumscribed Verrucalvaceae as the basal family in the Saprolegniales. A comprehensive molecular phylogenetic study of the genus *Aphanomyces* has shown that saprotrophic species, animal parasites and plant pathogens separate into three well supported sub-clades (Diéguez-Uribeondo et al. 2009). Dick et al. (1984) controversially also placed the graminicolus downy mildews in the Verrucalvaceae (Dick 2001) but this is not supported by molecular sequence data (Table 1; Hudspeth et al. 2000, 2003; Léclerc et al. 2000; Riethmüller et al. 1999, 2002; Thines et al. 2008).

The diverse genera of saprotrophic "water moulds" were traditionally all placed in a single family, the Saprolegniaceae containing a dozen or so genera (Table 1; Johnson et al. 2002; Sparrow 1960). Different genera were largely defined by their pattern of zoosporogenesis and asexual spore formation (Fig. 6d–h; Dick 2001; Johnson et al. 2002). However, it seems the best predictor of family-level relationships in the Saprolegniaceae is whether their mature oospores have centric/subcentric (as in Fig. 8k) or eccentric (as in Fig. 8l, m) organization (Léclerc et al. 2000; Spencer et al. 2002; Inaba and Tokumasu 2002). In some analyses (Inaba and Tokumasu 2002) genera with centric or subcentric oospores (*Aplanes, Aplanopsis, Calyptralegnia, Protoachlya, Newbya* and *Saprolegnia*, and possibly *Leptolegnia*) can be separated from those which produce strongly eccentric oospores (*Achlya* s. str., *Brevilegnia*, *Dictyuchus*, *Isoachlya*, and *Thraustotheca*). In the genus *Saprolegnia*, the mature ooplast often contains granules in Brownian motion as a result of the liquifaction of the matrix (Fig. 8k, g). However, even the archetypal water mould genus *Saprolegnia* is apparently not monophyletic, although molecular phylogeny is beginning to help resolve species boundaries (Diéguez-Uribeondo et al. 2007; Hulvey et al. 2007; Inaba and Tokumasu 2002; Sandoval-Sierra et al. 2014). Although we suggested a new family, the "Achlyaceae", might be warranted for the clade containing genera with strongly eccentic oospores, recent publications suggest this may be an an oversimplistic solution (Steciow et al. 2013, 2014; Sandoval-Sierra et al. 2014). Therefore we have decided not to formally split the Saprolegniaceae in this account (Table 1, Fig. 9b). Clearly further work is required before this large and complex family is formally split into well supported families.

Class: Peronosporomycetes M.W. Dick

The Peronosporomycetes are predominantly a terrestrial class. Most have a mycelial fungus-like thallus, although there are holocarpic species and many of the Rhipidiaceae have constricted thalli of determinate growth. Peronosporomycetes have been reported to have a requirement for exogenous sterols to complete oogenesis (Kerwin and Washino 1983) and the non-obligate pathogens of plants are able to utilize sulphate and variable nitrogen sources (Gleason 1976; Dick 2001), while there seems to be a tendency that non-obligate animal parasites and obligate plant parasites have defects in the pathways for the acquisition of inorganic nitrogen and sulfur (Baxter et al. 2010; Kemen et al. 2011; Sharma et al. 2015b). Peronosporomycetes produce only secondary type zoospores (Fig. 7i), which are differentiated within or transiently released into an evanescent extrasporangial vesicle in several genera (Fig. 6m). They have mono-oosporic oogonia in which the single oosphere is surrounded by a layer of periplasm (Fig. 3c, e, i; Dick 2001). Mature oospores often have complex multilayered walls (Fig. 3h, s) and a homogeneous (ooplast) vacuole (Fig. 3i).

Dick (2001) included the orders Rhipidales, Pythiales and Peronsporales within his Peronosporomycotina sub-class. Subsequent molecular studies revealed the white-blister rusts, form a separate basal order (the Albuginales) in their own right (Thines and Spring 2005). Many molecular studies suggest that the order level separation of the Pythiales and the Peronsporales along the lines proposed by Dick (2001) is not supported statistically (see discussion in Beakes et al. 2014a) and some genera, such as *Phytophthora*, were incorrectly placed (Hulvey et al. 2010; Thines et al. 2009a,). Furthermore, unpublished multigene sequencing of genera, is revealing much more diversity amongst the lagenidiaceous and pythiaceous species than has hitherto been suspected (Spies et al. 2014, 2016). However, until more statistically robust multigene sequence data are publically available, as in our previous review, we have adopted the historical position of including all these genera, into a single all-encompassing Peronosporales s. lat. and not suggested new orders and families (Fig. 16, Table 1) to account for a probably paraphyletic Pythiaceae. However, we feel that the recognition of a broad Peronosporales might be preferable over the creation of several new ill-defined orders. At least one clade, that contains the unusual recently-described lagendiaceous mycopathogen of dogs, *Paralagenidium karlingi* (de Grooters et al. 2013), appears to be located between the Rhipidiales and Albuginales and will will probably need to be placed in its own Order and Family (Table 1).

Order Rhipidiales M.W. Dick.

The Rhipidiales consists of a single family, the Rhipidiaceae, containing a small number of saprotrophic genera (Table 1), which often grow on submerged twigs and fruits. Many have determinate, often segmented, thalli with only a few genera showing typical hyphal growth (e.g., *Sapromyces*, Fig. 2p). Some genera, such as *Rhipidium,* have thalli that are anchored to their substrate by rhizoid-like structures (Dick 2001; Sparrow 1960). They typically produce uni-oosporiate oogonia with a

well differentiated periplasm (Sparrow 1960). To date only *Sapromyces elongatus* has been sequenced (Table 1). The phylogenetic placement of this species in phylogenetic trees has proven difficult and varies depending upon the gene sequenced and which other taxa are included in the analyses. Riethmüller et al. (1999) and Petersen and Rosendahl (2000) inferred a position basal to the 'saprolegnian line' in their LSU rDNA analyses, whereas Hudspeth et al. (2000) report it to form the basal clade to 'peronosporalean line'. The COII amino acid sequence derived from from the *cox*2 gene, showed that *Sapromyces* has the same signature amino acid insertion-deletion (indel) sequence (LEF/T) to that found in members of the Peronosporales s.l., and not the YTD indel sequence found in members of the Leptomitaceae (Hudspeth et al. 2000, 2003; Cook et al. 2001). It is clear that much work still needs to be done to resolve the precise relationships between families and genera that appear at the base of both main classes.

Order Albuginales Thines

Traditionally, the white blister rusts, the Albuginales (Fig. 5), were placed together with the downy mildews in the Peronosporales (Beakes 1987; Dick 2001). They are obligate pathogens of angiospermae producing small stalked globose haustoria (Coffey 1975; Mims and Richardson 2002, Soylu et al. 2003). They form blister-like lesions on the leaves (Fig. 4f, i) below the host epidermis in which the basipetal chains of deciduous conidiosporangia are borne on club-shaped sporogenous hyphae (Fig. 4g, h; Heller and Thines 2009). Molecular phylogenetic studies revealed that the white blister rusts form a well supported clade basal to the Peronosporales s. lat. (Fig. 9b; Hudspeth et al.; 2003, Riethmüller et al. 2002; Thines et al. 2009c). This clade has been given its own order designation, the Albuginales (Thines and Spring 2005), containing just one family, the Albuginaceae (Table 1). Members of this family have exceptionally thick, multilayered oospore walls (Stevens 1901; Tewari and Skoropad 1977; Beakes 1981), the outer layers of which appear to be mainly derived from the periplasm. Recent molecular studies have also revealed an unsuspected genetic diversity within this order (Choi et al. 2007, 2008, 2011; Mizaee et al. 2013; Ploch et al. 2010; Ploch and Thines 2011; Rost and Thines 2012; Thines and Voglmayr 2009; Thines et al. 2009c; Voglmayr and Riethmüller 2006) and two new genera, *Pustula* and *Wilsoniana,* have been established based upon conidiosporangium and oospore characteristics (Thines and Spring 2005). These three genera appear to be restricted to specific host orders or subclasses (Thines and Voglmayr 2009). It is also expected that more comprehensive taxonomic re-arrangement of this family will be required as more species and isolates are sequenced.

Order Peronosporales E. Fisch. s. lat

The order Peronosporales s. lat. (Waterhouse 1973) contains a large number of often diverse taxa (Table 1), presently placed in three families, the Salispiliaceae, ~Pythiaceae s. lat. and Peronosporaceae s. lat. (Beakes et al. 2014a). This classification has to be considered provisional, as many lagenidiaceous species have not yet been included in published molecular phylogenies. Within the Peronsporales s. lat.

There have been many published molecular phylogenetic studies on the important plant pathogenic genera (*Pythium*: de Cock et al. 2012; Lévesque and de Cock 2004; *Phytophthora*: Blair et al. 2008; Cooke et al. 2000; Kroon et al. 2004; Martin et al. 2014) and various downy mildew genera (Göker et al. 2003, 2004, 2007; Thines et al. 2009a, b; Voglmayr 2003; Voglmayr et al. 2004). The saprotrophic genera have been less well documented, but there have been accounts of the molecular phylogeny of *Pythiogeton* (Huang et al. 2012), *Phytopythium* (de Cock et al. 2015) and *Halophytophthora* (Nakagiri 2002), but molecular data for the "lagenidiaceaous" holocparic genera is sparse and incomplete (Beakes et al. 2006; Schroeder et al. 2012).

The Salispiliaceae is single genus family which forms a well-supported early-diverging clade in the Peronsporales s. lat. based on concatenated ITS and LSU sequences (Hulvey et al. 2010). They are saprotrophs isolated from salt marshes, with ovoid sporangia and smooth walled oogonia and oospores. However, unpublished trees based on an analysis of 16 genes do not support a basal phylogenetic position of this genus within the Peronsporales s.lat. (see Table 1; Spies et al. 2014 and personal communication). The ~Pythiaceae s. lat. as we have defined it (Beakes et al. 2014a) encompasses more than a dozen genera, including a many of holocarpic genera that were traditionally placed in the Lagenidiales (Table 1, Fig. 9b). However, a recent unpublished multigene analysis of a significant number of isolates identified as *~Lagenidium*, *~Lagena*, *~Myzocytiopsis, Pythiogeton, ~Pythium* and *Salilagenidium* has revealed at least six clades that may ultimately justify family level designation (Spies et al. 2014, 2016, and unpublished trees - summarised in Table 1). There are still a number of Pythiaceous genera, such as *Medusoides* described by Voglmayr et al. (1999) and placed by Dick (2001) in his Pythiogetonaceae, for which no sequence data are publically available. *Lagenidium,* as currently recognised, is a particularly complex paraphyletic or polyphyletic genus, with isolates occuring in several different clades. However, until detailed phylogenies become available, we have retained all of these holocarpic species in a broadly defined ~Pythiaceae s. lat. (Table 1). The genus *Pythium* contains well over a hundred species, most of which have sequence data available (Bedard et al. 2006; Briard et al. 1995; Lévesque and de Cock 2004; Martin 2000; Schurko et al. 2004; Villa et al. 2006). Lévesque and de Cock (2004) recognised 8 clades (A-K) of *Pythium*, some of which are now assigned to new genera (Bala et al., 2010; de Cock et al. 2015; Usuhashi et al. 2010). However, as the relationships of these clades have not been fully resolved, most are subsumed under *Pythium* s. lat. in this review. Species which have simple more or less filamentous sporangia now constitute the genus *Pythium* s. str. (Usuhashi et al. 2010) although some genera, including the animal pathogen *P. insidiosum* cluster with *Pythiogeton* (Huang et al. 2012).

The Peronosporaceae s. lat. family (Table 1, Fig. 9b) includes not only the hyperdiverse downy mildews, but a number of genera that had been been previously included in the Pythiaceae (Dick 2001). These include the genus *Phytopythium* (syn. *Ovatosporangium*, Usuhashi et al. 2010; formerly known as the *Pythium* K-clade, Lévesque and de Cock 2004) described by Bala et al. (2010) and which has been recently monographed by de Cock et al. (2015). A recent multigene analysis also

suggests that two other of the new pythiaceous genera introduced by Usuhashi et al. (2010), *Elongisporangium* and *Globisporangium* might also fall in the Peronosporaceae s. lat. clade (Spies et al. 2014, 2016). The polyphyletic marine genus ~*Halophytophthora* (Ho and Jong 1990; Ho et al. 1992; Nakagiri 2002) contains around 15 species many of which, including the type species, fall into a clade that sits between the *Phytopythium* and the *Phytophthora*/downy mildew assemblage. ~*Halophytophthora* spp. have ovoid to elongate sporangia, often with conspicuous papillar plugs (Nakagiri 2002, Nakagiri et al. 1994) and most show a transient vesiculate discharge of their zoospores (Fig. 6l). All have single-oospored oogonia with paragynous antheridia (Nakagiri 2002, Nakagiri et al. 1994). *Phytophthora* clades are probably paraphyletic with the hyperdiverse downy mildews, which appeared to have evolved from a clade of shoot- and leaf-infecting *Phytophthora* spp. (Cooke et al. 2000, Runge et al. 2011). Most *Phytophthora* taxa (Fig. 4a–e) have sequence data available (Blair et al. 2008; Brouwer et al. 2012; Cooke et al. 2001; Förster et al. 2000; Kroon et al. 2004; Martin and Tooley 2003a, b; Runge et al. 2011; Villa et al. 2006) and fall into 8 to 10 clades (usually referred to as groups). The clades can be broadly separated into two main evolutionary lines, encompassing those species (groups 6–8; Cooke et al. 2000) with non-papillate sporangia (e.g., *Ph. cinnamomi*; Fig. 4c) which are predominantly soil borne root or woody trunk infecting pathogens and those (Groups 1–5; Cooke et al. 2000) which have papillate sporangia (e.g., *Ph. infestans*) that often infect aerial foliage. Traditional morphological characters such as the morphology of the male antheridium and whether species are homo or heterothallic are not good markers of phylogenetic relatedness (Blair et al. 2008; Brouwer et al. 2012; Cooke et al. 2000; Kroon et al. 2004; Runge et al. 2011). In a recent phylogenetic analysis based upon whole genomes, albeit of the very restricted number of five taxa, Seidl et al. (2012) concluded that the downy mildews (represented by *Hyaloperonospora*) were sister to the *Phytophthora* clade rather than embedded within it, with the nonpapillate/semipapillate *Ph. sojae* and *Ph. ramorum* species forming a clade that was sister to the papillate *Ph. infestans* as in the analysis of Runge et al. (2011). In a recent phylogenomic analysis Sharma et al. (2015a) inferred again a sister-group relationship for *Hyaloperonospora* and *Phytophthora*, but also found that *Plasmopara halstedii* was embedded within the latter, highlighting the need for a an expanded taxon samping in future phylogenomic analyses, as the current taxon sampling is probably too low to infer robust phylogenomic trees, despite the generally high to maximum-support observed in these analyses.

The downy mildews (Fig. 4q–v) are a diverse, monophyletic, group currently encompassing 20 genera (Table 1) that are obligate parasites, predominantly of dicotyledons (Göker et al. 2007; Thines et al., 2009a, Thines 2014). Because of their importance as biotrophic plant pathogens they have been extensively studied and sequenced for phylogenetic analyses (Table 1; Göker et al. 2003, Göker et al. 2007; Riethmüller et al. 2002; Sökücü and Thines 2014; Telle and Thines 2012; Telle et al. 2011; Thines et al. 2008, 2009a; Voglmayr 2003). Downy mildews typically produce deciduous conidiosporangia (Fig. 4s) are that born on persistent conidiosporangiophores (Fig. 4u, s, v), although these may be evanescent in the

graminicolous genera *Baobabopsis*, *Eraphthora*, *Peronosclerospora*, *Sclerophthora*, and *Sclerospora* (Fig. 4n–p; Thines 2006, 2009, Telle and Thines 2012, Thines et al. 2015b). *Peronospora* and *Pseudoperonospora* have pigmented conidia and consititute the most species-rich downy mildew clade (Table 1). Features such as haustorium morphology map well onto the molecular clades (Göker et al. 2007; Thines 2006; Voglmayr et al. 2004). Downy mildews with pyriform haustoria (DMPH) form a monophyletic lineage (Fig. 9). Digit-like (hyphal) haustoria (e.g., *Peronospora viciae*; Beakes et al. 1982; Hickey and Coffey 1977, 1978) probably represent the ancestral state and are similar to those formed in *Phytophthora* (Coffey and Wilson 1983). Molecular studies have confirmed that the graminicolous downy mildew (GDM; Fig. 4n–p) genera (*Baobabopsis*, Thines et al. 2015b; *Eraphthora*, Telle and Thines 2012; *Peronosclerospora,* Hudspeth et al. 2003; Shivas et al. 2012; *Sclerophthora,* Thines et al. 2008; *Sclerospora,* Riethmüller et al. 2003) are all related to other downy mildews in the Peronosporaceae sensu *lato.* Three monotypic GDM genera, *Graminivora*, *Poakatesthia* and *Viennotia* (Göker et al. 2003, Thines et al. 2006, Thines et al. 2007) appear to exhibit characteristics intermediate between *Phytopththora* and the downy mildews sensu stricto (Thines 2009).

Maintenance and Cultivation

Saprophytic or facultative parasitic species of Oomycota can be collected very easily from soil and water, and obligate hyperparasites are sometimes found at the same time. Useful sources of information on suitable methods for isolating and culturing aquatic fungi are given by Dick (2001), Fuller and Jaworski (1987), Johnson et al. (2002) and Sparrow (1960). Obligate parasitic downy mildews and white blister rusts must be sought on their known angiosperm hosts, but the less host-specific root parasites can be isolated using various plating and baiting techniques. Reference should be made to papers cited in Karling (1981) for information on the collection of the less-known species of Oomycota. A useful source of information for collecting and maintaining hemibiotrophic species is found in Erwin and Ribeiro (1998).

Typically many species of Saprolegniaceae and a variety of *Pythium* species can be isolated from samples of soil or exposed or submerged mud by placing suitable baits (e.g., 3 or 4 autoclaved hempseeds, sesame seeds, or snakeskin scales) added to sediment slurries diluted with sterile pond water (Dick 2001; Dick and Ali-Shtayeh 1986; Fuller and Jaworski 1987; Sparrow 1960). These dishes should be left undisturbed for 1–3 days at 10°–20 °C. The baits should then be transferred to clean dishes of water and incubated at 10°–20 °C for a further 4–14 days. A wide range (about 40 species) of *Pythium* species has been isolated from soil using a dilution plate procedure (Al-Shtayeh et al. 1986; Dick and Al-Shtayeh 1986). Several species of *Phytophthora* can be isolated by dilution plate techniques using P_{10} PV hymexazol agar (for recipes see Erwin and Ribeiro 1998). Dilutions between 1:30 and 1:100 are recommended for infested soils. The same medium can be used for isolations from infected roots. Since *Mortierella* and *Pythium* are inhibited by hymexazol, the aliquots can be incorporated into the nutrient agar and the washing

stage outlined above is not needed. Incubation is at 25 °C and scanning of plates is carried out after 1–3 days of incubation. Baiting, e.g., with *Rhododendron* and other leaves is a common procedure to isolate leaf-infecting *Phytophthora* species.

For the collection of Rhipidiaceae, in situ baiting techniques are essential. A cage of plastic-coated wire mesh containing fruits (e.g., apples, oranges, tomatoes) is suspended just below the water surface or just above the bottom mud in shallow stagnant or slow-moving water for about 10 days. The fruit is then removed and the fungal pustules examined with a dissecting microscope. Filamentous oomycete saprophytes will also be found. Using selective keratin and chitin baits, species that may be parasites of nematodes and other invertebrates are often selectively isolated (Sally Glockling and Shigeki Inaba, personal communication).

A wide variety of agars is used for culturing these oomycetes, including ones based on glucose, peptone and yeast extract (GYP); glucose, soluble starch, and yeast extract; potato dextrose; potatos and carrots; V8-juice; cornmeal, and others. Agars incorporating up to 10 mg/1 of cholesterol are also used: the carrier for the sterol may be chloroform, ether, or a 1% v/v aqueous solution of Tween 80. Axenic cultures are usually achieved by using several cleansing steps, such as by growing through a Raper's ring. For more details, the reader is referred to Fuller and Jaworski (1987) and Tsoa (1970). Members of the Saprolegniaceae are often stored on infested hemp seeds in distilled water, or on infested hempseeds placed on sterilized dampened filter paper in sterile bottles (Clark and Dick 1974).

Obligate biotrophic species, like the downy mildews and the white blister rusts have so far not been grown on artificial media. There is an account of axenic cultures of graminicolous downy mildews (*Sclerophthora* and *Sclerospora*, cited in Thines 2009), which could apparently not be successfully repeated so far. Other downy mildews and white blister rusts can be maintained in the laboratory by using infected leaves to inoculate detached uninfected leaves or leaf disks of the host species with the spores from the former (e.g., by stamping onto moist leaves or spraying). After inoculation, leaves should be kept dark for 24 hours at moderate temperatures. After that, the inoculated leaves or leaf discs should be kept at 100% relative humidity and at moderate temperatures (10–20 °C depending upon the species) and light quality as close as possible to those encountered under natural field conditions and a regular day-night photoperiod cycle. White blister rusts usually have to be cultivated on whole plants and most do not tolerate high humidity during sporulation.

Evolutionary History

The Straminipila form a well-supported monophyletic clade that is sister to the alveolates (Keeling et al. 2005) within the larger SAR superkingdom (Burki et al. 2007, 2008; Burki and Keeling 2014). In analyses using multiple protein-encoding genes the Oomycota and Hyphochytiomycota appear to form a sister clade to the brown-pigmented photosynthetic algae, the Ochrophyta (Cavalier-Smith and Chao 2006; Rilsberg et al. 2009; Tsui et al. 2006). Together this monophyletic assemblage was sister to a second major heterokont clade which encompasses the fungal-like

Thraustochytrids and Labyrinthulids and the bacteriotrophic bicoecid flagellates (Beakes et al. 2014; Yubuki et al. 2010). It has been estimated that the stem origin of the Ochrophyta was around 571 million years ago (mya) although with a large margin of error (Brown and Sorhannus 2010). The Oomycota and Hyphochytiomycota probably evolved after this, which is consistent with previous molecular clock estimates had suggested the origins of the Oomycota lay somewhere between 524 and 1000 mya (Bhattacharya et al. 2009). Recent molecular clock analyses by Matari and Blair (2014) proposes that the modern pathogenic oomycetes originated around the mid-Paleozoic, approximately 430–400 mya, although they did not include data from any early diverging genera in their analyses.

From earlier single gene analyses, the marine flagellate genus *Developayella* forms the sister clade to the Oomycota (Leipe et al. 1996: Tong 1995), although they have apparently little in common. When Sekimoto (2008) included the 18S sequences derived from assorted unknown stramenopiles from diverse marine ecosytems (Diéz et al. 2001; Massana and Pedró-Alió 2008; Massana et al. 2002, 2004, 2006) in his phylogenetic analyses the heterokont tree topography was markedly altered. An unknown stramenopile clade (lineage 3), consisting of a dozen or so rather deeply branched sequences, formed the sister clade to the Oomycota, although with little statistical support. *Developayella*, clustered in a clade with the flagellate parasitoid *Pirsonia* and the Hyphochytridiomycota and formed the immediate sister clade to the Ochrophyta rather than the oomycetes. Molecular studies have also revealed that most early diverging genera are marine and many are parasites of seaweeds or marine crustaceans (Beakes and Sekimoto 2009; Beakes et al. 2011). This, together with the fact that most of their closest relatives are also marine (Tsui et al. 2006), supports the current view, contrary to that of Dick (2001), that the Oomycota are marine in origin, as saprotrophs or facultative pathogens (Beakes and Sekimoto 2009; Beakes et al. 2012, 2014a).

Molecular studies have confirmed that the Oomycota are monophyletic and have provided a sound framework for hypothesising likely evolutionary pathways within the phylum. A simplified scheme is presented in Fig. 9a. This shows that the evolutionary scheme originally proposed by Bessey (1942), in which the holocarpic Olpidiopsidaceae were evolving prior to the split of the Saprolegniaceae and Peronsporaceae, was remarkably perceptive. We now know that the earliest-diverging clades contain predominantly small, non-mycelial, holocarpic oomycete genera (Beakes et al. 2014a; Karling 1981; Sparrow 1960), none of which have been successfully cultured on artificial media. This suggests this was the likely thallus form of the ancestral Oomycota. Genera in the Haliphthorales, Atkinsiellales s.lat. (*Atkinsiella, Lagenisma*), Leptomitales s.lat. (*Apodachlya, Blastulidium, Chlamydomyzium, Leptomitus*) and Rhipidiales (*Araiospora, Rhipidium, Sapromyces*) all produce extensive, bulbous or constricted thalli (Beakes et al. 2014a), which appears to be the intermediate stage in the evolution of a more-typical branched mycelial thallus that may have occurred about the time, or shortly after, of the Saprolegniomycete-Peronosporomycete divergence. It may have been the development of long, apically extending, hyphal-like discharge tubes in genera such as *Haliphthoros* (Fig. 5j) and *Atkinsiella* that led to the hyphal thallus form, at least in the Saprolegniomycete clade.

Analysis of the host preferences in basal Oomycota also raises the possibility that these organisms might have migrated from the sea to the terrestrial/freshwater environment with their invertebrate or algal hosts. Once on land they may have switched to plant hosts, as evidenced by the morphological similiarity between nematode-infecting species of the genus *Myzocytiopsis*. (Glockling and Beakes 2006a) and the closely related (Spies, personal communication) root-infecting genus *Lagena* (Barr and Désaulniers 1987, 1990). However, it should also be borne in mind that as long as the oomycete communities in marine and estuarian detritus remain largely unexplored (Nigrelli and Thines 2013; Marano et al. 2016), other evolutionary scenarios, such as the multiple independent development of a parasitic lifestyle from saprophytic genera cannot be ruled out. The same is also true for the likelihood of the repeated transition of oomycetes from land to the sea and vice versa (Richards et al. 2012), which has occurred several times within the Peronosporomycetes (Marano et al. 2016; Thines 2014). However, on balance it seems plausible that, at least initially, oomycetes evolved in the sea from holocarpic nutritionally-versatile organisms, many of which were facultative parasites of either invertebrates and or algae.

With the possible exception of the freshwater *Olipidiopsis* spp. (Martin and Miller 1986c), all basal genera lack oogamous sexual reproduction. However, recently a sexual cycle involving conjugation of adjacent cysts or thalli has been reported in *Eurychasma,* although only on some hosts (Gachon et al. 2015), and also occurs in *Anisolpidium ectocarpi* (Johnson 1957), a species now known to be a basal oomycote (Gachon et al. 2015). The recent finding that *Lagenisma*, which also reproduces by means of conjugating meiocysts (Schnepf et al. 1977, 1978a), is a basal Saprolegniomycete (Thines et al. 2015b), could mean that oogenesis may have evolved independently in the two classes of Oomycota. This may also explain the fundamentally different morphological patterns of oosphere formation in the two classes.

A critical evaluation of the fossil evidence for ancient terrestrial oomycetes is given in a recent review by Krings et al. (2011). Stidd and Consentino (1975) describe structures that they suggested represented *Albugo* oospores in the megagametophyte seed tissue of an ancient gymnosperm, *Nucellangium glabrum,* from around 310 mya. However the structures that were described were not conclusively *Albugo* oospores (Krings et al. 2011). A more convincing, though still controversial, *Albugo*-like microfossil appears to be *Hassiella monosperma* from the 412 mya lower Devonian Rhynie chert (Taylor et al. 2006). Structures purported to be small oogonia in *Hansiella* fossils look much more like the small globose haustoria that are typical of the genus *Albugo*. If this fossil is accepted as representing an obligately biotrophic *Albugo*-like pathogen of Rhyniophyte plants, it would mean that the evolution of obligate biotrophy can be traced back nearly 400 mya, which accords with recent molecular clock deductions (Matari and Blair 2014). Obligate symbiotrophy exemplified by the Albuginales, is therefore of ancient origin and must have evolved independently at least twice in the oomycete lineage (Kemen and Jones 2012; Kemen et al. 2011; Thines and Kamoun 2010). All extant white blister rusts are obligate parasites of angiosperms and the latter only diversified from a

common ancestor about 150 mya, even though they can probably be traced back into the Permian. This implies that the white blister rusts have evolved on hosts other than those we know them on today.

Another fossil genus, *Combresomyces*, with spiny papillate oogonia with paragynus antheridia, resembling current-day *Pythium* species, has been recently described associated with the remains of a 300 mya seed fern, *Lygniopteris* (Strullu-Derrien et al. 2010). *Galteriella biscalitheceae* associated with a sporangium of a fern *Biscallitheca,* also from around ca 300 mya, has *Phytophthora*-like amphigynous and paragynous smooth-walled oogonia. Papillate multi-oospored oogonia, reminscent of those found in some present day genera in the Saprolegniaceae have also been found in Rhynie chert deposits from the same time period (Krings et al. 2010). Therefore by the early Mesozoic era, about 300 mya, fossils showing the complete range of oogonium morphologies found in present day genera in the Albuginales, Peronosporales, and Saprolegniales have all been documented and implies that most of the known oomycete diversity had already evolved by then, likely with the exception of the hyperdiverse downy mildews.

The hyperdiverse obligate parasitic downy mildews are thought to have evolved relatively recent from an ancestor belonging to one of the more derived shoot- and foliage-infecting *Phytophthora* clades with papillate sporangia (for an in depth discussion see Runge et al. 2011) and represent the pinnacle of oomycete diversity. Thines (2009) has also discussed a number of traits (indeterminate sporangiosphore development, intracellular hyphal development) in rare graminicolous downy mildew genera, such as *Viennotia* and *Poakatesthia,* that are shared with *Phytophthora* and suggests these may represent relicts of the evolution of downy mildews from *Phytophthora*-like ancestors on Poales.

Finally there appear to be a number of interesting evolutionary parallels between Fungi and Oomycota (Sharma et al. 2015b). The two earliest-diverging oomycete genera *Eurychasma* and *Haptoglossa*, have endobiotic plasmodial thalli and injecting infection mechanism, respectively. These features are mirrored in the early diverging cryptomycete *Rozella* and by microsporidia, respectively (Jones et al. 2011; Lara et al. 2009). The clade (MAST-1) of unknown marine stramenopiles that are the closest to the oomycetes (Sekimoto 2008; Yubuki et al. 2010) may be analogous to the recently described cryptofungal clade that appears to be the sister clade to the Fungi (Jones et al. 2011). This highlights that many phylogenetically critical organisms still remain to be described and we still have little idea what sort of organisms make up unknown stramenopile clades. They are probably being sampled from their zoospores, and it seems possibly that many are parasitoids or parasites. In the future, the systematic application of both genomics and multigene molecular phylogenetic studies should help resolve many of the unresolved evolutionary questions both within oomycetes and to their closest relatives.

Acknowledgments We would like to acknowledge the contribution made by the many colleagues who work on Oomycota for their helpful advice, discussions and sharing of phylogenetic data and illustrative material. In particular we would like to thank Satoshi Sekimoto, Sally Glockling, André

Lévesque, Shigeke Inaba, Markus Göker, David Cooke, Nicholas Money, Claire Gachon, Deborah Huspeth, Young-Joon Choi, Hermann Voglmayr, Sabine Telle, Sebastian Ploch, late Ovidiu Constantinescu. Funding by the German Science Foundation, the Landesstiftung Baden-Württemberg (Elite Programm for Postdocs), the Max-Planck-Society and support by LOEWE in the framwork of IPF and BiK-F to M.T. are gratefully acknowledged.

Labyrinthulomycota

14

Reuel M. Bennett, D. Honda, Gordon W. Beakes, and Marco Thines

Abstract

The Straminipila are characterized by their anterior flagellum with tripartite hairs and form a well-supported monophyletic branch of the larger Straminipila/Alveolata/Rhizaria (SAR) superkingdom. This is an account of the molecular systematics and phylogeny of osmotrophic and phagotrophic lineages of the Straminipila, comprising the slime nets and their thraustochytrid allies, as well as some lesser known lineages. The phylum Labyrinthulomycota *s. lat.* contains two main clades, one of which approximates to holocarpic thraustochytrids and the other to the labyrinthulids and aplanochytrids. Together with the flagellate bicosoecids and the protermonads and opalinids, they form a monophyletic clade

that is sister to the golden-brown algae and Oomycota. The systematics of the Labyrinthulomycota *s. lat.* is still in flux as recent studies employing environmental barcoding have revealed the presence of diverse lineages not branching within genera characterized in terms of their morphology. The current review deals primarily with the two major lineages of the Labyrinthulomycota *s. lat.* and discusses other lineages only briefly, due to the scarce knowledge about these organisms. Characteristics associated with zoosporogenesis and sexual reproduction are discussed in relation to other members of the Straminipila.

Summary classification of major lineages adapted from Tice et al. (2016). It should be noted that the higher level classification needs to be considered provisionally, as the deeper splits within Labyrinthulomycota are largely unresolved (Pan et al. 2017).

Introduction

General Characteristics

The osmotrophic fungus-like members of the kingdom Straminipila are characterized by absorptive nutrition and heterokont biflagellate zoospores. The term stramenopile was first introduced by Patterson (1989) in reference to the "straw hairs" (mastigonemes) that decorate the anterior flagella of this group of organisms (Fig. 1b, e). Dick (2001) pointed out this was an incorrect derivation of the Latin for "straw hair" and that the correct form should be straminipilous. However, Adl et al. (2005) favored the continued use of "stramenopile", the form of the name that is most widely used (Lévesque 2011). It is now apparent that the Straminipila have their evolutionary origins in the sea and that many of the fungal-like organisms seem to be ecologically important and widespread pathogens of algae, animals, and plants (Beakes et al. 2012, 2014; Thines 2014).

Apart from the posteriorly uniflagellate chytrids all of the zoosporic organisms traditionally studied by mycologists can now be placed in the still contentious Straminipila/Alveolate/Rhizaria (SAR) superclade (Burki et al. 2008; Hackett et al. 2007; Reeb et al. 2009).

This account reviews one of the smaller groups within this lineage, the Labyrinthulomycota (predominantly labyrinthulids and thraustochytrids), and updates the pre-molecular account of the group published in the first edition of the Handbook of Protoctista by Porter (1990). Most members of the Labyrinthulomycota are heterotrophic colorless or yellowish protists that absorb nutrients in an absorptive (osmotrophic) or phagotrophic manner. They typically feed saprotrophically (but parasites are known, e.g., Schärer et al. 2007) and are key players in the detrital food web, helping to break down often intractable plant and animal remains and making these substrates more accessible to grazing amoebae and ciliates (Raghukumar 2002; Bongiorni 2012). Many thraustochytrids can also feed phagotrophically (Raghukumar 1992), and some genera such as *Aurantiochytrium* (Fig. 2d) and *Ulkenia* (Fig. 4) have a free-living amoeboid stage. The Labyrinthulomycota are often referred to as "slime nets," which relates to the feature shown by many of the crown genera, the formation of a network of fine, often branching and anastomosing, cytoplasmic threads (Figs. 1c, 2c, and 3a, b, d) that extend into the

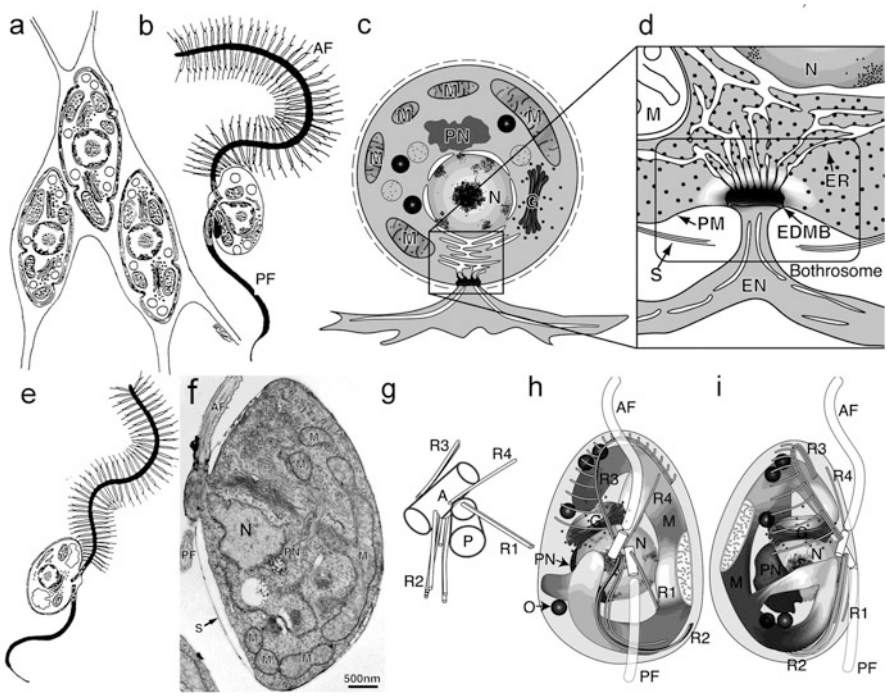

Fig. 1 Morphological features of labyrinthulids and thraustochytrids, part 1. environment from the cell bodies and originating from a unique structure, now generally called the bothrosome (Figs. 1d and 2g, j; Porter 1990; Beakes et al. 2014). These threads provide adhesion to the substrate and absorb nutrients (as in

thraustochytrids) or form trackways along which the cell bodies glide (as in the labyrinthulids; Figs. 1a and 2h, i).

The group also includes a number of unicellular colorless protist genera such as *Amphifila*, *Amphitrema* (Fig. 3e), *Archerella* (Fig. 3f), *Diplophrys* (Fig. 3a–c), and *Sorodiplophrys* (Fig. 3d) that produce fine rhizopodia-like structures (Anderson and Cavalier-Smith 2012; Gomaa et al. 2013; Takahashi et al. 2014). Some such as *Ulkenia* and related genera also have an amoeboid phase (Fig. 2d) in their life cycle (Beakes et al. 2014; Karling 1981; Porter 1990; Yokoyama et al. 2007).

The unusual set of characteristics associated with the Labyrinthulomycota has hampered their taxonomic assignment. As summarized recently (Beakes et al. 2014), labyrinthulids have been assigned to various unrelated groups, such as the Rhizopoda, Mycota, Amoebozoa, and different phyla of the Straminipila, such as Chrysophyta and Oomycota. Based on phylogenetic evidence, as summarized by Gomaa et al. (2013; Fig. 5), the labyrinthulids do not belong to any of these groups and are probably best treated as an independent phylum in the Straminipila, the Labyrinthulomycota, as proposed by Porter (1990).

The recent application of molecular phylogenetic techniques including extensive environmental sampling and sequencing of DNA has, similar to the fungi of the kingdom Mycota (Jones et al. 2011), revealed many, as yet mostly undescribed, and often probably uncultivatable, representatives of this group in diverse marine, freshwater, and terrestrial environments (Collado-Mercado et al. 2010; Diéz et al. 2001; Massana et al. 2002, 2006; Massana and Pedró-Alió 2008; Pan et al. 2017; Richards et al. 2012; Stoeck et al. 2003, 2006, 2007). This methodology has also revealed that several protist genera of previously unclear taxonomic affinity, such as *Amphitrema* and *Archerella*, which were formerly placed together with the filose testate amoebae, also belong in the Labyrinthulomycota (Gomaa et al. 2013; Pan et al. 2017; Tice et al. 2016).

Because of this phylogenetic uncertainty, as with many other protist groups, names in the Labyrinthulomycota have been published both according to zoological (ICZN) and botanical (ICBN/ICNfap) nomenclature. The majority of species within the traditional Labyrinthulomycota have been described by mycologists under the botanical code for nomenclature, whilst many recent changes were suggested under the code for zoological nomenclature and where possible both sets of nomenclature are given in this chapter.

Occurrence

The Labyrinthulomycota appear to be cosmopolitan and were considered to be saprotrophic or only weakly parasitic organisms, ubiquitous in marine and estuarine environments. The morphologically described part of the Labyrinthulomycota consists of a relatively small group of almost exclusively marine genera (Figs. 1b and 3) that typically feed saprotrophically and are an important part of the marine detrital food web (Raghukumar 2002; Bongiorni 2012). However, many thraustochytrids feed bacteriotropically (Raghukumar 2002), and some genera such as

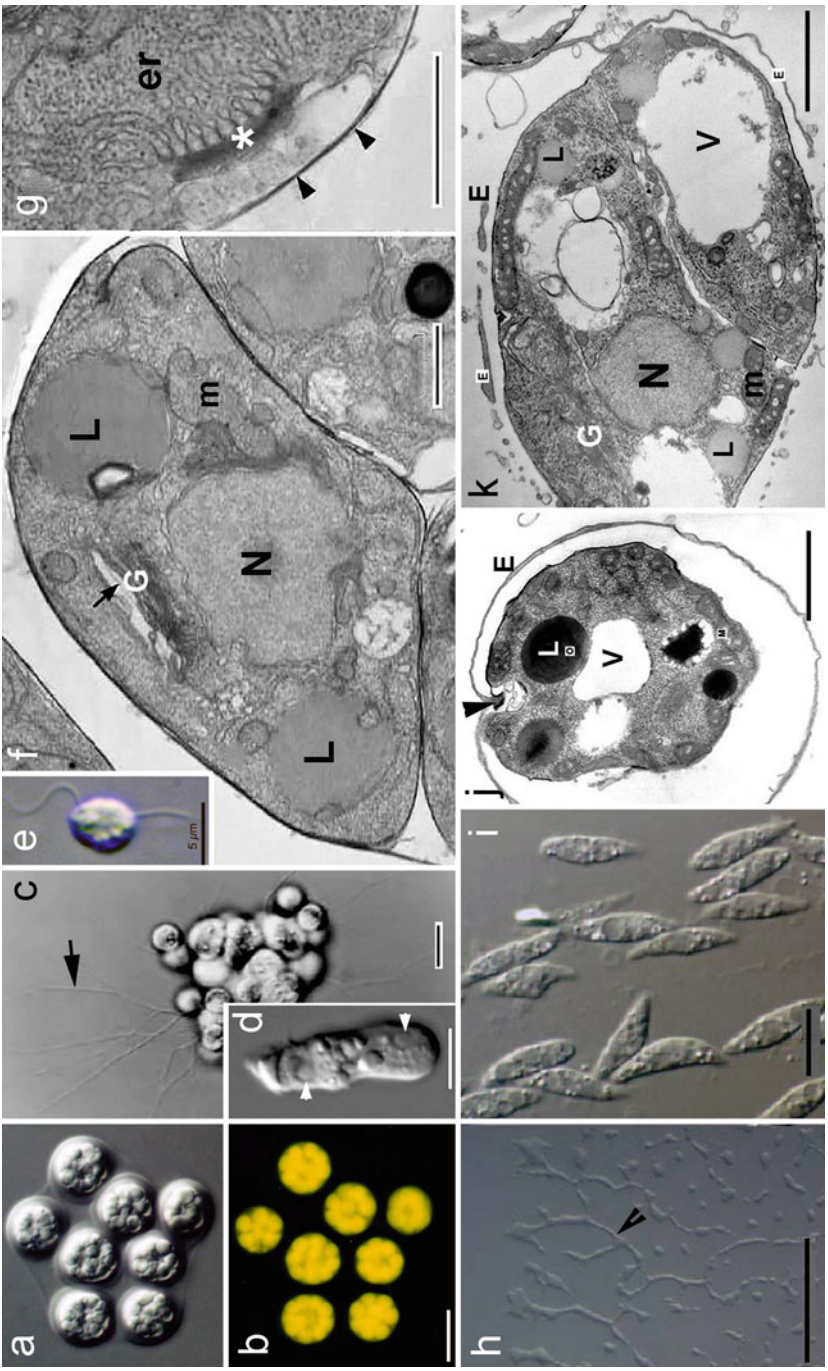

Fig. 2 (continued)

Ulkenia (Figs. 2 and 3h–j) have amoeboid stages engulfing their food. Thraustochytrids can be recovered in large numbers from marine sediments (Bongiorni 2012), including the deep sea (Raghukumar et al. 2001). Labyrinthulids are prevalent living on or within seaweeds and sea grasses, and there is an increasing evidence that they can live as parasites, commensals, or mutualists in plants (Bigelow et al. 2005; Bockelmann et al. 2012) and in other organisms, such as amoebae (Dykova et al. 2008) and mollusk tissues (e.g., Azevedo and Corral 1997).

However, most frequently they have been found associated with the surfaces of benthic algae, marine vascular plants, and detrital sediments (Porter 1990; Raghukumar 2002). Some, such as genus *Althornia*, are part of the free-floating eukaryotic plankton, and many others have been isolated from the marine water column (e.g., Collado-Mercado et al. 2010; Porter 1990), often in association with particulate "marine snow" (Naganuma et al. 2006; Raghukumar et al. 2001; Damare and Raghukumar 2008). Until the turn of the last millennium, the Labyrinthulomycota were considered to be exclusively marine organisms (Porter 1990), but about a decade ago, *Labyrinthula terrestris* has been described as a pathogen associated with turfgrass decline (Bigelow et al. 2005), and molecular studies have revealed an increasingly large number of freshwater members of this phylum (Anderson and Cavalier-Smith 2012; Gomaa et al. 2013; Richards et al. 2012). For instance, the testate protist genera *Archerella* and *Amphitrema* are common components of *Sphagnum* peatland, where they are often made visible by the endosymbiotic Trebouxiophyte algae (Fig. 3e, f) they contain (Gomaa et al. 2013). Many environmental sequences belonging to this clade have been isolated from anoxic sediments, which again suggests the habitats and roles occupied by these organisms is far more diverse than originally thought (Gomaa et al. 2013). Some members of the Labyrinthulomycota are genuine parasites which can have detrimental

environmental impacts (such as on seagrass beds) and cause diseases of economical and ecological importance (Hatai 2012).

Literature and History of Knowledge

Because they are a small group, there are no dedicated taxonomic monographs on the Labyrinthulomycota, although illustrations of the main thraustochytrid taxa were included in the monograph of simple holocarpic biflagellate fungal-like organisms by Karling (1981). They are also included in the major systematic review of straminipilous fungi by Dick (2001). *Labyrinthula* was first observed by Cienkowski (1867) associated with intertidal algae in the Black Sea. The genus *Thraustochytrium* was first observed by Sparrow (1936), who described *T. proliferum* associated with benthic algae from Woods Hole, Massachusetts, and later monographed zoosporic fungi from various habitats (Sparrow 1960, 1973, 1976). Thraustochytrids were initially included in the oomycetes until the mid-1970s, when ultrastructural investigations revealed significant differences with between them and other biflagellate "zoosporic fungi" of the oomycetes (reviewed by Beakes et al. 2014; Perkins 1976; Moss 1985, 1986; Porter 1990). Physiological aspects of the thraustochytrids were reviewed by Goldstein (1973) and again showed important differences with other biflagellate "fungi." The next significant advances in knowledge came with the advent of molecular systematics. Molecular phylogeny confirmed that labyrinthulids and thraustochytrids were part of the straminipilous lineage as suggested by their ultrastructure (Patterson 1989), although the precise branching order of the various straminipilous clades remained poorly resolved (Leipe et al. 1994). It was not until the advent of multigene analyses based on conserved protein genes that there was a clearer understanding of how the main lineages were related (Tsui et al. 2009; Tsui and Vrijmoed 2012 – see later sections). Only recently have environmental sequencing projects greatly expanded the knowledge on the diversity, habitats, and distribution of Labyrinthulomycota s.lat., as outlined by Pan et al. (2017) (Fig. 5).

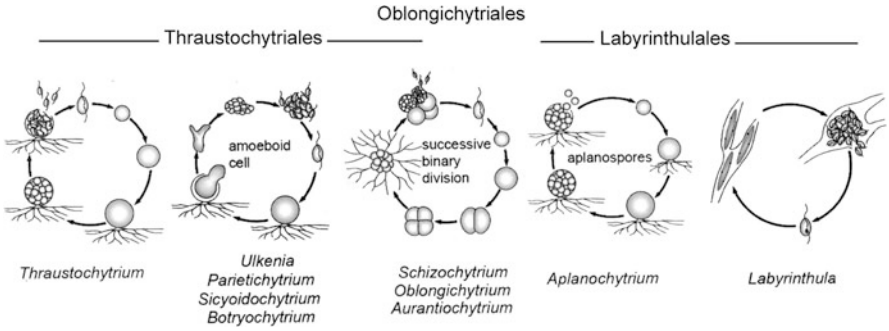

Fig. 4 Life cycles. Schematic drawings summarizing the variations in the life cycles of various thraustochytrid and labyrinthulid species (Adapted from http://syst.bio.konan-u.ac.jp/labybase/index_en.html)

Practical Importance

Thraustochytrids (Figs. 2a–g and 4) play important roles in nutrient cycling in marine ecosystems such as mangroves (Porter 1990; Raghukumar 2002), the open ocean, and sediments (Bongiorni 2012; Collado-Marcado et al. 2010; Kimura et al. 2001; Raghukumar et al. 2001). Although usually present in relatively low cell numbers, because of their large cell size compared with bacterioplankton, they nevertheless still make a significant contribution to the overall biomass of the oceans and probably play a significant role in the "microbial loop" by packaging and recycling nutrients in various communities of marine organisms (Raghukumar and Damare 2011).

Many labyrinthulomycetes (Fig. 2h–k) are parasites that can have a major impact on marine ecosystems or individual species. Muehlstein and Porter (1991) identified a new pathogenic species, *Labyrinthula zosterae,* as the causal agent of the eelgrass (*Zostera marina*) wasting disease. This disease of eelgrass first appeared in the 1930s and was responsible for the destruction of most of the vast subtidal stands of this vascular plant along the Atlantic coasts of North America and Northern Europe. Since larval stages of shellfish, such as oysters, scallops, and shrimp, all depend on eelgrass as a nursery bed, the loss of these stands has also detrimental effects on other ecosystems and the seafood industry. Since the discovery of *Labyrinthula zosterae* as a pathogen causing eelgrass disease, also the endophytic presence of *Labyrinthula* species in eelgrass has been documented, suggesting that various environmental factors might determine the virulence of *Labyrinthula* species (Bockelmann et al. 2012). However, also in terrestrial ecosystems, labyrinthulomycetes might play important, yet mostly unexplored, roles, as evidenced by the species *Labyrinthula terrestris*, the causal agent of a dieback disease of over-irrigated turfgrasses (Bigelow et al. 2005; Craven et al. 2005; Olsen 2007; Douhan et al. 2009) such as those found on coastal golf links and older reports of labyrinthulomycetes in inland habitats with high salinity (Amon 1978).

This tree also shows relationship of Labyrinthulomycota and other heterokont

Thraustochytrid infections can cause serious economic losses to commercially reared shellfish. The most well-studied examples include the so-called "QPX thraustochytrid parasite" of the northern Quahog clam (Azevedo and Corral 1997; Lyons et al. 2005, 2007; Garcia-Vedrenne et al. 2013) and *Aplanochytrium haliotidis* infecting abalone (Bower 1987a, b; Bower et al. 1989). Other thraustochytrid species have also been shown to cause mass mortality amongst marine animals such as the nudibranch, *Tritonia diomedea* (McLean and Porter 1987), and cephalopods such as the lesser octopus, *Eledone cirrhosa* (Polglase 1980), and a squid, *Illex illecebrosus* (Jones and O'Dor 1983).

There has been much interest in exploiting marine thraustochytrids for a wide range of products they synthesize (particularly lipids; Fig. 2b), including the production of biodiesel, long-chain omega-3 fatty acids, and exopolysaccharides (Chang et al. 2012). In particular it is hope to culture them as an alternative to fish as a source of polyunsaturated fatty acids (PUFAs), such as docosahexaenoic acid (DHA), which are important dietary supplements for both animals (Miller et al. 2007) and humans (Kabayashi et al. 2011; Ragukumar 2008). Recently genetic manipulation has been used to improve fatty acid production in thraustochytrids (Kobayashi et al. 2011), and this work has been the main driving force behind sequencing the genome of *Aurantiochytrium* (Liu et al. 2016). Currently, *Schizochytrium* species are used for the commercial production of DHA (Winwood 2013). Squalene, a compound reported to reduce the incidence of coronary heart disease and cancer, accumulates in the thraustochytrid *Aurantiochytrium mangrovei* grown in the presence of the terbinafine (Fan et al. 2010).

Habitats and Ecology

Methodology for Detection and Enumeration Labyrinthulomycetes in the natural marine environment, including the water column, have been documented using various methods. Culture-based methods for determining and quantifying the prevalence of thraustochytrids in nature, using serial dilution and pine-pollen baiting, were pioneered by Gaertner (1968). The direct observation epifluorescence technique described by Raghukumar and Schaumann (1993) is another quantitative method that was considered to be a more sensitive and direct method for detecting and enumerating labyrinthulomycetes. More recently the introduction of molecular techniques involving sequencing of extracted environmental DNA and developing labyrinthulomycete-specific molecular probes has further extended the places where these organisms have been recorded from (Pan et al. 2017). Until now, they have been found in such extreme environments as arctic, subarctic, and antarctic habitats

Fig. 5 (continued) members of the Straminipila. The tree was adapted from Gomaa et al. 2013. PLoS One 8(1) http://dx.doi.org/10.1371/ journal.pone.0053046 with permission. (Bahnweg and Sparrow 1974; Moro et al. 2003; Naganuma et al. 2006; Riemann and Schrage 1983; Stoeck et al. 2007), oceanic environments of the Indian Ocean (Damare and Raghukumar 2008, 2010), marine sediments (e.g., Bongiorni 2012), saline soils (Aschner 1958; Booth 1971; Bigelow et al. 2005), the deep sea (e.g., Amon 1978; Raghukumar et al. 2001), and shallow water hydrothermal vents (Colaco et al. 2006).

Environmental Tolerances of the Labyrinthulomycota Apparently, labyrinthulomycetes seem to have a wide range of tolerance to different salinity conditions. Some *Labyrinthula* isolates have been found associated with the roots and root hairs of trees in sandy soils irrigated with low salinity (4.3‰) water (Aschner 1958). Labyrinthulids have also been isolated from inland saline soils (Amon 1978). Many thraustochytrids (including isolates of the genera *Thraustochytrium*, *Schizochytriu*, and *Ulkenia*) have been isolated from habitats reflecting a wide range of salinities from weakly brackish waters (3‰) to briny salt evaporation ponds (150‰) indicating they may be thought of as euryhaline organisms (Jones and Harrison 1976). However, none of the species of thraustochytrids that Bahnweg (1979a, b) studied would grow in pure culture above a salinity of 40‰, and *Thraustochytrium pachyder um* appears to be one of the few species so far described that shows growth and zoospore formation at salinities up to 60‰ (Schneider 1981). There are also species and isolates found in habitats of more or less constant salinity and thus might actually be stenohaline.
The ability to withstand other extreme or fluctuating environmental or culture conditions has been reported amongst thraustochytrids (e.g., Banweg 1979a, b; Kuznetsov 1981) – some can apparently resist repeated cycles of drying and freezing (anabiosis). There are reports that thraustochytrids from both frozen arctic coastal soil samples and dried 50-year-old herbarium sheets of marine algae were successfully isolated and grown in culture (Kuznetsov 1981). Isolates of thraustochytrids also survived drying for several days (Jain et al. 2005) or even years (Kuznetsov 1981).

Habitats of Labyrinthulales Species of *Labyrinthula* are found in estuarine and near-shore marine habitats throughout the world associated with (or isolated from) organic detritus, macroalgae, diatoms, and particularly estuarine plants, such as mangroves and other marine vascular plants (Porter 1990). In hanging-drop or other laboratory cultures, the cells of *Labyrinthula* readily colonize a variety of vascular plant and algal tissues. They penetrate the cell walls and appear to decompose the cellular contents. In laboratory culture, labrinthulids are capable of decomposing many different microorganisms as a substrate, including bacteria, yeast, hyphal fungi, diatoms, filamentous algae, and other thraustochytrids (Perkins 1976; Porter 1990). Species of *Labyrinthula* are reliably isolated from submerged moribund or adrift leaves of marine vascular plants and pieces of filamentous or thalloid macroalgae. It has long been believed that healthy algae and marine grasses do not contain *Labyrinthula* cells within their tissues (Porter 1990), although these organisms can be regularly isolated from their tissues and Bockelmann et al. (2012)

reported their endophytic presence. However, *Labyrinthula* is usually not necrotrophic but rather feeds on epibiotic microorganisms and decomposing plant and algal material (Porter 1990). Based on current knowledge, the genus *Labyrinthula* is primarily associated with coastal environments. The genus *Stellarchytrium* associated with starfish has recently been described (FioRito et al. 2016) and represents a case in which an actual organism was found for a group otherwise only known from environmental sequencing, in this case, the LAB1/6/8 clade (Pan et al. 2017).

Habitats of Thraustochytriales Species of thraustochytrids (which includes species now classified in both the Thraustochytriaceae and Aplanochytriaceae) have also been isolated from estuarine and marine habitats throughout the world. Members of the thraustochytrids are able to grow in culture on a variety of plant- and animal-derived substrates (Perkins 1973). For instance, they have been observed growing on the spore cases of vesicular-arbuscular mycorrhizal fungi from barrier sand dunes (Koske 1981). They are generally isolated from decomposing algal and plant material, as well as from sediments, although they may also be found in plankton collected in offshore trails (Damare and Raghukumar 2010). In general, thraustochytrids seem to be mostly surface inhabitants of particulate organic material, primarily saprotrophic in their nutrition. In tropical and sub-tropical areas, mangrove plants (e.g., *Avicennia*, *Bruguiera*, *Kandelia*, and *Rhizophora*) are probably the most well-studied habitat in which to find labyrinthulomycetes (e.g., Fan and Chen 2006; Leaño 2001), where they appear to be primarily as saprobes colonizing the surface of organic detritus.

Thraustochytrids appear to be amongst the initial colonizers of fallen senescent mangrove leaves, alongside oomycetes (Thines 2014; Marano et al. 2016), and thus play an important role in nutrient cycling through exogenous production of their cellulase and xylanase degradation enzymes (Fan et al. 2002; Leaño 2001; Raghukumar 2002; Raghukumar et al. 1994). Thraustochytrids can be recovered in large numbers from marine sediments including from the deep sea (Bongiorni 2012). This group thereby contributes significantly to the biomass in the estuarine or marine environment.

In contrast to labyrinthulids, thraustochytrids appear to grow poorly on living algae and vascular plants. This has been primarily attributed to the presence of secondary metabolites with antimicrobial properties which limit the growth and propagation of these organisms (Raghukumar 2002). However, 7 days after leaf fall, thraustochytrids were found colonizing fallen leaves of *Rhizophora apiculata* (Raghukumar et al. 1995). Labyrinthulomycetes isolated from mangrove areas include *Schizochytrium* sp., *Thraustochytrium* sp., *Ulkenia* sp., and several unidentified strains of *Labyrinthula* sp. and *Aplanochytrium* sp. (Leaño 2001; Leander et al. 2004; Yokochi et al. 2001). The extensive colonization by thraustochytrid thalli on the surfaces of decomposing seaweeds has been noted (Miller and Jones 1983). Thraustochytrids, as epibionts, are probably feeding on other epibiotic microorganisms and decomposing plant and algal material. It is reported that the extent of colonization increased with the rate of decomposition; thus, they are probably saprotrophic followers of labyrinthulids, oomycetes, and

zoosporic fungi. Yokochi et al. (2001) reported not only *Labyrinthula* sp. as a saprobe on *Padina arborescens* and *Sargassum* sp. but also *Aplanochytrium* sp. on *Dictyota cervicornis*, *Chaetomorpha* sp., and *Cladophora* sp. (Leander et al. 2004). *Aplanochytrium minutum* and *Ulkenia visurgensis* were found associated with decaying *Sargassum cinereum* (Sathe-Pathak et al. 1993).

Some thraustochytrids may also be capable of necrotrophic/parasitoid growth on marine invertebrates, particularly mollusks such as nudibranchs (McLean and Porter 1987), squid (Jones and O'Dor 1983), and octopus (Polglase 1980). Thraustochytrids are also regular components of the gut microbiota of certain echinoids (Wagner-Merner et al. 1980) and have been found in a variety of Mediterranean sponges (Höhnk and Ulken 1979) and on the surface mucus of hermatypic corals (Harel et al. 2008). Thraustochytrids themselves may host viruses (Perkins 1976), e.g., herpes-type DNA virus particles (Kazama and Schornstein 1973). As herpes-type viruses are present in some vertebrates and invertebrates, (Segarra et al. 2010; Evans et al. 2017), this raises the possibility that thraustochytrids may be virus vectors for other organisms.

In spite of the many reports of thraustochytrids isolated from numerous substrates and locations, there have been surprisingly few direct observations of thraustochytrids in nature. *Schizochytrium*-like thalli were observed parasitizing colonies of the diatom *Thalassionema* collected from the North Sea (Gaertner 1979). Thraustochytrid-like thalli in Antarctic sediments fixed immediately after collection have been described (Riemann and Schrage 1983). Although diagnostic features were not presented, the thraustochytrids in these samples most closely resemble the genus *Aplanochytrium*.

Parasitic and Symbiotic Relationships Parasitism is another ecological strategy found in a few species of *Labyrinthula*. *Labyrinthula* spp. have been isolated from the marine algae *Chaetomorpha*, *Lyngbya*, *Cladophora*, *Rhizoclonium* (Raghukumar 1987a, b), and several marine vascular plants, such as *Cymodocea*, *Posidonia*, *Spartina*, *Thalassia*, and *Zostera* (Bockelmann et al. 2012; Garcias-Bonet et al. 2011; Stowell et al. 2005), although it is unlikely whether all these are parasitic associations. However, as mentioned previously, *Labyrinthula zosterae* has been identified as the cause of the wasting disease of eelgrasses (*Zostera capricorni*, and *Zostera marina*) resulting in the decline of eelgrass population (Armiger 1964; Muehlstein et al. 1988); and *Labyrinthula terrestris* has been identified as the cause of rapid blight on turfgrasses (Bigelow et al. 2005; Stowell et al. 2005; Craven et al. 2005; Olsen 2007). Garcias-Bonet et al. (2011) studied the occurrence and pathogenicity of *Labyrinthula* sp. in Mediterranean seagrass meadows. They found that their isolates could infect a number of different seagrass genera (*Posidonia, Cymodocea*, and *Zostera*) and indicates their isolate had a broader host range than found in most North American studies which indicated that pathogenicity was host genus-specific (Muehlstein et al. 1988; Short et al. 1993; Vergeer and den Hartog 1991, 1994). *Labyrinthuloides* (now classified as *Aplanochytrium*) *schizochytrops* was commonly isolated from living plants of the seagrass *Halodule wrightii* and was thought to be living as an endophyte, although may also have been responsible for a

brownish discoloration on the host leaves (Quick 1974). The *Schizochytrium*-like thalli parasitizing the diatom *Thalassionema* (Gaertner 1979) were later followed by additional reports of thraustochytrids as diatom pathogens. For example, *Ulkenia amoeboidea* was found capable of infecting a number of diatoms, including *Coscinodiscus* sp., *Grammatophora* sp., *Melosira* sp., *Navicula* sp., and *Nitzschia* sp. (Raghukumar 2006). However, it remains unclear if diatom parasitism constitutes a major ecological niche of Labyrinthulomycota and if these infections have a significant ecological impact.

Many marine invertebrates (e.g., corals, clams, flatworms, sea stars, and sea urchin) have been reported to harbor labyrinthulomycetes, and in some, this relationship may be parasitic, as with *Aplanochytrium haliotidis* on abalone (Bower 1987b) and the QPX thraustochytrid parasite on Quahog clam (Azevedo and Corral 1997; Lyons et al. 2005, 2007). The latter has been most extensively studied as an animal pathogen, and its genome has recently been sequenced in order to try and understand the basis of virulence (Garcia-Verdrenne et al. 2013). Recently a newly recognized species, *Thraustochytrium caudivorum*, was shown to parasitize the marine free-living flatworm *Macrostomum lignano* (Schärer et al. 2007), causing lesions that can lead to the dissolution of the posterior part or even complete animal. Three newly described Labyrinthulales species, *Stellarchytrium dubum*, *Oblongichytrium porteri*, and *Aplanochytrium blankum*, were isolated from dermal tissues of ochre sea stars (*Pisaster ochraceus*) that were exhibiting symptoms of starfish wasting disease (FioRito et al. 2016), although a direct causal relationship with the disease has yet to be established. Thraustochytrids are also capable of necrotrophic growth (perhaps parasitic) on marine invertebrates, particularly mollusks such as nudibranchs (McLean and Porter 1987), octopus (Polglase 1980), and squid (Jones and O'Dor 1983).

Other Labyrinthulomycota appear to have commensal relationships with their hosts such as *Labyrinthula* and *Oblongichytrium multirudimentale* on the coral *Fungia granulosa* (Kramarsky-Winter et al. 2006; Harel et al. 2008) or are saprobic such as *Aplanochytrium minuta* on scleractinian coral mucus (Raghukumar and Balasubramanian 1991). Thraustochytrids are regular components of the gut microbiota of certain echinoids (Wagner-Merner et al. 1980) and have been found in a variety of Mediterranean sponges (Höhnk and Ulken 1979), although details of these relationships are still unknown. Interestingly, thraustochytrids may host viruses (Perkins 1976), and herpes-type DNA virus particles have been described in a *Thraustochytrium* sp. (Kazama and Schornstein 1973). This is the only herpes-type virus to have been found in a host that is not a vertebrate and raises the possibility that thraustochytrids may be virus vectors for other organisms (Porter 1990). However, Labyrinthulomycota also carry RNA viruses of unknown host spectrum (Takao et al. 2005).

Freshwater and Terrestrial Labyrinthulomycota Until the advent of molecular systematics, it had been generally assumed that there were no genuinely freshwater or terrestrial members of the Labyrinthulomycota, although there were historic reports of *Labyrinthula* species infecting the freshwater alga *Vaucheria* (Zopf

1892). Recently it was shown that a number of phagotrophic freshwater protists (Fig. 3) such as the unicellular *Diplophrys parva* and *D. mutabilis* in the Thraustochytriales (Anderson and Cavalier-Smith 2012; Takahashi et al. 2014) and unicellular *Archella flavum* and *Amphitrema wrightianum* (Gomaa et al. 2013) and the sorocarpic *Sorodiplophrys stercorea* (Tice et al. 2016) in the Amphitremida all cluster in the Labyrinthulomycota clade. All of these heterotrophs are characterized by having fine filose pseudopodia. *Diplophrys parva* was isolated from the intestinal tract of a goldfish (Anderson and Cavalier-Smith 2012) and *D. mutabilis* from a freshwater lake (Takahashi et al. 2014), whereas *Archerella* and *Amphitrema* were both free-living protists isolated from wet Sphagnum moss (Gomaa et al. 2013). The coprophilic genus *Sorodiplophrys* was isolated from horse and cow dung (Tice et al. 2016). Environmental sampling has also revealed many more isolates belonging to the Amphitremida and Amphifilidae clades (Fig. 5), including isolates from various terrestrial soils, freshwater ecosystems, and anoxic sediments (Anderson and Cavalier-Smith 2012; Gomaa et al. 2013; Takahashi et al. 2014; Tice et al. 2016).

Characterization and Classification

Thallus (Cell) Morphology and Ultrastructure Members of the Labyrinthulaceae are characterized by forming colonies of spindle-shaped thalli (cells) that are ensheathed in a membranous ectoplasmic network which form a branched track system along which the cells freely migrate (Figs. 1a and 2h, i). Members of the Thraustochytriaceae on the other hand form ovoid or spherical thalli, which are associated with a fine ectoplasmic network of rhizoid (rhizopodia)-like threads (Fig. 3c–i) which act as anchoring and feeding structures (Perkins 1976; Bremer 1976; Moss 1985, 1986; Porter 1990). In terms of size and general appearance, this gives thraustochytrid thalli a superficial similarity to those of hyphochytrids and chytrid fungi (Karling 1981). The planktonic genus *Althornia* lacks rhizoids and absorbs nutrients directly from the environment (Karling 1981; Moss 1986; Porter 1990). The thalli of the Aplanochytridiaceae (now placed in the Labyrinthulales) superficially resemble thraustochytrids (Figs. 3g and 4) but are able to glide slowly along the surface of their ectoplasmic threads (Leander and Porter 2001). A number of previously enigmatic unicellular, sometimes colonial protists with fine-branching rhizopodia often arising bipolarly from the cells (Fig. 3a, b, d, f) have now been included in the Labyrinthulomycota, in a number of newly created families such as the Amphifilidae, Diplophryidae, and Sorodiplophryidae (Anderson and Cavalier-Smith 2012; Takahashi et al. 2014; Tice et al. 2016). In addition, the mixotrophic testate amoeba-like genera in the Amphitremidae, *Amphitrema, Archerella*, and *Paramphitrema* have cells protected in flask-shaped puncate shells (Fig. 3e, f) from which the rhizopodia emanate (Gomaa et al. 2013).

The Labyrinthulomycota have a typical straminipilous cytoplasmic ultrastructure with mitochondria with tubular-vesiculate cristae and prominent Golgi dictyosomes (Figs. 1f and 2f, g, j, k; Perkins 1976; Moss 1985, 1986; Porter 1990; Anderson and Cavalier-Smith 2012; Iwata et al. 2016). The cells usually contain cytoplasmic

vacuoles and oil globules (Figs. 1c and 2a, b, f, j, k). However, an ultrastructural feature that defines the Labyrinthulales and Thraustochytriales is that their ectoplasmic nets originate from the thallus body from a unique endomembrane complex associated with an electron-dense plaque on the plasma membrane (now known as the bothrosome – Figs. 1d and 2g) from which cisternae of endoplasmic reticulum radiate (Perkins 1976; Moss 1985, 1986; Porter 1990; Iwata et al. 2016). Previously this body has also been variously referred to as the sagenogenetosome (Perkins 1976) or sagenogen (Dykstra and Porter 1984). The early stages of the bothrosome complex development and net formation following zoospore settlement have recently been described in *Schizochytrium* by Iwata et al. (2016). This study has shown that the bothrosome forms within minutes of zoospore settlement at the anterior-ventral pole of the cell close to the Golgi body. Immunofluorescence labelling revealed that actin co-localized with newly formed bothrosome co-localized, and that within 18 min of settlement, the ectoplasmic net system had formed, with net filaments rich in actin (Iwata et al. 2016). The ectoplasmic net, unlike the rhizoid system of hyphochytrids and chytrids, is not walled (Figs. 1c, d, and 2j, k) and as well as containing actin, only contains cisternae of endomembrane (Moss 1985, 1986; Porter 1990; Takahashi et al. 2014). However, a classical bothrosome structure does not appear to be associated with slender rhizoids/filopodia of the unicellular protist-like members of the phylum in the Ampifilaceae (e.g., *Amphifila marina* – Dykstra and Porter 1984).

Another major difference between the thalli of the Labyrinthulomycota compared to other straminipilous fungi is that the thallus is surrounded by Golgi-derived ovoid, round or hexagonal scales (Fig. 3c; Perkins 1976; Moss 1985, 1986; Porter 1990) which are not cellulosic but composed of sulfated polysaccharides containing fucose or galactose (Bahnweg and Jäckle 1986; Honda et al. 1999; Moss 1985, 1986). In older thalli layers, scales can form a consolidated wall (Fig. 2f) around the thallus but do not coat the tracks or rhizoids (Perkins 1976; Dykstra and Porter 1984; Porter 1990). Surface scales are also a feature of the planktonic unicellular genus *Amphifila marina* (formerly *Diplophrys* – see Anderson and Cavalier-Smith 2012), which led Dykstra and Porter (1984) to suggest this enigmatic protist had Labyrinthulomycete affiliations. Cells of the freshwater heterotrophs *Diplophrys parva* (Anderson and Cavalier-Smith 2012) and *D. mutabilis* (Takahashi et al. 2014) are also coated in small Golgi-derived capsule-shaped or ovoid scales (Fig. 3c). In contrast, the cells of species in the Amphitremidae are contained in a thick rigid lightly pigmented shell (Fig. 3e, f; Gomaa et al. 2013).

Zoospore Formation and Fine Structure The ways in which these thalli differentiate into motile zoospores and proliferate have been the main defining characteristics (see Karling 1981) of the thraustochytrid genera (Fig. 4), although it now appears that this morphology is poorly correlated with underlying genetic relatedness (Yokohama and Honda 2007; Yokohama et al. 2007; Beakes et al. 2014). In some *Thraustochytrium* species, the whole thallus cytoplasm differentiates into biflagellate zoospores, which are released by the general splitting and disintegration of the thallus wall (Fig. 4; Karling 1981). In other *Thraustochytrium* spp., internal proliferation of

new thalli occurs from cytoplasm cleaved from the basal portion of thallus, concomitantly with the main compartment cleaving into zoospores (Karling 1981; Beakes et al. 2014). Development of the thallus in the genus *Aplanochytrium* is similar except that only non-motile aplanospores are formed (Fig. 4). The genus *Schizochytrium* has thalli which divide by successive bipartitions to form progressively smaller units (Figs. 2c and 4), in which the zoospores ultimately differentiate (Karling 1981). Several genera (*Botryochytrium*, *Parietichytrium*, *Sicyoidochytrium*, and *Ulkenia* – Fig. 4) in the Thraustochytriales have a more complex life cycle in which a free-living amoeboid cell (Figs. 2d and 4) is released from the original parental thallus and which then settles and eventually differentiates into zoospores (Beakes et al. 2014).

Straminipilous zoospores range in size between 3 and 15 μm (Dick 2001) and, as in the Labyrinthulomycota, many are reniform with laterally inserted flagella (Figs. 1b, e, f, and 2e). The straminipilous zoospore has a remarkably conserved overall organization and structure supporting the origin of this clade from a common flagellate ancestor (Tsui et al. 2009; Beakes et al. 2014). The anterior flagellum in all members of the Straminipila is decorated with two parallel rows of tripartite tubular hairs (TTH) and usually four to five times the overall zoospore body length (Fig. 1b, e; Perkins 1976; Porter 1990). The TTH are made of proteins and serve to reverse the flagellum thrust, in effect pulling straminipilous zoospores through the water (Dick 2001). Thraustochytrid, but not labyrinthulid, zoospores are unusual in that the zoospore body is also coated in small scales (Fig. 1e, f; Perkins 1976; Kazama 1980; Porter 1990).

All straminipilous flagellate cells share the same underlying flagellar rootlet system (Fig. 1g–i) which shows a remarkable degree of conservation throughout the lineage (Barr and Désaulniers 1989; Andersen et al. 1991; Dick 2001; Iwata et al. 2016). Zoospores of biflagellate members of the Straminipila have four rootlets, two associated with each flagellum (Andersen et al. 1991; Barr and Allan 1985; Barr and Désaulniers 1987; Iwata et al. 2016). The R3 anterior rootlet is composed of three microtubules, and curves around the anterior end of the zoospore and from which on one side emanate a series of microtubular ribs (Fig. 1h, i; Beakes et al. 2014; Iwata et al. 2016). Labyrinthulomycete zoospores appear to lack the striated fan between the kinetosomes that are a feature of oomycete zoospores (Fig. 1g; Barr 1981; Barr and Allan 1985; Porter 1990; Iwata et al. 2016). Unusually for members of the Straminipila, the Labyrinthulomycota do not have a typical transitional helix (TH) structure associated above the flagellar plate but do have a similarly placed cone-like structure and electron-dense plug (Barr and Allan 1985; Beakes et al. 2014; Cavalier-Smith and Chao 2006). Nuclear division has been investigated by Perkins (1970) and Kazama (1974) and shows similarity to other members of the Straminipila (Beakes et al. 2014).

Sexual Cycle Most members of the Straminipila appear to be diploid organisms that undergo gametic meiosis (Dick 2001; Sims et al. 2006). However, knowledge of the precise timing of meiosis and plasmogamy in the Labyrinthulomycota is still very uncertain (Porter 1990; Beakes et al. 2014). In labyrinthulids, evidence of meiosis

has been found in thalli dividing up to produce flagellate zoospores (Perkins and Amon 1969; Porter 1990), but precisely where syngamy takes place has still not been established. However, epibiotic resting spores are produced by some species of thraustochytrids, although it has not been established if these are the result of sexual reproduction (Karling 1981; Porter 1990).

Classification and Systematics

Even though investigations of the past three decades have revealed new species, cytological details, and development cycles, the complete life cycle of any species of *Labyrinthula* remains to be worked out (Porter 1990; Beakes et al. 2014). However, it has now been established that Labyrinthulomycetes together with the human pathogen *Blastocystis* and the ciliate-like opalinids formed one major, early diverging branch of the Straminipila and that the Hyphochytriomycota, Oomycota, and golden-brown photosynthetic Ochrophyta formed another separate lineage, although both share a common ancestor (Fig. 5).

Prior the era of molecular systematics, the Labyrinthulomycota were divided into two families, the Labyrinthulaceae and the Thraustochytriaceae (Karling 1981; Porter 1990; Dick 2001) within a single order, the Labyrinthulales (or Labyrinthulida). The Labyrinthulaceae contained a single genus, *Labyrinthula* whereas the Thraustochytriaceae had around a dozen genera, mainly defined by thallus morphology and differentiation (Perkins 1976; Karling 1981; Moss 1985; Porter 1990; Dick 2001). The first in-depth molecular systematic study of the group was carried out by Honda et al. (1999) based on SSU rRNA gene sequence comparisons. Their isolates fell into two major clades, which they named the "labyrinthulid phylogenetic group" (LPG) and the "thraustochytrid phylogenetic group" (TPG) (Honda et al. 1999). The LPG clade included *Labyrinthula* and *Aplanochytrium* (syn. *Labyrinthuloides*) in one subclade and *Schizochytrium minutum* and *Thraustochytrium multirudimentale* in another. The TPG clade contained genera such as *Schizochytrium*, *Ulkenia*, as well as many *Thraustochytrium* spp. (Honda et al. 1999). Rather than the straightforward separation of the labyrinthulids and thraustochytrids, these studies revealed for the first time that the labyrinthulids in particular were part of a more diverse monophyletic assemblage that included a number of species that had traditionally been considered to be thraustochytrids. However, the LPG and TPG clades correlated well with the sugar composition of their thallus walls (Honda et al. 1999), with genera in the LPG clade predominantly having fucose and those in the TPG clade having galactose as their major cell wall constituents (Honda et al. 1999). A concurrent study by Leander and Porter (2001) however, suggested there were three major clades within the Labyrinthulomycota. There was an additional clade that included two *Labyrinthuloides* species, *L. yorkensis*, and *L. minuta.* These were subsequently transferred to the genus *Aplanochytrium* in a new family, the Aplanochytriaceae/Aplanochytriidae (Anderson and Cavalier-Smith 2012; Leander et al. 2004), which was sister to the Labyrinthulaceae.

The third clade represented the residual Thraustochytriaceae, containing many of the traditional thraustochytrid genera together with the enigmatic, bothrosome-lacking, planktonic protist *Diplophrys* (now *Amphifila*) *marina* and two isolates of the Quahog clam pathogen (so-called QPX isolates). What these molecular studies also highlighted was that many of the traditional thraustochytrid genera, such as *Schizochytrium, Thraustochytrium*, and *Ulkenia,* which were based on patterns of thallus development, were paraphyletic or polyphyletic (Honda et al. 1999; Leander and Porter 2001; Leander et al. 2004) showing that traditional morphological characters were not good indicators of genetic relatedness. Subsequent studies have led to a radical revision in thraustochytrid nomenclature, with the introduction of many new genera (*Aurantiochytrium*, *Japanochytrium*, *Oblongichytrium*, *Parietichytrium*, *Sicyoidochytrium*, and *Stellarchytrium*) based on combined molecular and biochemical characteristics (Yokoyama and Honda 2007; Yokoyama et al. 2007; FioRito et al. 2016). A recent taxonomic analysis of labyrinthulomycetes phylogenies is shown in Fig. 5 (adapted Gomaa et al. 2013; Pan et al. 2017). The order Labyrinthulales *s. lat.* includes a number of genera (*Aplanochytrium*, *Stellarchytrium*, and some *Thraustochytrium* spp.) that would have previously been placed in the Thraustochytriaceae. Some recent analyses have also separated another, morphologically unremarkable, thraustochytrid-like clade encompassing the genus *Oblongichytrium*, into their own separate family (Oblongichytriidae; Fig. 5; Pan et al. 2017).

The taxonomic subdivision of the Labyrinthulomycota is still in flux and has changed significantly in the last decade as a result of molecular phylogenetic investigations of both the core labryrinthulids and thraustochytrids, but also other groups of heterotrophic protists that are now known to be related. As a consequence of the above taxonomic studies and a series of more recent phylogenetic investigations (Colladao-Mercado et al. 2010; Anderson and Cavalier-Smith 2012; FioRito et al. 2016; Gomaa et al. 2013; Pan et al. 2017; Takahashi et al. 2014; Tice et al. 2016), there seem to be four or five higher-level clades within the phylum (excluding clades only known from environmental sequencing), namely, Labyrinthulales/Labyrinthulida, Thraustrochytriales/Thraustrochytrida, "Amphifilales/Amphifilida," Amphitremidales/Amphitremida, and "Oblongichytriales/Oblongichytrida." However, what is becoming increasingly clear from environmental sequencing is that they are a diverse group of which the vast majority of species still awaits discovery (Worden and Not 2008; Collado-Mercado et al. 2010; Richards et al. 2012; Gomaa et al. 2013; Ueda et al. 2015; Pan et al. 2017). As for most environmental lineages, only partial SSU sequences are available which has been proven to have an insufficient resolution for the deeper splits of the Labyrinthulomycota; it remains unclear, how many of the lineages known only from environmental sequencing can be assigned to the orders given above. In the most comprehensive analysis of environmental sequences currently available, Pan et al. (2017) recognized several additional lineages of the Labyrinthulomycota basal to the known orders or in unresolved positions, which group in four clades, mostly with low to moderate support. These clades, such as the LAB1/6/8 clade containing *Stellarchytrium dubum*, might deserve family- or order-level status once their members have been studied in more detail, e.g., in multigene phylogenies.

Class Labyrinthulomycetes/Labyrinthulomorpha Labyrinthulea? (Lister 1891) Olive ex Cavalier-Smith 1986

Order Labyrinthulales/Labyrinthulida E A Bessey 1950/Doffein 1901

Family Aplanochytriaceae/Aplanochytriidae Leander Ex Cavalier-Smith 2012

A monotypic family formerly included in thraustochytrids. They have typical ovoid to spherical thalli, attached to their substrate by a basal ectoplasmic net that only form non-motile aplanospores. However, unlike members of the Thraustochytriaceae, the thalli are able to slowly glide along the rhizoids. The genus, *Aplanochytrium* (which subsumes the genus *Labyrinthuloides*), contains around half a dozen described genera, but there are probably many undescribed species based on environmental sequencing.

Family Labyrinthulaceae/Labyrinthulidae Haeckel 1868/Cinekowksa 1867

This family contains the classic "slime nets," which form a colony of spindle-shaped thalli that are contained within a branching ectoplasmic network within which the cells migrate. The gliding motility of the cells, which at times is as fast as 100 μm/min, probably driven by a calcium-dependent contractile system of actin-like proteins in the ectoplasmic network (Nakatsuji and Bell 1980). Each cell has a single bothrosome connecting it to the ectoplasmic network. There are around a dozen or so species that have been recognized (Dick 2001). Most are saprotrophs associated with marine debris and decaying macroalgae and marine macrophytes. However, some species have been shown to be the causal agents responsible for the wasting disease of eelgrass (*Zostera*) beds (Muehlstein and Porter 1991) and the turfgrass dieback (Craven et al. 2005).

Family-Level Clade "Stellarchytriaceae/Stellarchytriidae" Undescribed, LAB 1/6/8

This clade, which possibly needs to be described as a new family or even order, is provisionally placed in the Labyrinthulales and contains various lineages known only from environmental sequencing (Pan et al. 2017) and the recently discovered species *Stellarchytrium dubum* (FioRito et al. 2016). *Stellarchytrium dubum* was isolated from diseased starfish, but its role in causing starfish wasting disease still needs to be investigated in detail.

Order Oblongichytriales/Oblongichytrida

Family Oblongichytriaceae/Oblongichytriidae Cavalier-Smith 2012

This monotypic family was first recognized as a result of molecular sequencing by Yokoyama and Honda (2007). It contains around a half-dozen species that were formerly included in the genus *Schizochytrium* based on thallus development. The family name is derived from their slender oblong zoospores they produce rather than the more ovoid zoospores typical of the Thraustochytriales. It appears to form an early diverging clade from the same root as the Labyrinthulales lineage (Fig. 5).

Order Thraustochytriales/Thraustochytrida Sparrow 1973

Even though it has now been split, this still is the largest and most diverse order in the Labyrinthulomycota with the most genera and species. They produce relatively small epibiontic thalli usually attached to substrate by a fine ectoplasmic network of fine-branched anastomosing filaments, which have role in both substrate attachment and feeding. Most are marine organisms that are saprotrophic epibiontic colonizers of a variety of marine detritus, but there are a number of pathogens, mostly of marine invertebrates.

Family Althornidiaceae/Althorniidae Jones and Alderman 1972

This monotypic and monospecies (*A. crouchii*) is the only truly planktonic thraustochytrid as it completely lacks the usual ectoplasmic network. It is also the only genus for which there is at present no sequence data, and therefore its taxonomic placement must be considered as provisional.

Family Thraustochytriacae/Thraustochytriidae Sparrow ex Cejp 1959

Typically thraustochytrids are not colonial but grow by enlargement of cells which develop either into single ovoid or globular thalli or clusters of thalli depending if proliferation takes place before spore formation (traditionally referred to as sori). Within these, either zoospores are differentiated or an amoeboid stage is formed, which are both released by the breakdown of the thallus wall. There are at present six to eight genera within the family, a number of which have been recently created as a result of molecular studies (Yohoyama and Honda 2007; Yokoyama et al. 2007). Genera included in this family are *Aurantiochytrium*, *Botryochytrium*, *Japanochytrium*, *Monorhizochytrium*, *Parietichytrium*, *Schizochytrium*, *Thraustochytrium*, and *Ulkenia*. *Thraustochytrium* is the largest genus with around 20 described species.

Order "Amphitremidales"/Amphitremida Gomaa et al. 2013

Family "Amphitremidiaceae"/Amphitremidae Poch 1913

These organisms were formerly grouped with the testate amoebae. The cells are enclosed with ovoid, cup-shaped, or rectangular punctate shells (Gomaa et al. 2013). Many contain green algal trebouxiophyte endosymbionts and have a mixotrophic nutrition (Gomaa et al. 2013). There are currently three recognized genera, *Amphitrema*, *Archerella*, and *Paramphitrema*. Named species have been isolated from freshwater habitats, such as freshwater wetlands. However, environmental sequencing has revealed many uncultured sequences in a sister group from anoxic and micro-oxic deep-sea sediments.

Family "Diplophrydaceae"/Diplophryidae Cavalier-Smith 2012

This was one of the first of the colorless protist groups that was found associated with the Labyrinthulid clade, although the initial species studied *Diplophrys marina* (Dykstra and Porter 1984) has now been moved to the Amphifilida. The

Diplophryidae *s. str.* are small, largely freshwater heterotrophic protists with colorless spindle- to ovoid-shaped body cells from which a fine network of anastomosing filaments arises in bipolar fashion (Anderson and Cavalier-Smith 2012; Takahashi et al. 2014). The exact order placement of this family is not fully resolved, and it is placed with the Amphitremida on basis of recent phylogenetic investigations (Tice et al. 2016; Pan et al. 2017) although species also share morphological similarities with members of the next order.

Order "Amphifilales"/Amphifilida Cavalier Smith 2012

This is another order of colorless protists that have been phylogenetically elusive. They share many of the morphological characteristics of the genus *Diplophrys* described above, and the new genus was created by Anderson and Cavalier-Smith (2012) to contain the species *Diplophrys marina* which was in a separate clade from freshwater species of that genus. Another member of the family is the genus *Sorodiplophrys*, which had often been placed with dictyostelid amoebae (Tice et al. 2016).

Isolation Procedures

Thraustochytriales Isolation procedures have been summarized by Porter (1990) and are briefly reviewed in this account. Thraustochytrids can be isolated by plating tissue sections on seawater agar, peptone-yeast-glucose seawater agar (PYGSA, approximately 50% seawater), modified Vishniac's medium (KMV), or vegetable juice seawater agar, amended with penicillin and streptomycin to prevent bacterial growth. Small pieces (1 cm^2 or less) of carefully rinsed (e.g., with sterile 50% seawater) tissue sections are placed on agar media and incubated at room temperature for 3 days or until thraustochytrid colonies are visible on the periphery of the tissue samples. Often the bottom surface of the tissue that is in direct contact with the agar is similarly colonized. Slide purification is the easiest method for obtaining an axenic culture of thraustochytrid. This is done by transferring a minute quantity of thraustochytrid cells, often with a fine glass needle, to a drop of sterile water on a slide then serially diluting until few cells or thalli are visible. Individual thalli can then be streaked to another agarised medium used in the isolation process. Baiting samples with pollen, especially from pines, is a method commonly used for isolating chytrids but similarly helpful when isolating thraustochytrids. For pollen baiting, the carefully rinsed substrate is placed in Petri dishes containing sterile-filtered seawater, onto which pollen grains (preferably sterilized) are dispersed. Colonization of pollen grains is usually evident within 2–10 days in the Petri dishes, but these may be held for several weeks if necessary. Thraustochytrid thalli can be observed on pollen grains with a dissecting microscope, ideally at high magnification (60–100×). Individual pollen grains can be transferred with a loop to agar plates or to small drops of sterile seawater from which zoospores, if released, can be picked up and streaked onto agar plates. Alternatively, colonized pollen grains can be transferred in mass to agar plates. Often, especially if a small initial inoculum is used, all of the

colonized pollen grains will have colonies of the same species of thraustochytrid. It has been noted that not all thraustochytrids readily colonize pollen grains; thus, if a synoptic collection is desired, a variety of isolation procedures should be used. Maintenance of thraustochytrids can be achieved by regular subculturing or cryopreservation in 10% glycerol.

Labyrinthulales Several methods for isolating members of the Labyrinthulales have been published (Amon 1978; FioRito et al. 2016; Garcias-Bonet et al. 2011; Yokochi et al. 2001). Moribund (discoloured) but not decomposed seagrass, marsh grass, mangrove litter, and algal fragments collected adrift or recently washed ashore are reliable sources for labyrinthulids. Organic sediments from marine and intertidal aerobic zones and tissues of invertebrate species may also yield labyrinthulids. Successful isolation has been reported with 1% serum seawater agar (SSA) but also with plain seawater agar. Half- to quarter-strength concentration of vegetable juice seawater agar and PYGSA amended with antibiotics (e.g., penicillin, streptomycin, or ampicillin) are similarly useful in isolating *Labyrinthula*. Often the thickness of agar media is minimized to ~2 mm (Yokochi et al. 2001) for ease in observing colonies with an inverted microscope. Similar to thraustochytrids, rinsed plant or algal materials are placed onto agar media and usually incubated at room temperature. Vividly swarming colonies radiating from tissue pieces are usually visible within 7 days of incubation. An agar block containing a swarm of labyrinthula can then be subcultured or cocultivated with marine yeast or bacteria (e.g., *Vibrio*, *Psychrobacter*). This method has been practiced often, since these microorganisms serve as host or food for labyrinthulids. However, maintaining a culture of labyrinthulids is challenging as isolate cessation after subculturing several times occurs, probably because the full life cycle is not concluded under these cultivation conditions.

Evolutionary History

In the absence of any fossil record for this group, all evolutionary speculation has to be based on the evidence of recent molecular phylogenetic studies. All of the osmotrophic fungal-like organisms studied by mycologists, except the plasmodiophorids, fall within the straminipilous branch of the chromalveolate assemblage (Fig. 1a adapted from Tsui et al. 2009; Fig. 1b from Moreira and López-Garcia 2002). The kingdom Straminipila defined by Dick (2001) was often seen as synonymous with the kingdom Chromista (Cavalier-Smith and Chao 2006) which is the name often favored by online taxonomic databases, even though the chromista, as originally defined also contain organisms not belonging to the Staminipila or the SAR supergroup (Burki et al. 2009). However, Dick (2001) argued that because of the non-photosynthetic osmotrophic groups in this lineage that the etymologically correct name Straminipila would be a more appropriate kingdom name, as this would highlight the synapomorphy of a monophyletic group. Nonetheless, a widely adopted form of spelling for this kingdom is

Stramenopila (Adl et al. 2005; Lévesque 2011). Whether cryptophytes and haptophytes and their allies should also be considered as part of a wider supergroup is still debated (e.g., Reeb et al. 2009; Dorrell and Smith 2011).

Hyphochytrids and oomycetes are part of the lineage that shares a common ancestor with the photosynthetic ochrophytes (Tsui et al. 2009; Riisberg et al. 2009; Yubuki et al. 2010). It has recently been suggested that the stem origin of the Ochrophyta was around 571 millions of years ago, (a mean of estimates ranging from 735 to 434 million years ago: Brown and Sorhannus 2010). The Labyrinthulomycota are part of a sister clade, often collectively termed Bigyra which presumably evolved around the same time or only slightly earlier than the other osmotrophic Straminipila. The Labyrinthulomycota, Hyphochytriomycota, and Oomycota, as well as the ochrophyte straminipilous lineages share a common ancestor, which was most likely a photosynthetic mixotrophic marine flagellate (Tsui et al. 2009). The Labyrinthulomycota are part of one major straminipilous line and the Hyphochytriomycota and Oomycota of another (Fig. 5). This explains that whilst there are similarities between the Labyrinthulomycota and the other heterokont osmotrophs, they show much less in common than the other two groups.

The overall relationships between the major groups within the chromalveolate lineage, and the straminipilous groups in particular (see Beakes et al. 2014; Beakes and Thines, this volume), have been investigated using multiple protein-encoding genes (Tsui et al. 2009; Reeb et al. 2009; Riisberg et al. 2009). The statistically well-supported Alveolata kingdom, comprising Apicomplexa, Dinoflagellata, and Ciliata, forms the sister clade to the Straminipila (Keeling 2009). These can be divided into two main lineages: the first encompasses the bacteriotropic flagellate bicosoecids, the protistan gut-inhabiting opalinids (plus proteromonads and *Blastocystis* – equivalent to slopalinids defined by Patterson 1989) and the Labyrinthulomycota (Cavalier-Smith and Chao 2006; Tsui et al. 2009; Riisberg et al. 2009; Reeb et al. 2009), and the second straminipilous clade that includes the osmotrophic Hyphochytriomycota and Oomycota, the photosynthetic Ochrophyta, and a number of phagotrophic flagellates, such as *Developayella* and *Pirsonia* (Beakes et al. 2014). In this account, the Labyrinthulomycota is given phylum rank as in Porter (1990), and an emended Labyrinthulomycota *s. lat.* could be seen as containing other members of the phylum Bigyra (sensu Cavalier-Smith and Chao 2006), thereby replacing it.

The "chromalveolate hypothesis" proposes the red algal origin of the plastid in all chlorophyll c-containing algal groups (reviewed by Keeling 2009). However, recent comparative analyses of genomes of members of the Straminipila have led to the discovery of genes of green algal ancestry in both diatoms (Moustafa et al. 2011) and oomycetes (Richards et al. 2011; Jiang and Tyler 2012). It seems to cast doubt on such a simple "single-acquisition-multiple loss" interpretation (e.g., Maruyama et al. 2009; Stiller et al. 2009; Dorrell and Smith 2011). Theories involving multiple independent chloroplast acquisitions and horizontal gene transfer (HGT) have also been proposed as alternative explanations of the phylogenetic and genomic data (e.g., Martens et al. 2008; Stiller et al. 2009; Baurain et al. 2010). The eyespot in *Labyrinthula* zoospores (Perkins and Amon 1969) resembles those of photosynthetic

Straminipila and may be indicative of the remains of an ancestral chloroplast. However, the fact that such structures have only been observed in the most derived group does perhaps cast doubt on this suggested origin (Tsui et al. 2009). Thraustochytrids produce omega-3 PUFA using a desaturase enzyme that in algae is usually found in chloroplasts (Sargent et al. 1995). If, as suggested by Tsui et al. (2009), it is assumed the ancestor to the straminipilous lineage was a mixotrophic photosynthetic flagellate, then at least two independent plastid losses must have occurred in the straminipilous line, one prior to diversification of the Labyrinthulid clade and the other after the divergence of the ochrophytes leading to the heterotrophic Oomycota and related lineages (Beakes et al. 2014). Alternatively, if plastid loss was deeply seated within the straminipilous line, then an independent reacquisition of a chromistan type plastid must have occurred to give rise to the Ochrophyta as suggested by Leipe et al. (1994). Plastid genes have been widely found in sequenced oomycete genomes (see Lévesque et al. 2010; Jiang and Tyler 2012) but were not reported in the compact 18.8 Mb genome of the anaerobic human gut parasite *Blastocystis* (Doenoeud et al. 2011). The preliminary genome sequence for the thraustochytrid *Aurantiochytrium limacinum* has been recently released (Collier 2012), but preliminary analysis has not so far revealed evidence of genes of plastid origin (Collier personal communication).

The earliest-diverging Labyrinthulomycota clades appear to contain thraustochytrid clades that have still retained the ability of phagotrophic nutrition, which is considered to be the ancestral state (Tsui et al. 2009; Gomaa et al. 2013). The presence of endosymbiotic Trebouxiphyte algae in the cells of members of the Amphitremida indicates this group has retained the ability to feed phagotrophically (Gomaa et al. 2013).

According to the analysis of Tsui et al. (2009), the key evolutionary event in the evolution of the labyrinthulomycetes within the straminipilous lineage was the evolution of the naked ectoplasmic net. The most derived groups are the Labyrinthulids and Aplanochytrids which have lost the ability to feed phagotrophically and rely entirely on osmotrophic nutrition. But also they have evolved gliding movement on the ectoplasmic net. The Aplanochytrids became separated from the Labyrinthulids by the loss of flagella (although it would be interesting to know if flagella genes can be found in their genome) and the acquisition of polygonal scales (Tsui et al. 2009).

What has become apparent in the past decade is that the Labyrinthulomycota are a more diverse assemblage than previously thought (Fig. 5), both in terms of ecological niches they occupy and their morphology than was believed at the time of the last Handbook review (Porter 1990). It is likely, that many more species and hidden genera are yet to be discovered that will provide new insights into the origins and evolutionary develeopment of this enigmatic group of protists.

Opalinata

15

Martin Kostka

Abstract

The opalinids (Opalinidae: genera *Opalina*, *Cepedea*, *Protoopalina*, *Zelleriella*, and *Protozelleriella*) are highly unusual protists with large cells, multiple flagella, and two to hundreds of nuclei. The name *Opalina* is derived from the iridescent appearance when light reflects on the delicately folded surface of the cells. Opalinids are found exclusively in the intestines of frogs and some other hosts. They form the group Slopalinida together with two related genera of intestinal flagellates, *Karotomorpha* and *Proteromonas*. The former is a tetrakont flagellate that inhabits the intestines of certain amphibians, while the latter possesses only two flagella and is found in a wider spectrum of vertebrate hosts. Both morphology and molecular data suggest that *Karotomorpha* is phylogenetically closer to the opalinids, although both flagellates were traditionally classified in a single family, Proteromonadidae. Molecular data have shown that yet another unusual gut protist is closely related to Slopalinida: the genus *Blastocystis*. Unlike its relatives, it bears no flagella and is usually observed in the form of spherical cells with huge vacuoles. It is quite common in the intestines of many vertebrates (including humans) and invertebrates. Together, these organisms form Opalinata, a diverse assemblage of variously modified unicellular eukaryotes.

Introduction

General Characteristics

Opalinata Wenyon, 1926, comprises several types of protists morphologically so distinct that their relationship was recognized only relatively recently. The "core" of Opalinata is formed by opalinids, members of the family Opalinidae Claus, 1874. They are a lineage of unusual unicellular eukaryotes with several conspicuous morphological characteristics. They are quite large (some of them may reach nearly three millimeters) and have multiple flagella and two to many nuclei. The surface of an opalinid cell is arranged in parallel folds. Light interference that occurs on these delicate structures leads to the beautiful opalescence of opalinids when they are observed in reflected light (hence their name). Opalinid genera can be distinguished on the basis of two features: number of nuclei (two vs. numerous) and cell form (cylindrical vs. flattened). Multinucleate genera are *Opalina* Purkinje and Valentin, 1835 (flattened, Fig. 1a) and *Cepedea* Metcalf 1920 (cylindrical, Figs. 1b and 6a), whereas *Zelleriella* Metcalf 1920 (flattened, Fig. 1c) and *Protoopalina* Metcalf, 1918 (cylindrical, Figs. 1d and 6b) have two nuclei. The

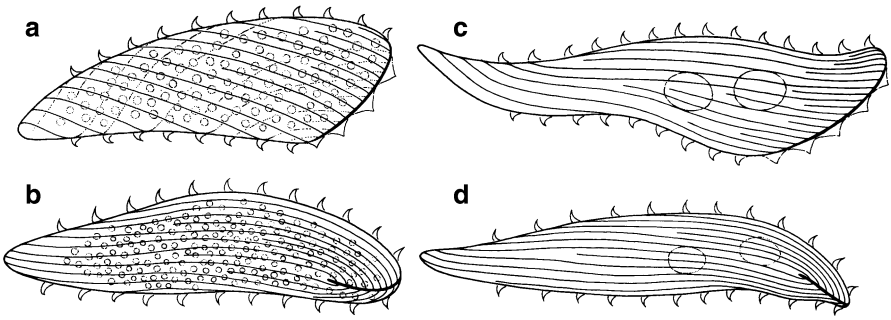

Fig. 1 Schematic drawings of four opalinid genera. *Circles* within the cells represent nuclei; the *lines* represent kineties (rows of flagella). Metachronal waves of beating flagella are symbolized by the waves at the periphery of the cells. The anterior part of cells with falx (*bold line*) points to the right. *Opalina* (**a**) is multinucleate, and its cell body is flat. The kineties run to the cell margin from where they continue on the other side (*dotted lines*). *Cepedea* (**b**) is also multinucleate, but its cell body is circular in cross section. *Zelleriella* (**c**) is binucleate with flat body, either caudate, as seen in the figure, or rounded posteriorly. *Protoopalina* (**d**) is a binucleate genus with cylindrical cells (Figure from Corliss (1989))

most recently erected genus, *Protozelleriella* Delvinquier, Markus, and Passmore, 1991, is similar to *Zelleriella* in appearance but is unique in having a hyaline margin without flagella (Delvinquier et al. 1991b). Two additional genera, uninucleate *Hegneriella* Earl, 1971 and *Bezzenbergia* Earl, 1973 with four nuclei are generally not considered valid. The number of described opalinid species reaches several hundred, but a critical revision of the family would probably lead to a reduction of the number (Sandon 1976).

Based on ultrastructural observations, proteromonad flagellates were recognized as the closest relatives of opalinids. The two genera of this paraphyletic group, *Proteromonas* Künstler, 1883 (Fig. 2a) and *Karotomorpha* Travis, 1934 (Fig. 2b) are represented by several species of rather thin, pointed intestinal flagellates with two or four flagella, respectively. Their Golgi apparatus, nucleus, and single mitochondrion are located in the anterior part of the cell near the kinetosomes. Grassé (1952) included two *incertae sedis* genera among proteromonads, *Dimoerium* Przesmycki, 1901 and *Dimoeriopsis* Hollande & Pesson, 1945. The latter is a parasite of freshwater snail eggs. There are no recent studies of these organisms and their biology and phylogenetic affinities should be rechecked.

The last, quite surprising addition to the group Opalinata was the genus *Blastocystis* Aléxéieff, 1911 (Fig. 3). Its members lack flagella completely and are best known as spherical cells with a large central vacuole and several nuclei since this is how they usually appear in culture. *Blastocystis* is morphologically very different from other members of Opalinata, and its recognition as their sister group was based primarily on phylogenetic analyses of molecular data (SSU rRNA gene sequences). *Proteromonas*, *Karotomorpha*, opalinids, and *Blastocystis* constitute a very interesting monophyletic group of intestinal protists that display extreme morphological disparity, ranging from "normal" flagellates to the complex

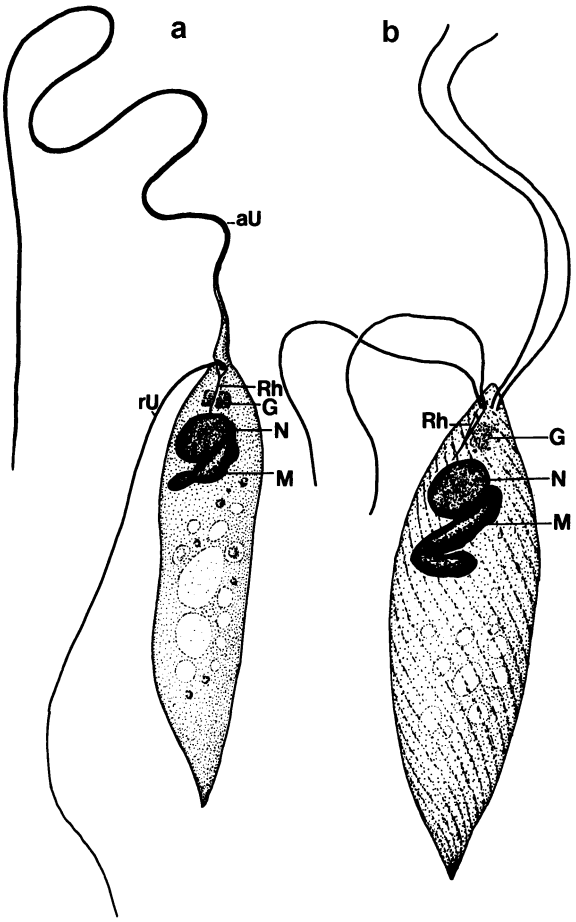

Fig. 2 Schematic drawings of *Proteromonas* and *Karotomorpha*. The cell of *Proteromonas* (**a**) bears one long, thick anterior flagellum (*aU*) and a trailing one (*rU*). The rhizoplast (*Rh*) passes through the Golgi apparatus (*G*) to the nucleus (*N*), behind which lies the mitochondrion (*M*). *Karotomorpha bufonis* (**b**) has two pairs of flagella, a short rhizoplast (*Rh*) running near the Golgi complex (*G*); the nucleus (*N*) is closely associated with a single mitochondrion (*M*). Sinistral surface striation (pellicular folds) is sometimes apparent (Figure from Brugerolle and Mignot (1989))

multiflagellated opalinids, on one hand, and to the morphologically reduced *Blastocystis*, on the other.

Occurrence

All members of Opalinata occur in the intestines of various animals. Opalinids are common inhabitants of the large intestines of frogs of all continents. Some other poikilotherm vertebrates can also be their hosts. *Karotomorpha* is common in some amphibians, while species of the genus *Proteromonas* are commensal in reptiles, urodelan amphibians, and in the caecum of certain rodents. *Blastocystis* has the widest host range: it is found in various mammals (including humans), birds, reptiles, and amphibians but also in some invertebrates such as cockroaches.

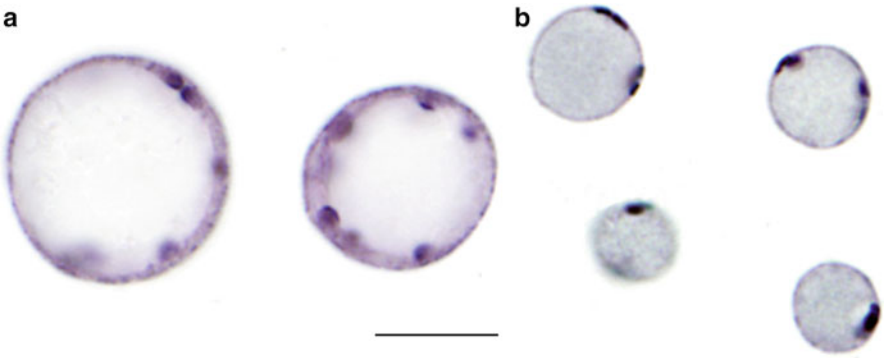

Fig. 3 Microphotographs of protargol-stained vacuolar forms of two cultured *Blastocystis* strains. Both were isolated from chelonians: strain GEEL (**a**) from *Geochelone elegans* and strain PYX (**b**) from *Pyxidea mouhotii*. The scale bar (10 μm) applies to both images. Note the differences in size and number of nuclei. The preparations were stained by Ivan Čepička

No cultures of opalinids are available. However, some frogs maintained in labs (e.g., *Xenopus laevis*) are infected with them, usually with *Protoopalina*. A single axenic culture of *Proteromonas* was established by Kulda (1973) and is available from the Dept. of Parasitology, Faculty of Science, Charles University in Prague, Czech Republic. It is also deposited in the American Type Culture Collection (ATCC PRA-286). *Blastocystis* is quite easily cultured xenically and may be axenized. There are many cultures available in laboratories studying *Blastocystis*; ATCC provides a number of isolates.

Literature

One of the most important early authorities on opalinids was Metcalf, who, among other studies, published two major works (Metcalf 1923, 1940). Later important works include Grassé (1952) and Corliss (1955). Opalinid life cycles and morphogenesis are discussed in Wessenberg (1961). Three very useful modern reviews are Wessenberg (1978), Corliss (1989), and Delvinquier and Patterson (1993). Delvinquier et al. (1991a, b, 1993, 1995a, b, 1998), Delvinquier and Desser (1996), and Delvinquier and Marinkelle (1996, 1997) published a series of papers on opalinid distribution in amphibians throughout the world and described a new genus (*Protozelleriella*).

Proteromonas and *Karotomorpha* are dealt with in detail in the works of Grassé (1952) and Kulda and Nohýnková (1978). Their ultrastructure was studied especially by Brugerolle and Joyon (1975). The phylogenetic affinities of the two genera and opalinids are discussed by Patterson (1985).

Older literature on *Blastocystis* is rather scarce. Extensive critical reviews appeared in the 1990s; the most notable were those published by Zierdt (1991), Boreham and Stenzel (1993), and Stenzel and Boreham (1996). Later, several reviews were published by Tan (2004, 2008). A detailed publication dedicated to

Blastocystis is that of Mehlhorn et al. (2012). Most recent advances are summarized in Clark et al. (2013). As if to outweigh the low number of older publications, a tremendous (and still growing) number of papers on various aspects of *Blastocystis* biology have been published in the last few decades.

History of Knowledge

The first observations of opalinids date back to 1683, when Leeuwenhoek investigated frog feces and saw numerous cells of *Cepedea dimidiata* swimming in his preparation (Dobell 1932). The genus *Opalina* was established by Purkinje and Valentin (1835). The name reflects the iridescent appearance of living cells. Opalinids were studied in detail by several investigators during the nineteenth century, most notably by Zeller (1877). A prominent author of opalinid studies during the first half of the twentieth century was Metcalf, who defined three new genera and described many new species. He concluded that opalinids were primitive ciliates and created the subclass Protociliata within Ciliata to accommodate them apart from true ciliates or Euciliata (Metcalf 1918). This approach was later abandoned by the majority of authors, who regarded opalinids as a unique group related to flagellates, but not to ciliates (e.g., Corliss 1955; Grassé 1952). A number of later studies added to the knowledge of opalinids, for example, those of Wessenberg (1961) and Kaczanowski (1971, 1973). Ultrastructural studies (Noirot-Timothée 1959; Patterson 1985; Pitelka 1956; Wessenberg 1966) provided new data and led to the current hypothesis on opalinid relationships.

The phylogenetic affinities between *Proteromonas* and *Karotomorpha* remained unrecognized for a long time. They were originally classified in distinct lineages of flagellates (bodonids vs. Polymastigidae or Tetramitidae). The first author who suggested a possible relationship between them was Grassé (1929, 1952). Further studies were conducted by Kulda (1961, 1973). An ultrastructural study by Brugerolle and Joyon (1975) further confirmed the evolutionary link between *Proteromonas* and *Karotomorpha* and, together with other works, informed the search for more distant relatives of proteromonads and thus to the discovery of their association with opalinids.

Blastocystis was described from various hosts more than a century ago by Aléxéieff (1911) under the name of *B. enterocola*, although a junior synonym, *B. hominis* (Brumpt 1912), is widely used for human isolates. For some 50 years since its description, *Blastocystis* was mostly overlooked and little studied. Its nature was not well understood – it was usually considered a harmless yeast or even a remnant/cyst of other organisms. The interest in it was reawakened mainly by Zierdt and his collaborators (e.g., Zierdt et al. 1967 and many later publications). He recognized that *Blastocystis* is not a fungus and continued to study its morphology, physiology, biochemistry, etc. His studies initiated further research on *Blastocystis* and many laboratories throughout the world study this organism today. The molecular phylogenetic study of Silberman et al. (1996) established that *Blastocystis* was a relative of slopalinids (represented by *Proteromonas* in the study).

Practical Importance

Although usually abundant in the cloacae of frogs, opalinids do not seem to cause any harm to their hosts. As quite common, yet rather enigmatic organisms, they have played, and can still play, an important role in research in the fields of cell biology, physiology, life cycle, host-symbiont interactions, (co)evolution, etc. *Proteromonas* and *Karotomorpha* may be numerous in the intestines of amphibians and reptiles but also seem to have no harmful effect; they are of no known economic importance.

Blastocystis is common in various hosts and is also one of the most frequently occurring eukaryotes found in the human intestine. Its role in pathogenesis is uncertain. *Blastocystis* is often connected with irritable bowel syndrome and other gastrointestinal symptoms. Some studies suggest a correlation between the presence of *Blastocystis* and these kinds of problems, but other studies indicate there is none (see, e.g., Clark et al. 2013; Poirier et al. 2012; Tan et al. 2010 for reviews and references). Even if there *were* such a correlation, it is still unclear whether *Blastocystis* can actually cause intestinal disorders or is just more efficient in colonization of the altered environment of unhealthy intestine. The whole issue is complicated by the fact that *Blastocystis* in human beings (and in animals, too) is genetically very variable – it is probable that some genetic lineages (subtypes) are more pathogenic than other ones. In some cases, *Blastocystis* was also associated with skin problems such as urticaria (Tan et al. 2010).

Habitats and Ecology

The vast majority of opalinids inhabit posterior parts of the intestine of frogs, but they can also be found in some other amphibians (e.g., Salamandridae, Ambystomatidae). Several species of opalinids were observed in freshwater fish, such as *Protoopalina symphysodontis* in *Symphysodon* (Foissner et al. 1979). They seem to be quite often found in Siluriformes (Sandon 1949). There are also a few marine species of *Protoopalina*: *P. saturnalis* lives in the intestine of the marine fish *Box boops* (Mignot and Molina 1988), while *P. polykineta* occurs in surgeonfish (Grim and Clements 1996) and *P. pomacantha* is found in angelfishes (Grim et al. 2000). Opalinids are occasionally seen in reptiles that presumably acquired them after ingestion of an infected frog (Delvinquier and Patterson 1993).

Because opalinids are so tightly bound to their amphibian hosts, their geographical distribution is dependent on the distribution of frogs. They are thus most diverse in tropical and subtropical regions. There are some patterns in the zoogeography of opalinids – some genera are absent or very rare in some regions: *Zelleriella* in Palaearctic, *Opalina* and *Cepedea* in Australia; conversely, *Protozelleriella* is known only from Africa (Delvinquier and Patterson 1993).

Opalinids themselves can serve as hosts to other protists, namely, amoebae of the genus *Entamoeba* (Chen and Stabler 1936; Stabler and Chen 1936; spelled "*Endamoeba*" in their works). Some metazoan parasites of frogs are predators of

opalinids: Hazard (1941) observed the trematode *Diplodiscus temperatus* feeding on opalines, possibly eliminating them from adult frogs.

Karotomorpha and *Proteromonas* also inhabit the intestines of various vertebrates, where they are usually found intermixed with other gut protists. *Karotomorpha bufonis* is common in certain amphibians, both urodelans and frogs (e.g., *Triturus* spp., *Bufo bufo*). *Proteromonas lacertaeviridis* is a commensal of a wide range of reptiles – not only European lizards of the genus *Lacerta* but also many other lizards, snakes, or even tortoises. Several other species of *Proteromonas*, some (or all) of which might be synonymous to *P. lacertaeviridis*, were described from various reptiles. Urodelan amphibians, for example, *Salamandra salamandra*, may harbor *Proteromonas longifilla*, and other species can be found in the caecum of some rodents, for example, *P. brevifilia* in guinea pigs. Interestingly, Maia et al. (2012) found *Proteromonas* in a few blood and tail tissue samples from reptiles.

Besides being frequently reported from humans, *Blastocystis* can be found in a vast number of hosts including insects (Zaman et al. 1993), amphibians (Yoshikawa et al. 2004), reptiles (Teow et al. 1992), birds, and many nonhuman mammals (summarized in Stensvold et al. 2009; see also Parkar et al. 2010 and Alfellani et al. 2013). It is rather unclear, however, how many *Blastocystis* species there actually are and what their host specificity is. Despite the relatively uniform appearance of vacuolar forms of *Blastocystis* strains isolated from different (or the same) host species, genetic markers (usually SSU rRNA gene sequences) suggest there are multiple lineages that are molecularly divergent and probably ancient. The initial recognition of this hidden diversity led to nomenclatural confusion that made the problem even more difficult. A consensus proposed by Stensvold et al. (2007) recognizes the lineages as subtypes and uses numbers to distinguish between them. Currently, there are 17 subtypes defined (Alfellani et al. 2013), but the number may grow. The host specificity and zoonotic potential of the subtypes is still little known, but an overall picture is slowly emerging as more hosts are screened. Some subtypes are probably more generalist, while others display at least some host specificity. There are possibly human-specific subtypes, as well as examples of human infections accidentally acquired from bird or mammalian hosts (Clark et al. 2013). A number of isolates from poikilotherm vertebrates and invertebrates do not belong to any subtype and form their own lineages.

Characterization and Recognition

Opalinidae

Identification of opalinids is usually not difficult. First, the host is significant. Their host is most often a frog and they are located in the posterior part of the digestive tract. Opalinid cells are medium sized to large and covered with multiple flagella that beat in metachronal rhythms. Metachronal waves of flagellar activity are initiated in the anterior region of living cells and can be seen traveling to the posterior end. The cells are opalescent in reflected light. Two or many nuclei are visible within the cells.

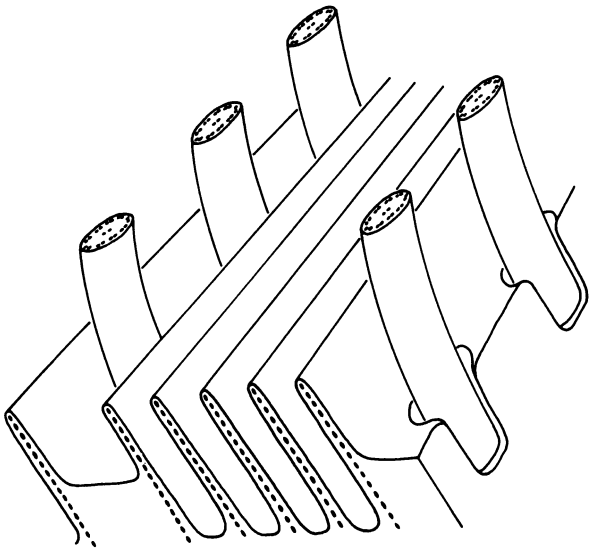

Fig. 4 Schematic representation of surface structure of an opalinid cell. A few flagella in two kineties and the folds between them are shown. The folds are supported by ribbons of microtubules (*dots*) (Figure from Corliss (1989))

Unlike ciliates, which they superficially resemble, opalinids lack any oral structures and their nuclei are not differentiated in micro- and macronuclei.

Morphology and Ultrastructure. The most studied genus of opalinids is *Opalina*. Its cells are characterized as flattened, flexible, elliptical to elongated and with multiple nuclei (Fig. 1a). The biggest specimens can be more than one millimeter long. The cell surface is organized in a complex manner. The flagella (cilia) are arranged in oblique rows (kineties) that run in parallel from the anterior to the posterior end, spiraling around the cell. Kineties arise at an important morphogenetic center, the falx. The falx is a structure composed of several rows of kinetosomes bearing flagella and is located along the anterior end. The falx plays a role in the initiation of flagellar beating. Between the neighboring kineties, the pellicle is heavily folded in several ridges that are parallel with the kineties and supported by ribbons of interconnected microtubules (Fig. 4). The folds themselves are also interconnected by external linkages that stabilize the cortex architecture and ensure regular spacing of cortical ridges (Wooley 2006).

The flagella have the usual $9 \times 2 + 2$ axoneme structure. The detailed ultrastructure of the transitional zone between kinetosomes and axonemes (Fig. 5) is of phylogenetic importance as it is very similar in *Karotomorpha* and *Proteromonas* (Patterson 1985). The bases of flagella are cupped by a membranous pocket. Neighboring kinetosomes within a kinety are connected by an electron-dense connective ("desmos").

The kineties are underlain by bands of microfilaments that are interconnected by additional perpendicular bands arising in regular intervals. Numerous vesicles are located between these lateral microfilament bands, just under the bottom level of the pellicular folds. Interestingly, rows of two vesicular types, spherical and flattened, alternate regularly at this level (Wessenberg 1978). The two types are randomly

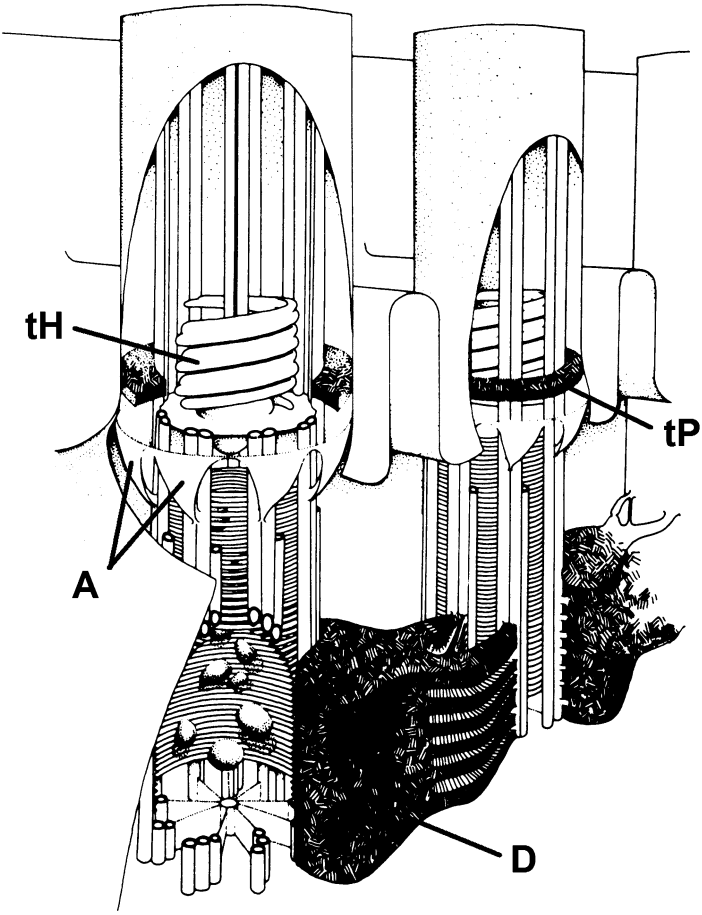

Fig. 5 Schematic drawing of flagellum ultrastructure of opalinids. The flagellar transitional region contains several conspicuous features: double transitional helix (*tH*), transitional plate (*tP*), and nine curved arms (*A*). The advanced basal bodies are interconnected by the desmos (*D*) (Figure from Corliss (1989))

intermixed a little deeper in the cell. The spherical vesicles are coated and are formed at the bottom of the folds via pinocytosis. The flattened vesicles are believed to be exocytic and to compensate for the membrane demand of endocytosis (Delvinquier and Patterson 1993; Grim and Clements 1996). Endocytic vesicles fuse a bit further into the center of the cell to form larger digestive vacuoles (up to 4 μm in diameter).

Golgi complexes occur among the vacuoles, with their concave (trans) face oriented to the surface. In the central part of the cell are numerous ribosomes, mitochondria (formerly known as "Zeller bodies"), and nuclei. The mitochondrial cristae are tubular, and the mitochondria are often accompanied by lipid droplets.

Fig. 6 Microphotographs of two protargol-stained opalinids. *Cepedea* sp. (**a**) was isolated from *Kassina senegalensis*. Note multiple nuclei and kineties originating in the anterior (upper) part of the cell. *Protoopalina intestinalis* (**b**) was isolated from *Bombina bombina*. Its two nuclei are much larger than in *Cepedea* and are visibly connected. Some flagella are faintly apparent around the cells. The scale bar (10 μm) applies to both cells. The preparations were stained by Ivan Čepička

The nuclei of *Opalina* are flattened and 5–7 μm in diameter. Prominent masses of nucleoli are apparent after staining.

The ultrastructure of other opalinid genera does not differ substantially from that of *Opalina*. The falx of the cylindrical genera (*Cepedea* and *Protoopalina*) is parallel rather than perpendicular to the axis of the cell and is shorter. The number of kineties, which twist helically around the cell, is thus lower. The nuclei of the binucleated genera can be much bigger than those of *Opalina* and *Cepedea*: up to 40 μm in *Protoopalina* (cf. Fig. 6a, b). *Protoopalina* and *Cepedea* have a complex, branched network of microfibrillar bundles within the cell (Mignot and Affa'a 1995). Grim and Clemens (1996) report abundant bacterial endocytobionts in *P. polykineta*. *Protozelleriella* is a morphologically unique opalinid. It has a broad, *Zelleriella*-like cell with a thin anterior falx. However, the kineties originating on the falx are very short, forming a central fan-like array surrounded by a hyalinous margin devoid of flagella (Delvinquier et al. 1991b).

Mitosis, Cell Division, and Life Cycle. The nuclear division, chromosomes, and ploidy in *Zelleriella* were extensively studied by Chen (1936a, b, 1948). The nuclear membrane remains intact during mitosis; the mitotic spindle is formed within the nucleus. After the chromosomes are separated near the poles of the dividing nucleus, its central area is constricted and elongated, but the two daughter nuclei can remain

joined by a narrow link for a long time. In *Zelleriella*, cytokinesis often precedes karyokinesis, leading to mononucleated daughter cells whose nuclei will proceed to telophase. Mitosis in other genera is similar, nuclei of multinucleated opalinids divide asynchronously, and mitosis is not strictly dependent on cytokinesis, although the number of nuclei is increased prior to cell division.

Binary fission in *Opalina* remains controversial in some respects: it is unclear whether transverse division (i.e., that cleaves the cell perpendicularly to its longitudinal axis) is a mechanism of actual propagation. Wessenberg (1961, 1978) was one of those who proposed this. The kineties are interrupted in transverse division, however, and for division to be successful, the posterior daughter cell would have to regenerate its falx de novo, which some other authors find dubious (e.g., Delvinquiér and Patterson 1993). Longitudinal division, on the other hand, is common. It is preceded by falx elongation, the falx is then bisected by a cleavage notch, and the cell is divided from the anterior to the posterior end along the kineties, which untwist during the process.

The life cycle of opalinids (Fig. 7) was studied notably by Wessenberg (1961). It is quite complex and is synchronized with the life cycle of the frog host. The best known example is the life cycle of *Opalina*: for the most of the year, the trophonts described above are the only stage found in the rectum of frogs. As the breeding season of frogs draws near, the opalines start to divide without growth (palintomy) producing tomonts and finally small tear-like individuals (progamonts) with a few nuclei. These stages round up and encyst. The cyst are spherical and 20–45 μm in diameter and contain several (most often 4–8) nuclei. They are released with feces into the water, where they remain viable for approximately 3 weeks. Young tadpoles feeding on detritus ingest the cysts. After the excystation in the digestive tract of a tadpole, the released stages – gamonts – divide further to produce unicellular gametes. Meiosis occurs during this process (Kaczanowski 1971). Opalines are anisogamous, producing macro- and microgametes. Both types are slender cells, approximately 40 μm long, with 8–10 kineties. Microgametes are much thinner and a bit shorter than the macrogametes and have a narrow "tail" which may lack cilia and seems to be sticky. They often swim with this part pointed anteriorly to attach themselves to macrogametes. It is not known which point of the life cycle is the stage where the sex of the gametes is determined. After syngamy, zygocysts are formed. These leave the tadpole in its feces and infect other tadpoles feeding on detritus. Upon ingestion and excystation, the sexual processes can repeat. Only in older tadpoles nearing metamorphosis do the excysted stages cease to produce new gametes and instead grow while their nuclei divide without cytokinesis. The resulting cells are "protrophonts" with an axial row of several nuclei. As they grow further, they become wider and flatter and change into trophonts. Some of these early trophonts may switch to palintomy again and produce some new cysts. They have a last chance to infect new hosts, which at this time are becoming young frogs and are already leaving the water. The perfect synchronization of the life cycle of opalinids and their hosts is believed to be achieved in part by an ability of opalinids to properly react to hormonal changes in frogs during the breeding season (El Mofty and Smyth 1964).

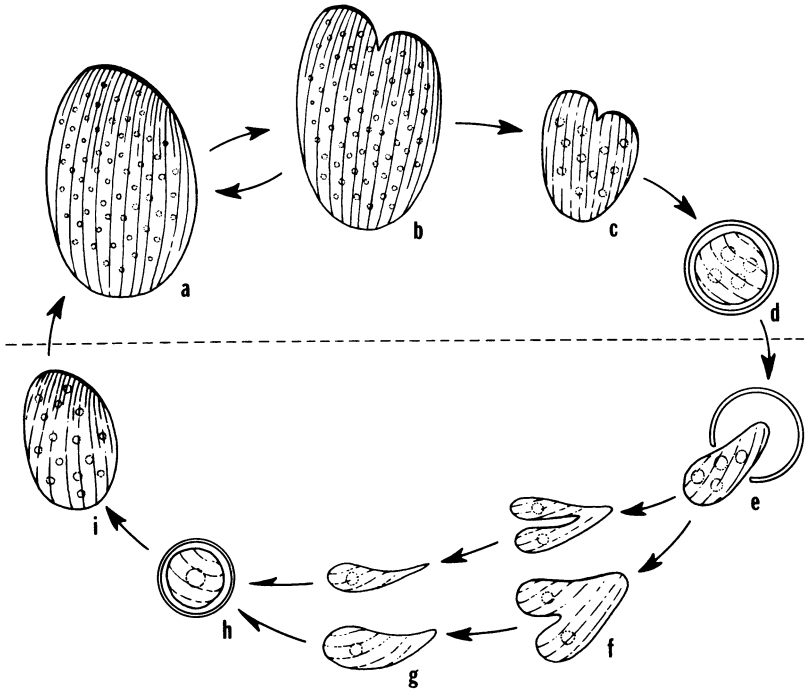

Fig. 7 Diagrammatic and abbreviated life cycle of *Opalina*. Rounded trophonts (**a**) reproduce by longitudinal division (**b**). During the rearing season of the host, they undergo palintomy (**c**) and infective cysts (**d**) are finally released. After excystation (**e**), the gamonts (**f**) divide further, and eventually uninucleate gametes are produced (**g**). They fuse to form a zygote that encysts as a zygocyst (**h**). Excysted stages metamorphose into young trophonts (**i**). Stages **a**–**d** are found in adult frogs, with the infective cysts (**d**) passing out into the water with fecal material. Stages **e**–**i** are found in tadpoles; zygocysts (**h**) are again released into water to be reingested (Figure from Corliss (1989))

Proteromonas and *Karotomorpha*

Assuming that one is studying the intestinal contents of an appropriate host, both *Proteromonas* and *Karotomorpha* are best recognized by their slender cells and agile movement. Their cells typically measure about 15–20 × 5 μm. After Giemsa staining, the number and arrangement of flagella can also help to distinguish them from other flagellates. Fine striations may be visible on stained *Karotomorpha* cells (Fig. 2b).

Morphology and Ultrastructure. Proteromonas (Figs. 2a and 8a) has two apical flagella of different lengths. The longer one (about 40–50 μm) points forward during swimming and is thickened – its axoneme (of the typical eukaryotic structure) is accompanied by a striated fiber attached to one of the microtubular doublets and by additional microfibrils. The second, recurrent flagellum is about 30 μm long. Membranes at the bases of the two flagella are in close contact, forming a gap junction. The two kinetosomes are perpendicular and are interconnected by a short striated

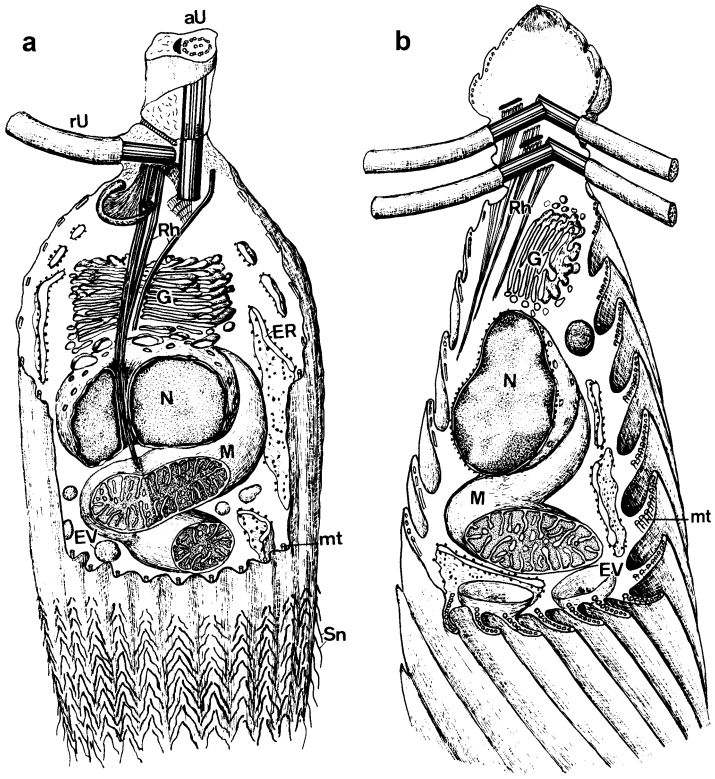

Fig. 8 Diagrammatic reconstruction of the ultrastructure of *Proteromonas* and *Karotomorpha*. *Proteomonas* (**a**) has two flagella; the anterior one (*aU*) is thicker than the posterior one (*rU*) because its axoneme is accompanied by a fiber and fibrils. Between the two flagella, the cell membrane forms a gap junction. The rhizoplast (*Rh*) is a cytoskeletal structure connecting the kinetosomes with the nucleus (*N*) and mitochondrion (*M*). The rhizoplast runs through the Golgi complex (*G*). The surface of the cell is highly folded, with the ridges supported by single microtubules (*mt*). In the posterior part, the cell is covered with fine hairs – somatonemes (*Sn*). Endoplasmic reticulum (*ER*) and endocytic vacuoles (*EV*) are also present in the cells. *Karotomorpha* (**b**) differs mainly in having four laterally pointing flagella and deeper folds supported by ribbons of microtubules (*mt*). Its rhizoplast (*Rh*) does not reach the mitochondrion (*M*) and does not run through the Golgi (*G*). *Karotomorpha* lacks somatonemes. The cell contains nucleus (*N*), reticulum, and endocytic vacuoles (*EV*) (Figure from Brugerolle and Mignot (1989))

fibril. Two additional bundles of microtubules attach to the kinetosome of the posterior flagellum and a dense fiber to the other one (Brugerolle and Joyon 1975). Together, they form the rhizoplast, a structure that runs in the posterior direction through the Golgi complex, passes the nucleus (making a groove in its surface), and ends on the mitochondrion. In *Karotomorpha* (Figs. 2b and 8b), its four flagella point laterally out of the cell and all beat anteroposteriorly. They are arranged in two pairs – each pair is homologous to the two flagella of *Proteromonas*. Kinetosomes of each flagellar pair are again perpendicular and lie in a plane

perpendicular to the cell axis. One kinetosome of each pair (the one homologous to the kinetosome of the posterior flagellum of *Proteromonas*) is associated with the two microtubular bands of the rhizoplast. The rhizoplast of *Karotomorpha* is shorter and does not reach the mitochondrion – it ends near the cell surface at the level of the nucleus. Several delicate features of phylogenetic significance can be found within the transitional region of the flagella of both genera. They include double transitional helix or transitional disk between the peripheral microtubules and the cell membrane, both of which are also present in the proximal region of opalinid flagella.

The cell surface is formed into about 30 shallow ridges in *Proteromonas* and about 20–25 deeper folds in *Karotomorpha* that twist helically around the cell (Brugerolle and Joyon 1975). These surface structures are supported by a cortical cytoskeleton (Fig. 8) in the form of single microtubules, each associated with a microfibril (*Proteromonas*) or ribbons of about ten interconnected microtubules (*Karotomorpha*). In the posterior two thirds of the *Proteromonas* cell, the cortical ridges bear somatonemes that cover the cell surface. Somatonemes are tripartite fine hairs consisting of a bent base, a tubular rod, and a terminal filament. Pairs of somatonemes are anchored to the cortical microtubules at regular intervals. The somatonemes have a similar structure to the mastigonemes associated with the anterior flagellum of typical stramenopile flagellates; the two structures are apparently homologous. Cavalier-Smith (1998) suggests that somatonemes protect the cell surface from larger particles which could either directly damage it or block pinocytosis. The much deeper folds of *Karotomorpha* would then serve a similar role and compensate for the loss of somatonemes.

The anterior region of *Proteromonas* and *Karotomorpha* cells contains three important organelles: the Golgi apparatus, nucleus, and a single mitochondrion. Endoplasmic reticulum is also concentrated here. Cisternae of the Golgi apparatus of *Proteromonas* are ring shaped, since the rhizoplast passes through them. The Golgi plays an important role in the assembly and transport of somatonemes, which are synthesized in cisternae of endoplasmic reticulum, then are transferred to the Golgi, and finally migrate to the cell surface (Brugerolle and Bardele 1988; Brugerolle and Joyon 1975). The nucleus is oval and has a nucleolus and peripheral chromatin. The mitochondrion lies posterior or posterolateral to the nucleus. It is roughly the same size as the nucleus and is surrounded by glycogen particles. The mitochondrial cristae are tubular. The cytoplasm may contain symbiotic bacteria, often near the mitochondrion (Brugerolle and Joyon 1975). The flagellates of both genera feed by pinocytosis; pinocytic vesicles are formed in the posterior part of the cell, among the rows of somatonemes or at the bottom of the cortical folds. Inside the cell, the vesicles fuse to form larger digestive vacuoles.

Cell Division and Life Cycle. The trophozoites of *Proteromonas* and *Karotomorpha* divide longitudinally. Cell division is better understood in *Proteromonas* (Grassé 1926, 1952). It begins with duplication of the kinetosomes and flagella; the rhizoplast is also doubled. The two pairs of kinetosomes then migrate away from each other. Meanwhile, division of the nucleus begins: chromosomes become visible, the nucleus extends perpendicularly to the cell axis, and the spindle forms within it. The membrane of the nucleus remains intact during mitosis.

Rhizoplasts attach to both poles of the dividing nucleus; after karyokinesis, the two daughter nuclei remain associated with the rhizoplasts and through them also with the respective kinetosome pair. The mitochondrion divides during the telophase. Cytokinesis continues from the anterior to the posterior end of the cell. The life cycles of *Proteromonas* and *Karotomorpha* include cysts, which permit transmission from one host to another. The cysts are spherical, have a distinct cyst wall, and contain a single nucleus and a single mitochondrion surrounded with abundant glycogen granules. The rhizoplast is retained near the nucleus. Neither subpellicular microtubules nor flagella (or kinetosomes) were observed in cysts, however, the cysts may contain bacteria (Brugerolle and Joyon 1975).

Blastocystis

Unlike other Opalinata, *Blastocystis* is easily overlooked in fecal samples and may be confused with other objects. It does not move and may be of variable size and morphology. Therefore, molecular methods or cultivation might be preferred in routine diagnostics. The most commonly observed (and most easily diagnosed) form is the vacuolar form (see below).

Morphology and Different Forms. The described variability of sizes and shapes of *Blastocystis* cells is somewhat confusing. It is important to bear in mind the unusual genetic variability among *Blastocystis* isolates, which may account for differences among reports. Moreover, some observed forms may represent culture artifacts or degrading cells (Vdovenko 2010). A single *Blastocystis* strain can alternate between several forms. The best known of them is the vacuolar form (Fig. 3). Cells of this morphotype are spherical and usually have a diameter of several to about 15 μm, although much larger cells (up to hundreds of micrometers in diameter) were also observed (Zierd 1991). Their central vacuole occupies the majority of the cell volume. The vacuole most probably serves a storage function. It is surrounded by a layer of cytoplasm with one or more nuclei, mitochondria, Golgi complexes, and other typical eukaryotic organelles (Stenzel and Boreham 1996). The surface of vacuolar form cells is often covered with a fibrillar layer (surface coat), especially in freshly isolated cells. Although several mechanisms of multiplication were described, binary fission seems to be the predominant (if not the only) reproductive process (Tan 2008). Under certain conditions, granular forms may appear in cultures: these are similar to the vacuolar forms, but contain granules in the vacuole and/or cytoplasm (Dunn et al. 1989). Rarely, other forms were also reported, often from fresh stool samples: avacuolar and multivacuolar forms, with no or multiple vacuoles, and the amoeboid form (Stenzel and Boreham 1996). The latter also appears if *Blastocystis* is cultured on solid agar. Amoeboid cells are irregular in shape, seemingly nonmotile (although producing pseudopodia-like appendages), may or may not contain the central vacuole, and may differ in their ultrastructure (cf. Dunn et al. 1989; Tan and Suresh 2006). *Blastocystis* infects new hosts via small (up to about 5 μm) spherical-to-ovoid cysts (Stenzel and Boreham 1991; Tan 2008; Zaman et al. 1995).

Genomic Data. The growing interest in *Blastocystis* has resulted in the sequencing of several genomes, both mitochondrial (Pérez-Brocal and Clark 2008; Wawrzyniak et al. 2008) and nuclear (Denoeud et al. 2011). Both genomes are relatively small and show considerable reduction in gene number compared to other stramenopiles (Clark et al. 2013). The mitochondrial genome of *Proteromonas* has also been sequenced (Pérez-Brocal et al. 2010). Although its gene content is very similar to that of the *Blastocystis* mitochondrial genome, the two genomes differ strikingly in structure: it is circular in *Blastocystis*, but linear in *Proteromonas*. Because these organisms are anaerobes and the metabolism of their mitochondria is highly modified (Stechman et al. 2008), the mitochondria are often called "mitochondrion-like organelles."

Maintenance and Cultivation

Opalinids can be easily retrieved from the frog intestine in large numbers. They can survive for up to several weeks in various media based on buffered saline solutions that are commonly used for the culturing of intestinal protists (see Delvinquier and Patterson 1993). It seems, however, that long-term cultures of opalinids are quite hard to establish and maintain (e.g., Wessenberg 1978), although several reports of successful cultivation exist. Lwoff and Valentini (1948) established a bacteria-free culture of *Cepedea* in a complex medium containing (among other ingredients) boiled frog liver and autoclaved frog rectal content. Interestingly, during late spring, cysts appeared in their cultures. After the cultures were contaminated by Gram-negative cocci, the opalinids grew better. Cultivation was also achieved by Yang and Bamberger (1953) and Yang (1960), who initially used egg slants overlaid with buffered saline (pH 7.8) supplemented with inactivated serum and antibiotics and later substituted the slants with liver concentrate.

Kulda (1973) established an axenic culture of *Proteromonas lacertaeviridis* at room temperature on Diamond's TYM medium (Diamond 1957) supplemented with inactivated horse serum and a trace of agar. Before reaching the axenic state, proteromonads were for some time (several weeks) cocultivated with a yeast (*Candida* sp.) from the lizard host. They were later separated from the yeasts by repeated migration. Bacteria were eliminated from the primary culture with the use of antibiotics. For short-term purposes, both *Proteromonas* and *Karotomorpha* can survive several hours or days in various saline solutions commonly used for isolation of intestinal flagellates, for example, Ringer's frog solution: NaCl 6.5 g, KC1 0.14 g, $CaCl_2$ 0.12 g, and $NaHCO_3$ 0.20 g in 1000 ml H_2O (Brugerolle and Mignot 1989).

Blastocystis grows well xenically in various media and may be axenized (Tan 2008). For xenic cultures, Jones' medium (Jones 1946) is often used. Axenized strains may be cultured in commercially available Iscove's modified Dulbecco's medium + horse serum (Clark and Diamond 2002). The ability of *Blastocystis* to form colonies on agar plates may be exploited during axenization and cloning (Tan et al. 2000).

Evolutionary History

There is no direct (i.e., fossil) evidence of the evolutionary history of Opalinata. The close link of opalinids to frogs (and also the geographical distribution of opalinid genera) suggests that their main radiation dates back to the Mesozoic. Hypotheses on the evolution within the group are based on morphological data: the number of nuclei (two/many) and cell shape (flat/cylindrical). Because all four possible combinations of the character states are found among opalinids, every evolutionary scenario requires convergence and/or reversal of some of these characters. Generally, the binucleated state is considered primitive and the multinucleated genera are believed to form a monophyletic derived group (Opalininae). Relationships among the three binucleated genera and Opalininae are unclear, but it has been suggested that *Protozelleriella* might be the most primitive representative of Opalinidae, indicating that the cells of *Zelleriella* are primitively flattened. The monophyly of Opalininae is supported by their geographical distribution and several ultrastructural features (Patterson and Delvinquier 1990), as well as by molecular data (Nishi et al. 2005). However, both electron microscopy and PCR-based sequencing were applied to a very limited number of species (and none belonging to *Protozelleriella*!).

Relationships of opalinids to other protists were mysterious for a long time. Their superficial resemblance to ciliates had led nineteenth-century protistologists to place opalinids in this group, although some criticism of this concept appeared early on. Phylogenetic affinities of opalinids were discussed in detail by Metcalf (1918), who erected a new subphylum Protociliata to accommodate opalinids separately from "other," true ciliates. This arrangement satisfied many authors as it reflected both the morphological uniqueness of opalinids and the possibility that they formed a phylogenetic connection between flagellates and ciliates: the presence of two (or many) nuclei, cilia arranged in kineties, and sexual processes in the life cycle of opalinids were long perceived as features that one would expect in a hypothetical ancestor of ciliates (Wessenberg 1978). The debate – whether or not opalinids represent an intermediate stage between flagellates and ciliates – went on for several decades, with the majority of authors deserting the idea of a close affinity between ciliates and opalinids. They thus remained orphaned as an isolated taxon among flagellates (Corliss 1955; Grassé 1952), which is, more or less to say, an isolated taxon among eukaryotes.

The situation changed when substantial electron microscopy data emerged. A key study was that of Patterson (1985), who highlighted that there are several ultrastructural characteristics shared by opalinids, *Proteromonas* and *Karotomorpha*, as already noticed by Brugerolle and Joyon (1975). The arrangement of kinetosomes and associated structures is very similar and another synapomorphy is the folded cell surface, with the folds supported by single microtubules (*Proteromonas*) or microtubular ribbons (*Karotomorpha* and Opalinidae). These and other similarities led Patterson to postulate a close relationship between opalinids and proteromonads and to establish a new order Slopalinida comprising the two groups. The paraphyly of proteromonads was also recognized;

Karotomorpha, with its pellicular folds supported by ribbons of microtubules and more flagella, is more closely related to opalinids than to *Proteromonas*. Some of the details of the kinetosome ultrastructure link slopalinids to other stramenopiles, as do other features of *Proteromonas* in particular (e.g., somatonemes). The molecular phylogenetic study of Silberman et al. (1996) not only supported the monophyly of stramenopiles and the placement of slopalinids among them but also revealed an unexpected relationship between slopalinids and *Blastocystis*. The close relationship between *Proteromonas*, *Karotomorpha*, and Opalinidae was later confirmed by molecular studies based on SSU rDNA (Kostka et al. 2004, 2007, Nishi et al. 2005). Interestingly, the study of Nishi et al. (2005) did not refute a possible link between opalinids and ciliates: phylogenetic analyses of tubulin genes tend to connect the two groups, although probably artefactually. Opalinata relationships are further discussed by Cavalier-Smith (1997, 1998) and Cavalier-Smith and Chao (2006). In these works, *Karotomorpha* and opalinids were treated together in the group Opalinea to the exclusion of *Proteromonas*. In later papers, *Proteromonas* was included (Cavalier-Smith and Scoble 2013; Ruggiero et al. 2015) – the expanded Opalinea group has then exactly the same composition as Patterson's Slopalinida; the group containing only *Karotomorpha* and opalinids was called Opalinida therein.

Abstract

The phylum Apicomplexa is a large group of parasitic protists with more than 6,000 described and possibly thousands of undescribed species. All species are obligatory parasites, and potentially every vertebrate and majority of invertebrates host at least one apicomplexan species. More frequently apicomplexans are specialists with rather high host specificity; nevertheless, generalists with low host specificity exist. Many species are highly pathogenic to their host including human and domestic animals and from medical perspective represent the most important eukaryotic parasites. Coccidians are omnipresent in vertebrates, e.g., virtually all poultry and rabbits are infected by several host-specific *Eimeria* spp.;

theileriosis is responsible for enormous losses in cattle farming; about 20% of global human population is infected by *Toxoplasma gondii*; and, finally, *Plasmodium falciparum* and other *Plasmodium* species cause globally distributed malaria, which kills millions of people in tropical countries.

The phylum Apicomplexa includes morphologically and ecologically diverse protists, such as the gregarines, cryptosporidia, coccidia, haemosporidia, and piroplasms. The life cycle of majority of Apicomplexa involves sexual and asexual multiplication in the parasitized host and an environmentally resilient cyst forms. Transmission strategies are diverse, from direct transmission to intricate cycles in trophic webs between predators and their prey or involving arthropod vectors.

The phylum is highly successful, thanks to morphological and molecular adaptations. The name is derived from two Latin words, *apex* (top) and *complexus* (infolds), and refers to a set of organelles composed from spirally arranged microtubules, polar ring(s), and secretory bodies, such as rhoptries and micronemes. Apical complex structures mediate entry of the parasite into the host cells, where they usually survive inside a parasitophorous vacuole. Most apicomplexans possess a unique organelle called the apicoplast, which is a highly reduced non-photosynthetic plastid, which retains few functions essential for a parasite survival. The phylum evolved from a photosynthetic flagellate, and core apicomplexans form a sister group to a free-living marine and freshwater protists (*Chromera*, *Vitrella*, and *Colpodella*).

Introduction

General Characteristics

The Apicomplexa (Telosporea, Sporozoa) are parasitic.[1] heterotrophic protists that form uniformly banana-shaped uninucleate stages. Apicomplexans move by gliding motion, and at least one stage is characterized by apical secretory organelles releasing their content through a microtubule-anchored ring. The rod-shaped micronemes and bulk-shaped rhoptries are both essential components typifying the phylum Apicomplexa. A majority of species have complex parasitic life cycles, with alternating asexual and sexual multiplication. They either possess a respiring mitochondrion or a non-respiring mitosome. Apicomplexa contain a multimembranous compartment, now known to be a modified chloroplast, termed apicoplast, acquired via endosymbiosis of a photosynthetic alga. The apicoplast is neither photosynthetically active nor present in all extant members of the phylum; however, if present, it is an indispensable organelle.

The core of Apicomplexa is traditionally divided into three major obligatory parasitic classes (hematozoa, coccidia, and *gregarines*). The sister group of the core apicomplexans has been widely debated over the past 30 years. Colpodellids, free-living predatory protists of previously uncertain status, are now considered a sister group to the monophyletic hematozoans, coccidians, and gregarines.

[1]Parasitism is a type of symbiotic relationship between two different organisms – parasite and host. Three distinct types of parasitism are considered: biotroph, hemibiotroph, and necrotroph. Apicomplexans should be classified as biotrophs and partially as hemibiotrophs. Necrotrophs utilize dead animal tissues as a source of nutrients, while apicomplexans benefit from a prolonged, close association with the living host cells only.

Parasitic apicomplexans have a bad reputation for causing malaria, toxoplasmosis, coccidiosis, and other serious diseases of humans and animals. Recently discovered photosynthetic alveolates *Chromera velia* and *Vitrella brassicaformis* are together with heterotrophic colpodellids closely related to the core apicomplexans.

History of Knowledge

The symptoms of malaria were first described more than 5,000 years ago in Egyptian papyri, and this plague appears in historical records of Greeks and Romans (Cox 2010). Yet the first apicomplexan was spotted by Antony van Leeuwenhoek, who in 1674 observed under his famous microscope coccidian oocysts in the bile of a rabbit. However, thanks to their size, gregarines were the first apicomplexans to attract interest of early protozoologists. The genus *Gregarina* from an insect was described by Leon Dufour in 1828, and they already appeared as a protistan group in the classification of Ernst Haeckel in 1866.

Meanwhile, research on malaria, one of the major scourges of humankind, gathered momentum. In 1880, Charles Laveran became convinced that the pigment in erythrocytes of his patients is a parasite. Within the same decade, Alexander Danilewski discovered several other intracellular parasites in the blood of vertebrates and called them haemosporidians, while Ilya Metchnikow recognized their relationship with coccidians. It was, however, not firmly established until 1897, when Ronald Ross proved that the parasites causing malaria are transmitted by mosquitoes, for which he was awarded the Nobel Prize in 1902. A major contribution to the understanding of the malarial life cycle came also from Giovanni Battista Grassi ("there is no malaria without *Anopheles*"). One more Nobel Prize for research on malaria went to Julius von Wagner-Jauregg, who in 1917 discovered that syphilitic patients can be treated by controlled malaria infection. William Trager is credited for seminal discoveries, such as continuous cultivation of the erythrocytic stages. The last Nobel Prize for research on malaria went in 2015 to Youyou Tu for her discoveries concerning a novel therapy.

The first piroplasmid was described from the blood of cattle during the 1880s epidemic of the Texas cattle fever in the USA. Intracellular blood stages, later included in the genus *Babesia*, were described in 1888 by Victor Babeş. Only a few years later, Theobald Smith and Frank Kilbourne successfully transmitted a related organism to a noninfected cattle via a tick, being first to show that invertebrates can serve as vectors of a parasitic disease. Another Nobel Prize was awarded in 1951 to Max Theiler for his breakthrough studies of the life cycle of *Theileria*. The most widespread apicomplexan, *Toxoplasma gondii*, was first observed in 1908 by Charles Nicolle in a semidesert rodent, the common gundi (*Ctenodactylus gundi*), which was being used for leishmaniasis research in the laboratory of the Pasteur Institute in Tunis (Dubey 2014). Yet it took most of the twentieth century to decipher its intriguing life cycle, because the cat was successfully identified as the host shedding the oocysts only in 1970.

Since their description, the systematics of the apicomplexans had undergone periodical changes. Early influential reviews were published more than a hundred years ago by Labbé (in 1899) and Minchin (in 1903), later followed by the system proposed by Wenyon (in 1926). The pre-electron microscopy era was summarized by Pierre-Paul Grassé (in 1953). The intense studies by electron microscopy in the 1960s and 1970s that resulted in the identification of common ultrastructural features at the apical end prompted Norman Levine to propose the name Apicomplexa for these protists.

Mutual relationships of major groups within the phylum were differently assessed by influential authors, such as Emile Vivier and Isabelle Desportes (in 1980). An exhaustive list of all named species was compiled by Norman Levine (1988), and a recent account of the classification of the parasitic Apicomplexa is reviewed by Frank Perkins et al. (2000). Avian blood parasites have been reviewed exhaustively by Gediminas Valkiūnas (2004).

Practical Importance

Apicomplexans represent an obligatory parasitic lineage with an enormous diversity and more than 6,000 named species infecting invertebrates and mostly vertebrates. Even though under natural conditions most parasitoses are asymptomatic, some Apicomplexa are causative agents of serious human and animal diseases. With no doubt, the main importance rests in the pathogenic character of the species described below (see also Seeber and Steinfelder 2016).

Although the majority of haemosporidians are parasites of wild animals (reptiles, birds, and mammals) exerting only a negligible effect on their hosts, some are responsible for very serious, even fatal diseases. Most notorious are several species of *Plasmodium*, the causative agents of malaria, responsible for enormous human suffering and economic loss in most tropical countries. Human malaria used to be widespread also in the temperate zone, from where it was successfully eradicated after the Second World War. *Plasmodium* is considered one of the most frequent agents of deaths in the history of humankind, even now killing about half a million people annually, particularly children in sub-Saharan Africa (Gething et al. 2011). For good reasons, it is one of the most well-studied protists, yet only a few effective drugs and no fully protective and effective vaccine against human malaria are available.

The east coast fever (theileriosis) and bovine tropical theileriosis in cattle and water buffaloes are caused by *Theileria parva* and *T. annulata*, respectively (Bishop et al. 2004). Several *Babesia* species are responsible for babesiosis of cattle, horses, dogs, and rarely also humans. Poor growth, low milk production, and mortality of infected animals resulted in several efforts to control piroplasmoses. Before implementation of successful eradication programs focused on vectors, the costs of the piroplasmosis were estimated at more than 100 million dollars in direct and indirect annual losses in the USA only. While under control in developed countries, these

diseases still cause serious economic loss in tropical and subtropical countries. Since the eradication of tick vectors is not realistic in most tropical countries, there is a demand for effective control of piroplasmoses by alternative approaches. Vaccines using live attenuated *Babesia bovis* and *B. bigemina* are commercially available and millions of doses of the combined vaccine have been used in the New World and Australia (Jackson et al. 2001). The development of live vaccines against bovine babesiosis was prompted by early observations indicating that cows that recovered from natural *Babesia* spp. infections developed long-lasting immunity. However, vaccines using live *Theileria* parasites, soluble antigen from *Babesia* species (e.g., the vaccine for canine babesiosis was marketed in parts of Europe), or vaccines composed of subunits are being developed or have even reached the stage of clinical trials but have yet to be tested on a large scale.

Toxoplasma gondii, causing toxoplasmosis, is the most widespread protozoan parasite capable of infecting virtually every mammalian (and bird) host species including man, with 15–70% of the human population seropositive (Tenter et al. 2000). Most infections in humans are asymptomatic or mild, even in the acute phase. Yet on the other hand, congenital toxoplasmosis in fetuses can result in serious eye (chorioretinitis) and brain damage (encephalitis and hydrocephalus). Equally important may be the impact of chronic toxoplasmosis on human behavior (Flegr 2007). Neosporosis, caused by *Neospora caninum*, a parasite closely related to *T. gondii*, is found worldwide in dogs, cattle, and other mammals. Relatively recently, *N. caninum* has been implicated as an important cause of abortion in cattle due to congenital infection (Reichel et al. 2013). Numerous *Sarcocystis* species form cystic stages in muscular tissues of various wild animals and under certain circumstances make these hosts more vulnerable to their predators, which represent definitive hosts.

Several *Eimeria* species causing coccidiosis are widespread in poultry farms and represent a major cause of morbidity and decreased weight gain implying economic losses to the industry by direct mortality, decreasing food conversion rate and expenses connected to anticoccidial medication or vaccination. With about 40 billion chickens raised annually worldwide, the disease is estimated to cost upward of 800 million US dollars per annum. Management of coccidiosis through anticoccidial drugs and vaccines using live attenuated *Eimeria* species has critical implications for the poultry industry, while other species negatively affect rabbits and farm ruminants (Allen and Fetterer 2002). *Cystoisospora suis* is the causative agent of an acute diarrhea in piglets. The waterborne *Cyclospora* and *Cryptosporidium* species are important for public health as the causes of diarrhea. Recent Global Enteric Multicenter Study identified *Cryptosporidium* as the second most common pathogen in infants in developing countries (Kotloff et al. 2013). Cryptosporidiosis may cause, under favorable conditions, diarrhea of epidemic proportions even in developed countries. Several *Cryptosporidium* species cause watery diarrhea in humans and are held responsible for gastrointestinal disease and morbidity of HIV-infected patients.

Similar to other infectious diseases and pathogens, several apicomplexan parasites have been introduced to nonnative continents, with their subsequent spreading

through the new areas, as in the case of avian sarcosporidiosis (*Sarcocystis rileyi*) introduced to Europe from North America. Moreover, some etiological agents could be considered as emerging diseases, as in the case of small intraerythrocytic piroplasm *Cytauxzoon felis* in domestic cats or cyst-forming sarcosporidia, *Besnoitia besnoiti*, an emerging pathogen of cattle coursing besnoitiosis mainly in Europe.

Several poorly studied species are also known to infect invertebrates. The most common among them are gregarines, which could inflict serious damage to insect farms or in laboratory colonies. At the same time, various apicomplexan parasites have a potential as agents for biological warfare against the crop, animal, and human pests and vectors, yet for such applications, they have never been put into effect on a large scale.

Habitat and Ecology

Apicomplexans are obligatory parasites, fully dependent on their hosts throughout most of their life cycle. As highly sophisticated parasites, apicomplexans benefit from their prolonged and close association with the host, which they exploit for food, habitat, and dispersal in order to increase their fitness. The act of parasitism reduces host fitness in causing pathology or altering the behavior or social status of the host. In the wild the pathology of most species is low, and the infected hosts usually show no signs of the disease. However, under intensive farming conditions or after the introduction into new susceptible hosts in non-endemic areas, these parasites may cause high morbidity and mortality.

Obligatory Dependence on the Host

The Apicomplexa obtain food (nutrient sources) from the host. Being dependent on a host requires tools and mechanisms to access its metabolites. The apical complex with its repertoire of secretory organelles is the key to the global success of this group of protists. While the apical complex is the unifying morphological feature of the phylum, the means of host exploitation are enormously diverse. By attaching to the host cell via their apical end, gregarines remain extra- or epicellular, with the host cell remaining virtually unaltered. In the case of cryptosporidia, the host cell envelopes the parasite with its flat membrane folds, while the only contact zone between both cells, termed the feeder organelle, is a highly modified interface. Coccidians and hematozoans are intracellular parasites, usually with a complex life cycle, undergoing remarkable morphological transformations allowing them to persist in diverse locations within their hosts. For example, *Plasmodium* is capable of flourishing in both mosquitoes and humans, where it can modify the surface of the infected red blood cells by exporting its proteins through membranes and the lumen of the host cell.

Localization in the Host

In the initial stage of invasion, the motile zoite (Fig. 1) will find the target tissue and establish the infection (Fig. 2). During the development, the intra- and extracellular phases may alternate, although a vast majority of species develop inside of the host cell (Bartošová-Sojková et al. 2015). The life cycle is terminated by a stage resistant to unfavorable conditions that is usually excreted during the host's life, or is released into the environment after its death. Some heteroxenous species do not form any exogenous stages as they are transmitted via ingestion/inoculation by blood-feeding arthropods.

Extracellular parasites. All extracellular species belong to the gregarines. They develop mostly in the digestive tract but can also be found in the respiratory and excretory organs. Even the extracellular gregarines are almost permanently attached to the host cell, this association is being terminated only prior to the extrusion of the parasite into the environment. The epicellular localization represents a transitional form between the extra- and intracellular parasitism. It is characteristic

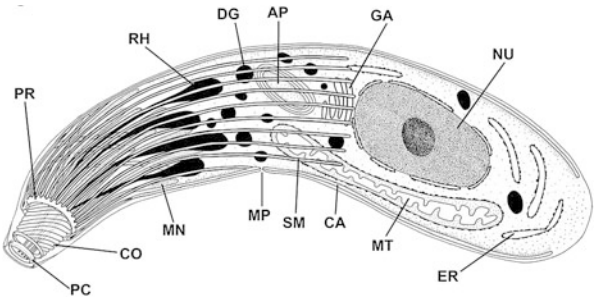

Fig. 1 3D structure of a typical sporozoite or merozoite. *AP* apicoplast, *CA* cortical alveoli, *CO* conoid, *DG* dense granules, *ER* endoplasmic reticulum, *GA* Golgi apparatus, *MN* micronemes, *MP* microporus, *MT* mitochondrion, *NU* nucleus, *PC* pre-conoidal rings, *PR* polar ring, *RH* rhoptries, *SM* subpellicular microtubules

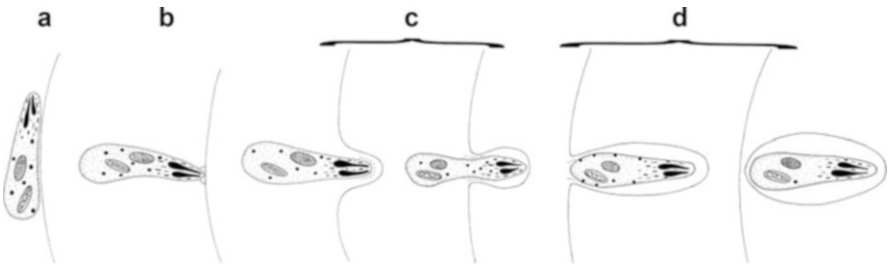

Fig. 2 Invasion of the apicomplexan zoite into a host cell. Primary contact of the zoite without orientation (**a**); attachment followed by the apical reorientation (**b**); induction of the parasitophorous vacuole (**c**); translocation of the zoite into the vacuole (**d**)

for cryptosporidians, which communicate with the host cell via a specialized feeder organelle, which closely resembles the attachment site of some gregarines. Many intracellular species have an extracellular phase in their life cycle, during which a cystic stage is released into the environment, where it awaits ingestion by a new host.

Intracellular parasites. The Apicomplexa are able to invade almost any cell type, *T. gondii* being a prime example of such an indiscriminate strategy. The parasites are either in direct contact with the host cell cytoplasm or are encircled by a "parasitophorous vacuole" formed by components of both the host and parasite cells. Several types of location within the host cell can be distinguished: (i) intracytoplasmic location is typical for most coccidians and hematozoans; (ii) extracytoplasmic location on the periphery of the epithelial cell facing the lumen, during which direct communication with the host cell cytoplasm is maintained, is characteristic for some coccidians of cold-blooded vertebrates; (iii) some coccidians are localized inside the host cell nucleus.

Furthermore, the intracellular stages can be subdivided based on their activity. Usually, upon host cell invasion, the zoite starts to divide and the life cycle proceeds fairly rapidly. However, when the zoite transforms into a dormant stage (dormozoite), the growth becomes arrested, and the stage can persist unchanged for years. It will, however, be awakened by stimuli, such as a change in the health state of the host or by the ingestion of the host by a predator. Another life form, the oocyst, is usually released into the external environment, where it may exist for a long period of time without growth, supporting itself from storage organelles until the next host is encountered.

Multiple Species in One Host

It has been predicted that each multicellular organism hosts at least one apicomplexan species, yet this simplified view is incorrect. Detailed studies of the medically and veterinary important hosts revealed that a single host species may be exploited by more than a dozen of distinct apicomplexan species affecting different host tissues. However, for most host organisms, only an incomplete record exists, keeping the diversity of apicomplexans largely unknown.

Fowl coccidia, the major problem in the poultry industry and the cause of chicken coccidiosis, are an example of such multispecies phenomenon. At least seven distinct *Eimeria* species are found in chicken, each occupying a specific habitat within the gastrointestinal tract (Clark et al. 2016). The most devastating species is *Eimeria tenella*, a parasite of caeca (Sharman et al. 2010). The enormous capacity to propagate is illustrated by the fact that each oocyst of *E. tenella* is theoretically capable of producing 2.5×10^6 oocysts within just 5 days. Besides their specific location within the intestinal tract, individual species invade mucosal cells either at the tips of the villi or in the crypts, while others found the interior of the villi as the most suitable environment. A complete set of economically significant coccidia infecting rabbits along with their specific location with the host is shown in Fig. 3

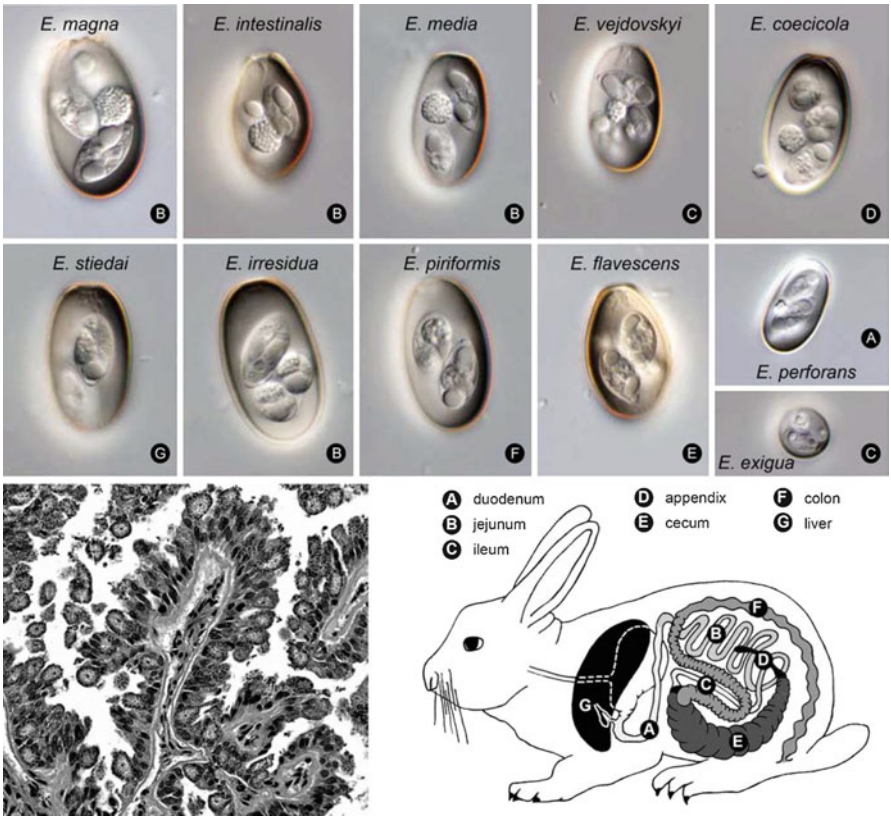

Fig. 3 Multiple *Eimeria* species infecting rabbit. Sporulated oocysts of 11 named *Eimeria* species parasitizing rabbits. Morphologically similar oocysts are distinguished by their size, shape, the presence of the micropyle, and the presence/absence and characteristic structure of the oocyst residuum. Individual species differ in the location in and pathogenicity for the host. The picture in the lower left corner shows proliferative changes in bile ducts with multiple gamogonial stages of *E. stiedae*

(Duszynski and Couch 2013). Thus, each parasite secures its distinct niche within the host organism. *Cryptosporidium* species exploit both the gastric mucosa and the intestinal mucosa. Similarly, human malaria is caused by four distinct worldwide distributed species – *Plasmodium falciparum*, *P. vivax*, *P. ovale*, and *P. malariae* – circulating among humans via the *Anopheles* mosquito vectors; however, at least one more species, *P. knowlesi*, sometimes called the fifth human malarial parasite, which is principally a pathogen commonly found in nonhuman primates in Southeast Asia, may also infect humans (Tenter et al. 2000; Singh and Daneshvar 2013). Each human *Plasmodium* is characterized by a distinct life cycle pattern in the host. By far the most devastating is *P. falciparum*, causing malignant tertian malaria with indefinite multiplication of asexual stages in the red blood cells.

Parasitism and/or Mutualism

The apicomplexans often affect their hosts in highly sophisticated ways. In the two-host life cycles and particularly in those exploiting the predator-prey relationship, the success of the parasite is directly linked to the consumption of the infected prey by the predator. Thus, any mechanism that increases susceptibility to predation enhances the parasite's fitness (Vorisek et al. 1998). On the other hand, (very) low virulence of the parasite for the predator, as often seen in species such as *Toxoplasma* and *Sarcocystis*, can be considered as commensal or even mutualistic rather than parasitic. Since mutualism is a form of coexistence (symbiosis) enhancing the fitness of both partner organisms, it is not surprising that in evolutionary terms the long relationship between coccidians and their hosts frequently developed from parasitism into commensalism or mutualism. For example, *Sarcocystis* (syn. *Frenkelia*) *microti* and *S. glareoli* circulate between buzzards and small rodents, its definitive and intermediate hosts, respectively. While in buzzards it causes no symptoms, large cysts in the brains of rodents make them more vulnerable to the predator. The mechanisms behind such an increased susceptibility do not seem to be associated with cellular pathology, but the parasite most likely changes the social status or behavior of the infected individual. In another example, rats and mice infected with *T. gondii* lose fear of the odor of feline urine. Importantly, humans may also be manipulated by the ubiquitous *Toxoplasma* that may alter our behavior, psyche, and response to certain stimuli (Flegr 2013). However, the extent of alterations during human toxoplasmosis remains controversial.

The development of some monoxenous coccidians seems to follow circadian rhythms (Martinaud et al. 2009). It has been shown that oocysts of *Isospora* are significantly more prevalent in the feces of passerine birds excreted in the afternoon as compared to other parts of the day. Preferential shedding of the environmentally resistant oocysts in the afternoon can be explained by the avoidance of initial and/or prolonged harmful desiccation and UV.

Distribution

The Apicomplexa are virtually omnipresent. As parasites of the majority of vertebrates and invertebrates, they are distributed on all continents, on the ocean floor as well as in the air. Many species produce environmentally resistant envelopes that protect the parasite for months or years, either in the soil or water. *Cryptosporidium* is a typical example of a waterborne pathogen, the oocysts of which contaminate water sources and are passively transmitted to large areas, spreading the disease to new locations. Because of their minute size, these resistant stages can even be passively carried by insects. Blood-feeding arthropods also play a key role in the life cycles of medically and veterinary important hematozoans and piroplasms, the distribution of which follows the geographical range of their vectors. In fact some

estimates consider the Apicomplexa as the most specious group of eukaryotes, predicting the existence of million(s) of species (Pawlowski et al. 2012).

In the past, human colonization of remote places dramatically affected the distribution of many apicomplexan parasites. Transmission of the bird malaria caused by *Plasmodium relictum* is impossible without the compulsory vector mosquito *Culex quinquefasciatus*. Its introduction to Hawaii in 1826 triggered outbreaks of the avian malaria imported to the islands either by exotic birds released in the late nineteenth century or by migratory birds breeding in the Arctic. The total lack of immunity of the endemic Hawaiian birds to malaria caused by thousands of years of the absence of malaria resulted in epidemic mortality bringing some endemic species to the margin of extinction. Similarly, the appearance of avian malaria on the Bermuda Islands is directly linked to human encroachment. A Spanish sailor shipwrecked in 1603 on uninhabited Bermuda reported a total absence of mosquitoes. It is thus likely that the extinction of the endemic passerine birds in Bermuda was caused by the introduction of mosquitoes and alien passerines with malaria that had a similar devastating effect on the resident birds. Bovine babesiosis which has probably haunted farmers since the beginning of livestock production in warm regions of the Old World was later introduced into the New World by early settlers with imported cattle and the first documented reports date from around 1810 in North America.

One of the most successful parasites is undoubtedly *T. gondii* propagated in the form of an asexual clonal population. It is highly prevalent in all warm-blooded vertebrates, its success being supported by several key adaptations of its life cycle. The disease caused by asexually multiplying *Toxoplasma* is in most cases mild and self-limiting, leading to formation of dormant cystic stages in tissues. However, the host will remain an infectious passive carrier for life. Importantly, unlike other cyst-forming coccidians, *Toxoplasma* is able to bypass sexual development. The dormant cysts are capable of inducing an infection in any predator or scavenger munching on the animal tissues containing parasite cysts. The astonishing success of *T. gondii* has been recently explained by unique and ancient North and South American dichotomy of its former population that occurred prior to the reconnection of the Panamanian land and was coupled with a recent global sweep of few clonal populations. More than 95% of isolated strains in North America and Europe belong to just three clonal lineages (Howe and Sibley 1995) that have arisen ~10,000 years ago.

Characterization and Recognition

The Apicomplexa are distinguished by the complex and characteristic organization of the apical part of the invasive stages (the zoites, usually present both in sporozoites and merozoites, which alternate in the life cycle) and by the presence of a small inconspicuous organelle in the cytoplasm of all developmental stages – the apicoplast.

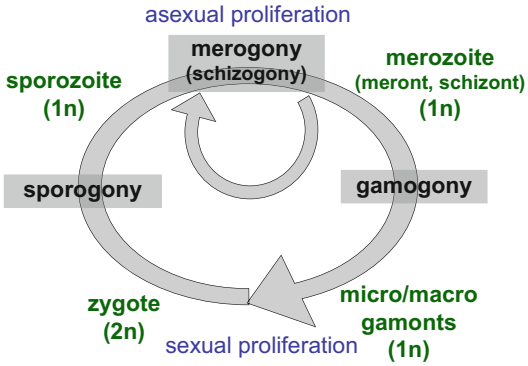

Fig. 4 Schematic drawing of a typical apicomplexan life cycle. See text for explanation

The Life Cycle

The life cycle of apicomplexans is rather complex and comes in several significantly different forms characteristic for main subgroups of the phylum. Its most simple form is known in gregarines, where it is composed of gamogony (the sexual phase) and sporogony (the asexual phase) (Fig. 4) (Ferguson et al. 2008). The life cycle of coccidians and haemosporidians contains asexual multiplication – merogony.

The life cycle usually commences with the release of a sporozoite from the oocyst/sporocyst (see below), an event that often takes place in the intestinal content of the host. The gliding sporozoite has a relatively short time to find a host cell, which it will penetrate by means of its apical complex and thus initiates the infection (Fig. 2). Shortly thereafter, organelles of the apical complex undergo resorption, and the elongate sporozoite transforms into an oval meront that starts growing. Upon reaching a critical size, the meront divides into a dozen to hundreds of merozoites (Fig. 5). These are similar in ultrastructure to the sporozoite and are destined to spread the infection to other host cells, where the cycle proceeds by a new generation(s) of meronts and merozoites. The next phase is characterized as gamogony, since some merozoites are predetermined to become female macrogametocytes, while the rest evolve into male microgametocytes (Fig. 6). The life cycle proceeds by fusion of a small flagellated microgamete with a large and nonmotile macrogamete. This conversion from a haploid into diploid phase is termed sporogony (Figs. 6 and 7) and is characterized by a species-specific number of cell divisions, leading to the formation of sporozoites, usually enclosed in a resistant sporocyst and/or oocyst wall (Figs. 6, 7, and 8). Upon the release of the sporozoites under favorable conditions (Fig. 9), the life cycle is completed, as their function is to transmit the infection into a new host.

Host Cell Invasion and Parasite Multiplication

The Apicomplexa are experts in host cell manipulation and immune evasion. *Toxoplasma gondii*, *Theileria* spp., *Plasmodium* spp., and others secrete different

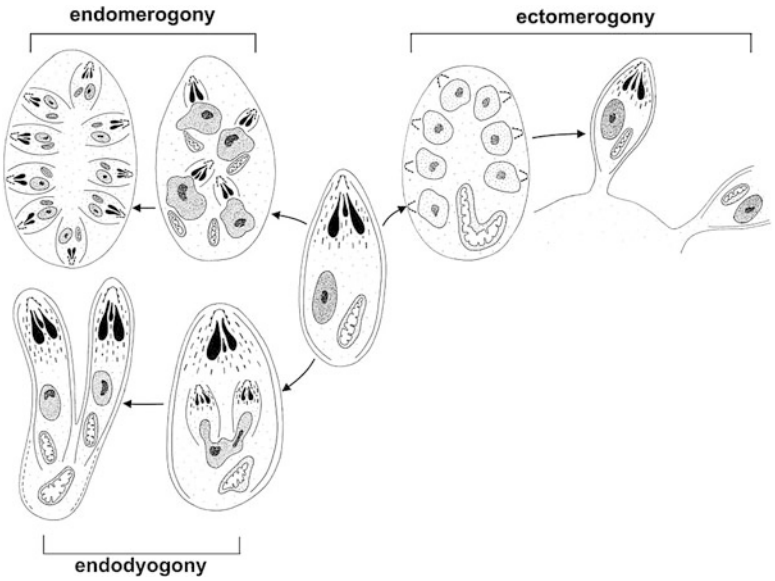

Fig. 5 Schematic drawing of main types of merogonial division. Merogonial division can proceed either via endomerogony (*upper left*), ectomerogony (*upper right*), or endodyogony (*lower left*)

effector molecules into the host cell to reach this aim. Invasion of an apicomplexan into the host cell is a complex action, some parts of which have yet to be elucidated (Baum et al. 2008). Generally, it consists of four phases: (i) primary contact without orientation, (ii) attachment followed by apical reorientation (with the exception of the genus *Theileria*), (iii) induction of the parasitophorous vacuole, and (iv) translocation of the parasite into the vacuole (Fig. 2). Attachment to the host cell via the apical end is followed by establishment of a connection through sequential secretion from the secretory organelles of the parasite. These unique extrusive organelles, represented by few claviform rhoptries, numerous filamentous micronemes, and round dense bodies contain molecules required for the interaction with the host cell (Besteiro et al. 2009). They are deployed in the course of the invasion and play various roles during intracellular development. Apically secreted adhesins from the micronemes are translocated along the parasite length and are shed at the site of the moving junction. This circumferential zone of moving junction is associated with a constriction of the parasite that moves from its apex to the posterior end. The parasite enters the nascent parasitophorous vacuole by capping the moving junction down its body, and components from the rhoptries are secreted into this newly formed compartment (Shen and Sibley 2012). Ultimately, the apicomplexan cell becomes enclosed within a cavity delimited by the invaginated host cell membrane. This protects the parasite against host immune mechanisms. On the other hand, brisk trade of nutrients is in motion among the parasite's surface, inner

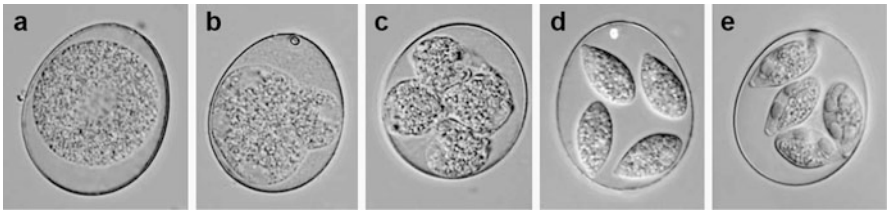

Fig. 7 Sporulation of *Eimeria maxima* from the intestine of a chicken. Unsporulated oocysts are shed with feces into the environment (**a**). When exposed to oxygen in an environment of appropriate humidity and suitable temperature, they undergo sporulation (it takes about 48 h at 25 °C before they become infectious). Upon asexual division through four sporoblasts (**b**, **c**), four sporocysts are formed initially full of granular material (**d**) that during sporulation wanes, until mature infectious sporozoites with remaining sporocyst residuum appear (**e**); note also process of formation of prominent Stieda bodies on poles of sporocysts (**d**, **e**)

membrane of the parasitophorous vacuole, and outer membrane of the infected cell (and thus with the surrounding environment).

Apicomplexan parasites replicate by internal budding termed merogonial division or merogony (schizogony in older literature) to create either two daughter cells (endodyogony) or multiple progeny (endopolygony, multiple synchronized endopolygony, and ectomerogony) that differ mainly in the preservation or loss of the maternal cell (see below) (Striepen et al. 2007). The apicomplexan nucleus divides by cryptomitosis (the nuclear membrane remains intact throughout the process), and karyokinesis occurs without chromosomal condensation.

The Sporozoite

This is the most characteristic stage of the phylum. The sporozoite is invariably elongated with a polar organization of its intracellular structures (Morrissette and Sibley 2002). Its size varies from less than 1 μm to about 25 μm in length. The tapered end is equipped with a conserved and specialized set of structural and secretary organelles labeled the apical complex (Fig. 1). Their extraordinary

Several types of the inner organization of the oocysts are shown: *Isospora*-like (two sporocysts, each with four sporozoites) (**b**); *Cyclospora* (two sporocysts, each with two sporozoites) (**c**); *Caryospora* (single sporocyst, containing eight sporozoites) (**d**); *Eimeria*-like (four sporocysts, each with two sporozoites) (**e**); *Wenyonella* (four sporocysts, each with four sporozoites) (**f**)

combination constitutes the very effective invasion apparatus responsible for an enormous evolutionary success of these parasites. The apical tip contains a polar ring, to which subpellicular microtubules are attached that stretch into the cell. Adjacent to the conoid are one or two apical rings composed of spirally arranged microtubules. The most prominent components of the apical complex are rhoptries and micronemes, secretory organelles full of molecules important for the invasion (see below). This cargo is of protein and lipid nature, specialized for intracellular parasitism. Rhoptries are often very prominent club-shaped organelles, whereas micronemes are usually rather thin, prolonged, and abundant ducts. Dense granules, usually located more distal from the conoid, have also recently been implicated with invasion. The specialized parasitophorous vacuole is formed with their help and its main purpose is to protect the apicomplexan from host attack, while the parasite can still obtain nutrients from the host. The most intensely studied organelle of the sporozoite is the apicoplast (see "Evolutionary History").

Sporozoites, same as all the other apicomplexan stages, also contain standard equipment of the eukaryotic cell, such as the nucleus, Golgi apparatus, endoplasmic reticulum, plasma membrane, and mitochondrion (Fig. 1). At first, the omnipresent

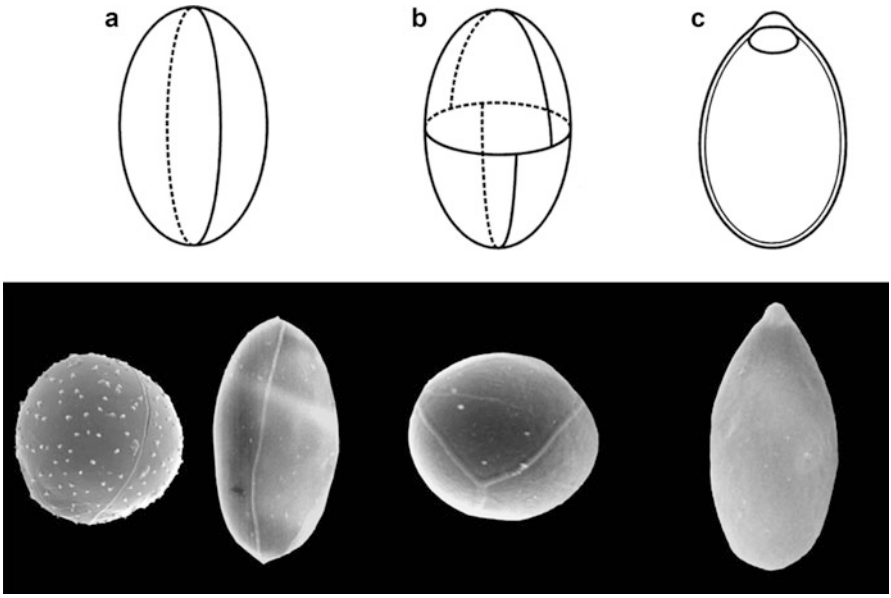

Fig. 9 Excystation structures of coccidian; schematic drawings and scanning electron microscopy of sporocysts. Probably ancestral opening of the sporocyst along a single longitudinal slit (*Goussia janae*, *Aggregata octopiana*) (**a**). Alternative opening by sutures in the sporocyst wall composed of four valves (*Cystoisospora suis*) (**b**). mitochondrion appeared to be missing from the *Cryptosporidium* species. Only recently, it was shown that this organelle is present in an extremely reduced form, termed mitosome, sandwiched between the nucleus and the crystalloid body (Keithly et al. 2005). The position of genus *Cryptosporidium* on the evolutionary tree of Apicomplexa is unresolved largely due to its highly divergent genome and unusual cellular biology (see below).

With the exception of some gregarines, sporozoites enter the host cell, and an intracellular development proceeds. The sporozoites of gregarines also penetrate the cell wall, and the apical portion of the cell develops into a family-specific attachment apparatus. While gregarine sporozoites of the family Ganymenidae and Lecudinidae attach via the so-called mucron, the remaining gregarines develop into a morphologically prominent epimerite, via which they penetrate into the host cell (Figs. 10 and 11). With most of its body extracellular, the sporozoite feeds on the epithelial cells, substantially increases its size, and develops characteristic longitudinal folds that likely propel its movement thru the intestine to other epithelial cells (Fig. 11).

Sporozoites are motile and for host cell invasion utilize gliding motility, which is propelled by the actin cytoskeleton and myosin motors. During the motility phase, micronemes secrete adhesions onto the apical part of the parasite's surface; hence, they are gradually translocated by an actomyosin-based complex. Visualization of the adhesions deposited during a sporozoite's movement can reveal its gliding

movement. In apicomplexans, host cell invasion always initiates by the attachment of the apical end to the host cell, and with just a few exceptions, in the next step, the parasitic cell induces invagination of the plasma membrane. This host membrane transforms into the parasitophorous vacuole enclosing the parasite and subsequently becomes massively altered by the insertion of various proteins and lipids primarily secreted by the rhoptries.

Meront and Merogonial Development

The intracellularly established meront starts intense feeding on the host cell via numerous micropores. In intracellular gregarines and all coccidians, the increase in size is characterized by the accumulation of amylopectin and lipid granules in the cytoplasm and nuclear division(s). The merogonial division (also called schizogony in older literature) may lead to the formation of only two cells within an intact, fully polarized mother cell, a process termed endodyogony (Fig. 5). Nuclear division in the polarized mother cell is followed by the formation of two buds, each composed of newly formed membrane complex and subpellicular microtubules (Striepen et al. 2007). The mature daughter cells finally appear from the mother cell.

However, in the course of more frequent merogonial division through multiple divisions, dozens to thousands of merozoites are formed, their number being usually

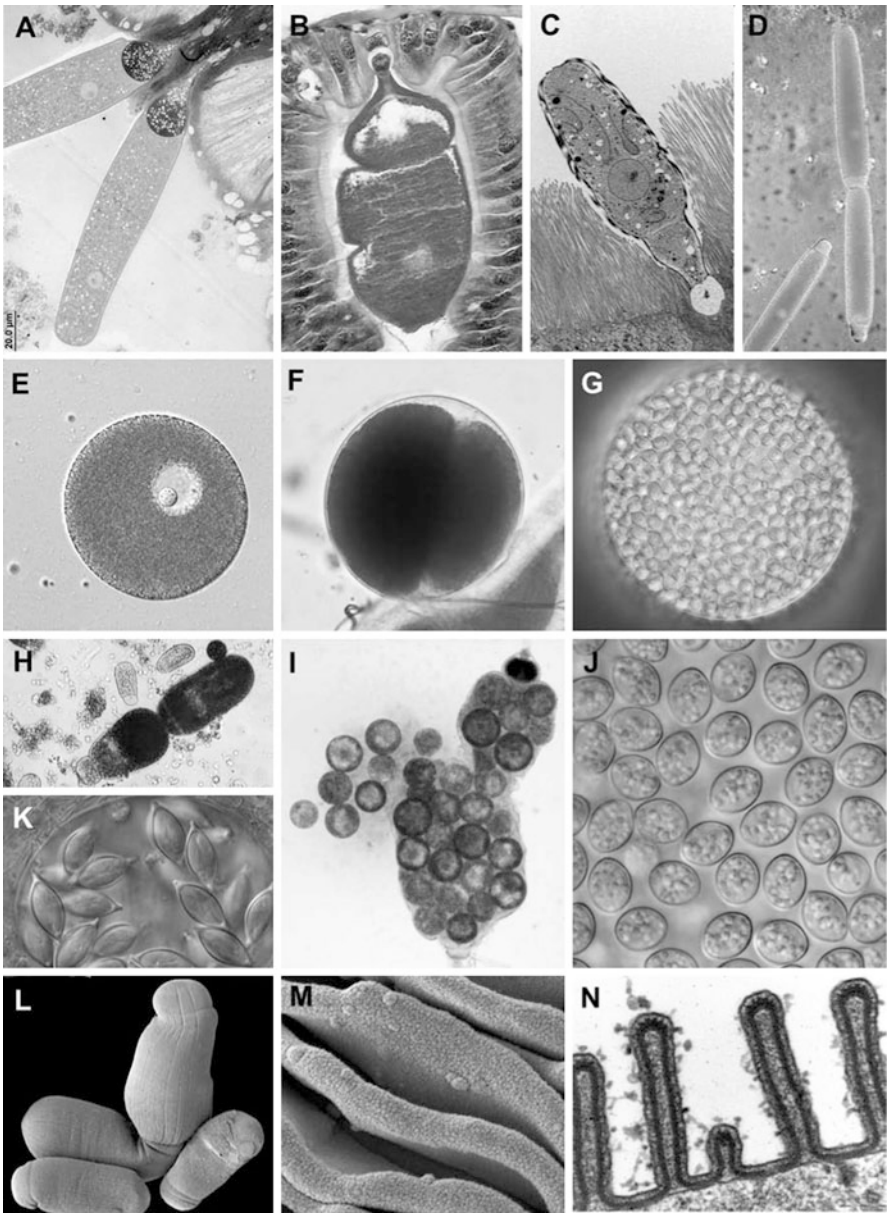

Fig. 11 Representative morphology of life cycle stages of gregarines. Mature trophozoites of *Gregarina polymorpha* (**a**) and *Gregarina garnhami* (**b**) attached to the host cell; mature trophozoite of *Gregarina steini* with a well-developed epimerite, invading a host cell (**c**); caudo-frontal syzygy of *G. polymorpha* (**d**); aseptate gamont of *Ascogregarina chagasi* containing a large nucleus and a prominent nucleolus (**e**); maturing gametocyst of *A. chagasi* with two gamonts separated by partition (**f**) and a gametocyst filled with numerous oocysts (**g**); gamonts of *Gregarina katherina* associated by caudo-frontal syzygy (**h**); sporulated biconical oocysts of *Monocystis* sp. (**i**); flea's

characteristic for a given species. The merogonial division exists either as endomerogony, during which the merozoites are formed within the mother cell, while exomerogony is characterized by merozoites that bud outside of the dividing mother cell (Figs. 5 and 6). The formation of progeny in the merogonial stage usually occurs in the host cell cytoplasm, although this phase of the life cycle may also be located in nucleoplasm of the host cell.

Upon their release from the ruptured host cells, polarized merozoites rely on energy sources that support only a short-time search (usually a few minutes) for a new host cell that they will invade. Following the invasion, the apical complex disassembles, the cell becomes oval and increases in size, the nucleus repeatedly divides, and another generation of merozoites is formed. The number of merogonial generations is usually species specific, ranging from one to a dozen or up to hundreds. Subtle morphological differences often allow assignment of given meront/merozoite to specific generations. The merogonial stages are responsible for rapid proliferation and most of the pathogenicity.

Sexual (Gamogonial) Development

The last generation of meronts enters the sexual phase of the life cycle by evolving into either micro- or macrogametes (Fig. 6); however, in hematozoans and piroplasms, gamonts emerge continuously as a product of specific part of meront populations. Sexual (gamogonial) development results in the production of large numbers of microgametes, or male sexual cells, and a much lower quantity of female macrogametes. Isogamous apicomplexans, haemogregarines and gregarines, where gamonts of each sex are equally numerous, represent exceptions. Young microgamonts contain numerous peripherally arranged nuclei and a homogeneous cytoplasm full of ribosomes, cisternae of endoplasmic reticulum, while lipid inclusions and other granules are small and relatively scarce. During maturation, the nuclei are juxtaposed to the cell surface, and the cell membrane forms dense thickening at the contact site, termed perforatorium anlagen. Mature microgamonts are usually large oval cells with invaginations on their surface. From their periphery, microgamonts emerge, equipped with an apical dense protrusion (perforatorium), one to three prominent flagella, a mitochondrion, and a dense elongate nucleus (Fig. 6). Each flagellum is supported by microtubules in the classical eukaryotic 9 + 2 arrangement (peripheral doublets with two centrally located microtubules).

Fig. 11 (continued) midgut filled with unsporulated gametocyst (**j**) and developing elliptical oocysts of a undescribed gregarine (**k**); two single gamonts of *G. garnhami* and two gamonts associated in caudo-frontal syzygy (**l**); epicytic folds of the apical region of protomerite of *G. garnhami* (**m**); cross-sectioned epicytic folds of *G. garnhami* with a newly formed fold rising between them (**n**). Histological sections (**a**, **b**), light microscopy (**d**, **e**–**k**), and scanning (**l**, **m**) and transmission electron microscopy (**c**, **n**)

The number of microgametes emerging from a single microgamont varies from dozens to thousands.

Early macrogamonts are large oval cells with a central nucleus and prominent nucleolus. The cytoplasm usually contains abundant, concentrically arranged cisternae of endoplasmic reticulum, electron-lucent amylopectin granules, lipid inclusions, electron-dense membrane-bound vesicles of various sizes, and mitochondria (Fig. 6). The amount of amylopectin inclusions as well as various vesicles increases in more advanced stages, and the cytoplasm becomes denser due to high number of ribosomes. Each macrogamont matures into a single macrogamete, which is fertilized by a microgamete, propelled by its flagella. All stages described so far were haploid, but fusion of the nuclei of micro- and macrogametes leads to a zygote, the status of which is diploid.

Sporogonial Development

In most cases fertilization occurs in the same tissue where the merogonial development is located, and this is also the site of the sporogonial phase, or sporogony (Fig. 7), with hematozoans and piroplasms representing exceptions. The zygote forms a protective wall around itself and sporogony, another process of asexual multiplication, yields a sporozoite-filled oocyst. Within the oocyst there are sporocysts, and within these are the sporozoites (Figs. 7 and 8). The oocyst and/or sporocyst wall is composed of several layers which possess a key role in the protection of the infectious and motile sporozoites that in many aspects resemble the merozoites (Figs. 1 and 8) (Belli et al. 2006). The sporozoites are usually released when the sporulated oocyst is eaten by another host. The morphology of oocysts, sporocysts, and sporozoites is one of the key characters of the taxonomy of most apicomplexan groups (Figs. 8 and 9).

Methods of Recognition

Absolute majority of apicomplexans are tiny protists not exceeding dozens of μm in size. They may be recognized with classical light microscopy, which usually suffices for taxonomic diagnosis. Exact species assignment requires the presence of morphologically informative stages. In gregarines and coccidian, these are in most cases trophozoites and oocysts, respectively. The determination of hematozoans is based on the morphology of stages in the blood cells. Thanks to their size reaching hundreds of μm, gregarines such as those infecting seminal vesicles of earthworms can be observed even by the dissecting stereomicroscope. Similarly, the cystic stages of some cyst-forming coccidia can sometimes be observed even with the naked eye, for example, as white nodules in the esophagus of infected sheep (e.g., *Sarcocystis gigantea*) or white fine threads in skeletal muscles (e.g., *Sarcocystis rileyi*).

Diseases caused by apicomplexans have been well recognized prior to the identification of the causative agent. Due to their impact on human health, certain apicomplexans are routinely associated with specific clinical symptoms in given endemic areas. Malaria is a prime suspect in all cases of cyclic fevers in tropical areas. Cryptosporidiosis is globally suspected in travelers' diarrhea. Coccidiosis manifested as diarrhea is always a threat in crowded conditions of intense farming, particularly of young animals.

For observing ultrastructural features, which are sometimes necessary for exact determination, the transmission and scanning electron microscopy are preferred approaches. Morphology is often insufficient, so host specificity is thus considered a leading criterion for species assignment. Completion of the life cycle, observation of the entire development, and elucidation of the host range are in many instances necessary. Public health authorities are particularly interested in the reservoir hosts for the zoonotic species and identification of the complete spectrum of vectors. Increasingly, molecular biology methods based on polymerase chain reaction (PCR), barcoding, and recently also next-generation sequencing (NGS) are being widely applied for detection and identification of apicomplexan species important in human and veterinary medicine. Genetic signatures linked to zoonotic transmission and clinical syndrome play an important role in current epidemiological investigations. In human malarias, fostered by multiple genome sequences and single nucleotide polymorphism (SNP) maps, gene modifications are being linked to antimalarial drugs.

Classification of Apicomplexa

The Apicomplexa comprise five principal working groups: gregarines, haemogregarines, coccidia, hematozoans (malarial parasites), and piroplasms, traditionally grouped into four classes. Besides these dominant groups, there is a myriad of small transitional groups or species, for example, the medically important cryptosporidia forming an independent group. The phylum classification is presented down to the suborder level. We annotate only major families, and for those with single or few representatives, we refer the reader to the work of Perkins et al. (2000), Tenter et al. (2002), and Adl et al. (2012).

The vividly discussed ancestry of the parasitic apicomplexans from predatory non-photosynthetic colpodellids can be found in Adl et al. (2012). Yet it is the photosynthetic chromerid species isolated from stony corals by Moore et al. (2008) that are currently the most favored as the closest living relative to the common ancestor of the phylum. Within this chapter, colpodellids and chromerids are considered "relict apicomplexa", while all the parasitic species are considered "core apicomplexa" (Table 1). The core apicomplexans represent a solid and well-defined group of eukaryotes, in contrary to their sister groups, here represented by, but not exclusive to, the two aforementioned groups. The quest for the basal relict apicomplexan is far from over (Table 1).

Table 1 Classification of Apicomplexa

Phylum: **Apicomplexa** Levine, 1970 emend. Adl et al., 2005	
Core apicomplexans (obligatory parasites)	
Subphylum: **Conoidasida** Levine, 1988	
Class: **Gregarinida** Dufour, 1828	Gregarines
Class: **Coccidia** Leuckart, 1879	Coccidia, haemogregarines
Cryptosporidida *incertae sedis*	Cryptosporidia
Subphylum: **Aconoidasida** Mehlhorn, Peters and Haberkorn, 1980	Hematozoa
Class: **Haemosporidia** Danielewsky, 1885	Haemosporidia (malarial parasites)
Class: **Piroplasmida** Wenyon, 1926	Piroplasms
Relict apicomplexans (free-living)	
Colpodellida Cavalier-Smith, 1993 *incertae sedis*	Colpodellids
Chromerida Moore et al., 2008 *incertae sedis*	Chromerids

Note: Commonly used vernacular names are indicated on the right. Colpodellida are ranked at the same level as Conoidasida and Aconoidasida in Adl et al. (2012)

Phylum Apicomplexa Levine, 1970 Emend. Adl et al., 2005

Apical complex generally consisting of polar ring(s), rhoptries, micronemes, conoid and subpellicular microtubules present at some stage; micropores present at some stage; cilia absent; all species parasitic; about 6,000 named species. The Apicomplexa has become more frequent in recent literature but not exclusive.

Subphylum Conoidasida Levine, 1988

Complete apical complex, including a conoid in all or most asexual motile stages; flagella, where present, found exclusively in microgametes (male gametes); with the exception of microgametes, motility generally via gliding with the possibility of body flexion and undulation of longitudinal pellicular ridges; heteroxenous or homoxenous. This group is not monophyletic. Subdivisions are artificial and unclear at this time.

Class Gregarinida Dufour, 1828 (Syn. Gregarinia Dufour, 1828, Gregarinasina Dufour, 1828)

Mature gamonts extracellular, large; mucron or epimerite, derived from conoid, ordinarily present in mature organism; sexuality usually by syngamy of gamonts; gametes generally very similar; similar number of male and female gamonts produced, zygotes form oocysts within gametocysts; life cycle consists of gametogony and sporogony; parasites of digestive tract or body cavity of invertebrates or lower chordates; generally homoxenous; about 1,800 named species. (*Gregarina*, *Lecudina*, *Mattesia*, *Monocystis*, *Selenidium*).

Class Coccidia Leuckart, 1879 (Syn. Coccidiasina Leuckart, 1879)

Mature gamonts intracellular, small; conoid not modified into mucron or epimerite; syzygy generally absent (if present involves gametes); sexual stages generally very different; different number of male and female gametes; microgametes without flagella; zygote forms oocyst from fertilized macrogametocyte; homoxenous or heteroxenous life cycles consist of merogony, gamogony, and sporogony; parasites of vertebrates and invertebrates about 3,500 names species (Adeleorina Léger, 1911: *Adelina*, *Haemogregarina*, *Hepatozoon*, *Klossiella*; Eimeriorina Léger, 1911: *Caryospora*, *Cyclospora*, *Eimeria*, *Goussia*, *Isospora*, *Lankesterella*, *Neospora*, *Sarcocystis* (syn. *Frenkelia*), *Toxoplasma*; *Aggregata*, *Lankesterella*).

Subphylum Aconoidasida Mehlhorn, Peters and Haberkorn, 1980 (Syn. Hematozoa Vivier, 1982)

Secondarily incomplete apical complex; conoid absent in asexual motile stages (some motile zygotes [ookinetes] contain conoid); formation of macrogametes and microgametes independent; heteroxenous.

Class Haemosporida Danilewsky, 1885

Motile zygote [ookinete] with conoid; flagellated microgametes produced by merogony; oocyst with sporozoites; heteroxenous; parasites of vertebrates; invertebrates serve as vectors, in which sporogony occurs; about 500 named species (*Haemoproteus*, *Leucocytozoon*, *Plasmodium*).

Class Piroplasmida Wenyon, 1926

Conoid and flagella absent in all stages; piriform, round, rod shaped, or amoeboid; no oocyst; sexual stages still uncertain but probably associated with the formation of the large axopodium-like stages; heteroxenous; parasites of vertebrates (in blood cells); ticks serve as vectors; about 200 named species (*Babesia*, *Theileria*).

Gregarines

Gregarines represent an extremely large and highly abundant group of early-branching apicomplexans that exploit exclusively invertebrate hosts, such as annelids, mollusks, nemerteans, phoronids, echinoderms, sipunculids, crustaceans, hemichordates, appendicularians, and insects (Fig. 10). Gregarines have monoxenous life cycles consisting almost exclusively of gamogony and sporogony, since only very few species display merogony. The life cycle of most gregarines commences by the release of young trophozoite from a sporocyst engulfed by the host. The trophozoite generally attaches to the epithelial tissue in the gut lumen of the host and occupies it (Fig. 11). However, some species can be found in coelomic cavities and tissues associated with the reproductive system. After an enormous increase in size, the trophozoite is released from the host tissue into the gut lumen. It transforms into a

gamont that will attach to a partner in a species-specific orientation (head-to-head, tail-to-tail, or head-to-tail) in a process called syzygy (Figs. 10 and 11). In the next step, the gametocyst enclosing both gamonts is formed. Several mitotic divisions inside the gametocyst give rise to hundreds of gametes. Next, the gametes fuse with their partners from the other gamont and produce numerous zygotes. Newly formed sporocyst (oocyst) wall confines each zygote, and subsequent meiosis produces four or more sporozoites per sporocyst (oocyst). Gametocysts filled with mature sporocysts (oocyst) are then released into the environment and ingurgitated by a new host, repeating the cycle. This general scheme has numerous genus- or species-specific modifications, a feature not surprising for organisms displaying such an extreme diversity. The gregarine trophozoites can move and change direction through a mechanism unique among eukaryotes, called gliding motility. This may be accomplished via a cytoskeleton composed of actin and myosin. Gregarines seem to lack the apicoplast, as do the closely related parasitic cryptosporidia.

Gregarines are taxonomically subdivided into three orders: basal archigregarines, advanced eugregarines, and neogregarines. Such a branching order has been inferred from life cycles of these parasites and is, at least to some extent, supported by molecular phylogeny (Leander et al. 2003a, b; Leander 2008; Desportes and Schrével 2013).

Order Archigregarinida Grassé, 1953

This order contains extracellular intestinal parasites of annelids, sipunculids, hemichordates, and ascidians. Their trophozoites are anchored in the host epithelium via the epimerite (or mucron). They are characterized by the absence of septa (aseptate), the persistence of zoite organelles, the pairing of trophozoites (syzygy), and the encystment of gamonts. Sporocysts contain four to eight or even more sporozoites. Archigregarines are parasites of marine invertebrates, with the life cycle completed within the intestinal lumen of a single host. Trophozoites of some species may use myzocytosis-based feeding. This ability, together with the number of infective sporozoites, links archigregarines to colpodellids, free-living biflagellated predators that form a sister group to the parasitic apicomplexans.

Order Eugregarinida Léger, 1900 (Syn. Eugregarinorida Grassé, 1953)

Extracellularly parasitic eugregarines represent the most abundant and best studied group within the class Gregarinida. The trophozoites use epimerite (septate gregarines) or mucron (aseptate gregarines) for their attachment to the host epithelium. Pairing of trophozoites is, same as in Archigregarinida, followed by the encystment of gamonts, producing sporocysts each with eight sporozoites. Eugregarinida

comprises over 1600 species belonging to about 240 genera containing aseptate or septate species.

Order Neogregarinida Grassé, 1953 (Syn. Neogregarinorida Grassé, 1953)

Neogregarines develop intracellularly in the host tissue. After invading the host, they undergo multiple rounds of merogony. The resulting stages known as merozoites spread the infection to other tissues of the host, such as gonads. Usually small gamonts produce a low number of gametes and neogregarinid sporocysts contain eight sporozoites. The order is subdivided into six families of insect parasites.

Cryptosporidia

The genus *Cryptosporidium* was established to accommodate tiny epicellular parasites found in the mouse gastric glands (*C. muris*) and intestine (*C. parvum*). Following their discovery almost 100 years ago, Tyzzer experimentally verified the life cycle and correctly speculated about an autoinfection within the host (Šlapeta 2009). Yet it was only in the 1980s that cryptosporidia were identified as causative agents of cryptosporidiosis, an important waterborne human disease. In 1993 a large waterborne outbreak affected an estimated 400,000 persons in Milwaukee, mostly infected by contaminated water (MacKenzie et al. 1995). The cryptosporidiosis manifests as potentially devastating diarrhea, for which no effective therapy is currently available.

After being released from oocysts in the gastrointestinal tract, the infective sporozoites attach themselves to the host cell membrane and become enveloped by its extended folds (Fig. 12) (Valigurová et al. 2008). A specialized structure called the feeder organelle is formed at the attachment site to facilitate the uptake of nutrients from the host cell by the parasite (Fig. 13). *Cryptosporidium* then undergoes asexual and sexual reproductions, which both have the potential for autoinfection, leading to persistent infection with massive shedding of oocysts in the feces (Fig. 13).

Environmentally resistant oocysts measure 4–8 μm in diameter and are characterized by a single suture at one pole (Fig. 12). *Cryptosporidium* completes the development within a single host, and the oocysts are fully infectious when excreted. The oocysts are spread via host-to-host transmission and indirectly as the waterborne or food-borne pathogens. There are 30 named species affecting virtually all vertebrates. Genotyping of diverse isolates revealed a diverse spectrum of host-specific and zoonotic genotypes. Cattle are considered to be the reservoir for the zoonotic (animal-to-human) transmission.

The traditional classification of *Cryptosporidium* within the coccidians has now been securely rejected, based on comparative ultrastructural and genomic data. The current view holds that the phylogenetic position of cryptosporidia is at the base of the core apicomplexan and gregarine divergence (Morrison 2009).

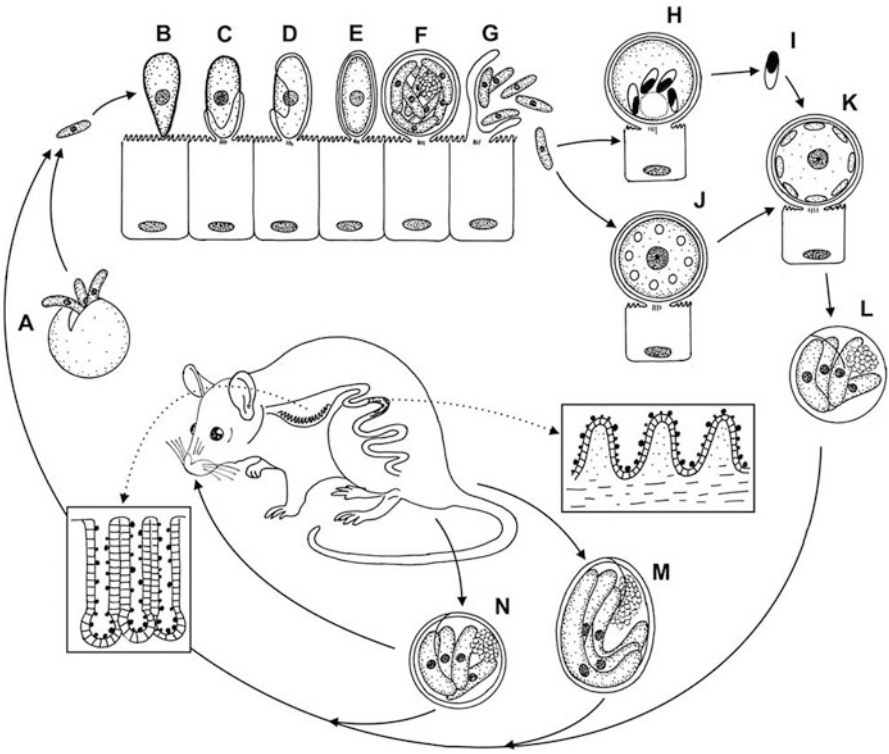

Fig. 12 Schematic drawing of the life cycle of *Cryptosporidium parvum* and *Cryptosporidium muris* in a mouse. Sporozoites are released from a mature oocyst through an open suture (*A*); upon contact with the host epithelium (*B*), sporozoites are enveloped by extended folds of the host membrane (*C–E*); upon epicellularly located merogony (*F*), merozoites are released (*G*) and transform into either microgametocytes (*H*), which produces microgametes (*I*) or macrogametocyte (*J*); upon their fusion (*K*) four sporozoites are formed during sporogony (*L*). Mouse can be infected with either *C. parvum* (*M*) and/or *C. muris* (*N*), confined to the intestine and gastric glands (insets), respectively

Coccidia

Order Eucoccidiorida Léger and Duboscq, 1910

Merogony is present, mostly parasites of vertebrates and less frequently of invertebrates. Besides the order Eucoccidiorida, there are some 20 named species from marine invertebrates classified into separate classes Agamococcidiorida and Protococcidiorida, distinguished by the absence of merogony and/or gamogony, respectively.

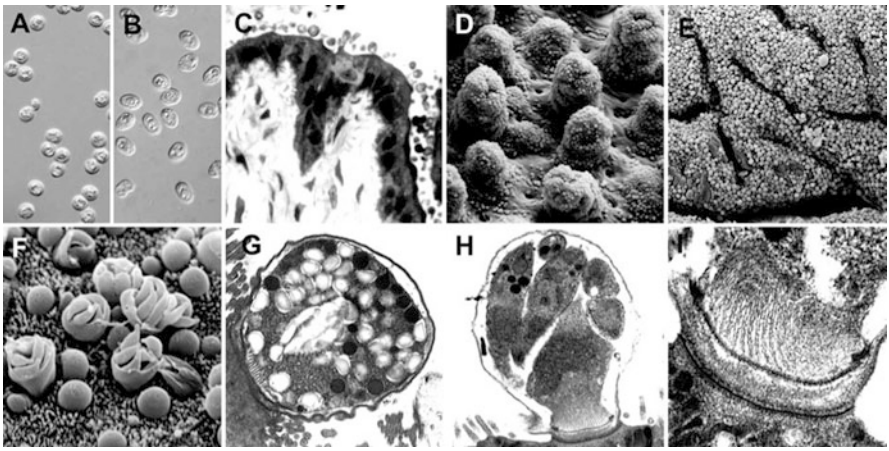

Fig. 13 Representative morphology of cryptosporidian life cycle stages. Spherical oocysts of intestinal *Cryptosporidium saurophilum* (**a**) and ellipsoidal oocysts of gastric *Cryptosporidium muris* (**b**) from a lizard and a mouse, respectively; surface of the intestinal mucosa showing numerous developmental stages of *C. saurophilum* (**c**); surface of the swine intestinal mucosa with prominent villi virtually covered with stages of *C. parvum* (**d**); detail of the gecko intestinal mucosa, heavily infected with *C. saurophilum* (**e**); various developmental stages of *C. saurophilum*, with merozoites undergoing liberation (**f**); macrogamont of *C. parvum* on the surface of an infected enterocyte, revealing the feeder organelle (**g**); developing meront of *C. parvum* (**h**) and detail of the feeder organelle of the same species (**i**). Light microscopy (**a**–**c**) and scanning (**d**–**f**) and transmission electron microscopy (**g**–**i**)

Suborder Adeleorina Léger, 1911

Two groups belong to this suborder: (i) monoxenous coccidians of invertebrates (herein referred to as adelines) and (ii) heteroxenous coccidians cycling between blood-feeding invertebrates (definitive hosts) and various vertebrates (intermediate hosts), usually referred to as haemogregarines. The genus *Klossiella* (Klossiellidae), involving monoxenous coccidia of mammals and reptiles, represents an exception. Phylogenetic studies indicate that entire group is monophyletic, characterized also by several morphological and developmental features. Microgamonts produce usually only one to four microgametes, which associate with the macrogamete in syzygy. Other characteristic features of Adeleorina are the absence of endodyogony and the enclosure of sporozoites in sporocysts and/or oocysts.

So far, there are ~500 named species, almost certainly a great underestimate of the real diversity. Members of the genera *Adelina* and *Adelea* infect mostly insects, whereas *Klossia* is a well-studied coccidium from mollusks. The haemogregarines (Hepatozoidae, Haemogregarinidae, and Dactylosomatidae) comprise several genera, including pathogens of vertebrates, such as *Hepatozoon* from carnivores and reptiles and *Haemogregarina* from fish and turtles (Karadjian et al. 2015). In any case, invertebrates play a role of the definitive host with gamogony in their digestive

system. Then, basically two modes of transmission occur: (i) the inoculative way (*Haemogregarina*, *Dactylosoma*), when the infectious sporozoites enter the vertebrate host during blood feeding, and (ii) alternatively, the parasite is transmitted via the ingestion of an infected definitive (invertebrate) host by the appropriate vertebrate host (*Hepatozoon*, *Haemolivia*, *Karyolyssus*). The latter mode of transmission may even involve a paratenic host (Fig. 14). Regardless of the mode of transmission, the merogonial division of haemogregarines usually takes place in the parenchymatous organs of vertebrates, followed by the formations of infective gametocytes in the circulating red (in the case of *Hepatozoon* also white) blood cells. The next definitive host is infected exclusively by blood feeding (Fig. 14).

Suborder Eimeriorina Léger, 1911

Macrogametes and microgametes develop independently and syzygy is absent. Anisogamous microgamonts produce a large number of flagellated motile microgametes, while the zygote is invariably nonmotile. Sporozoites are always enclosed in a sporocyst. For ~2,500 named species, homoxenous or heteroxenous life cycles have been recorded. Two families comprise species of economic and medical importance.

Family Eimeriidae Minchin, 1903

This family traditionally contains the monoxenous coccidians and arguably is one of the most diversified protist taxa. The formation of environmentally resistant oocysts, usually expelled in host feces, is one of the principal features of Eimeriidae. The general morphology of this easily detectable stage, and especially the numbers of sporocysts and sporozoites within the oocyst, has been widely used to define individual coccidian genera (Figs. 8 and 15). Results of recent phylogenetic studies, however, correlate only poorly with current taxonomy. They also showed that several diagnostic features considered hitherto unique are in fact synapomorphies, shared by several non-related genera.

Life cycle of a typical eimeriid coccidium starts by the ingestion of a sporulated, environmentally resistant oocyst. Following an immediate excystation in the proximal part of the digestive tract, upon invasion of the host epithelia, the sporozoites transform into meronts. These produce numerous merozoites that are consequently released from the ruptured host cell and initiate the next round of merogonial division. Usually there are two to seven asexual generations that differ in the number and morphology of merozoites. The last generation of merozoites eventually becomes intracellular macro- and microgamonts. Macrogamonts can be distinguished by the presence of numerous electron-dense wall-forming bodies, thought to contribute to the formation of the oocyst wall during a later stage of development (Fig. 6). Coccidia of aquatic hosts usually lack this feature, which is attributed to the

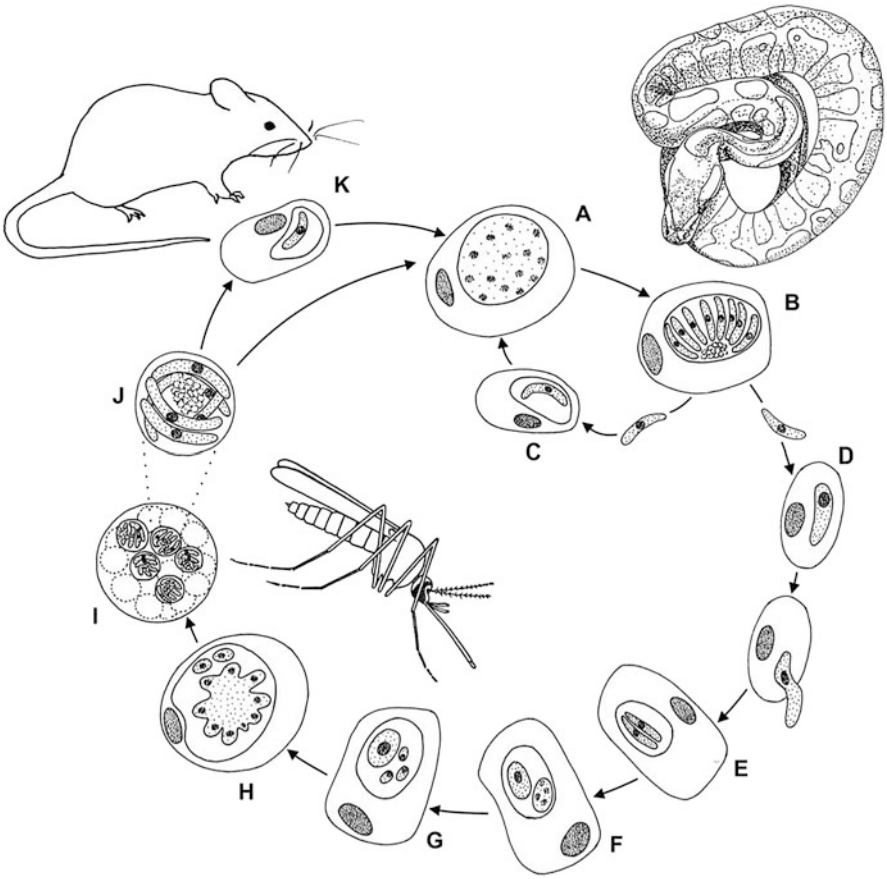

Fig. 14 Schematic drawing of the life cycle of mosquito transmitted *Hepatozoon ayorgbor* in a snake and a mouse. After ingestion of the first intermediate host, merogony takes place in the liver and kidneys of a royal python (*A*, *B*); released merozoites form dormant stages (hypnozoites, *C*) that can probably initiate further merogonial division; merozoites enter red blood cells and transform into gametocytes (*D*); after ingestion by mosquito definitive host, gametocytes enter the fat body cells in host hemocoel, where they associate in pairs in so-called syzygy (*E*); microgamont divides into low number of microgametes (*F*), one of which fuses with the macrogametocyte (*G*) and together form a zygote or young oocyst (*H*); sporoblasts, formed during the asexual division inside the oocyst (*I*), finally develop into sporocysts (*J*); each sporocyst contains several elongated sporozoites and a residual body; an infected mosquito is ingested either by the intermediate host (a phyton) or by the paratenic host (a mouse), in which dormant stages develop (*K*) and wait for the ingestion by a phyton

absence of a prominent oocyst wall in these species. Young oocysts are usually expelled in feces unsporulated and noninfective, as their development is only terminated in the external environment, where further divisions of their contents lead to the formation of sporozoites enveloped by sporocysts (Fig. 7). The entire life cycle is usually completed within 1–3 weeks.

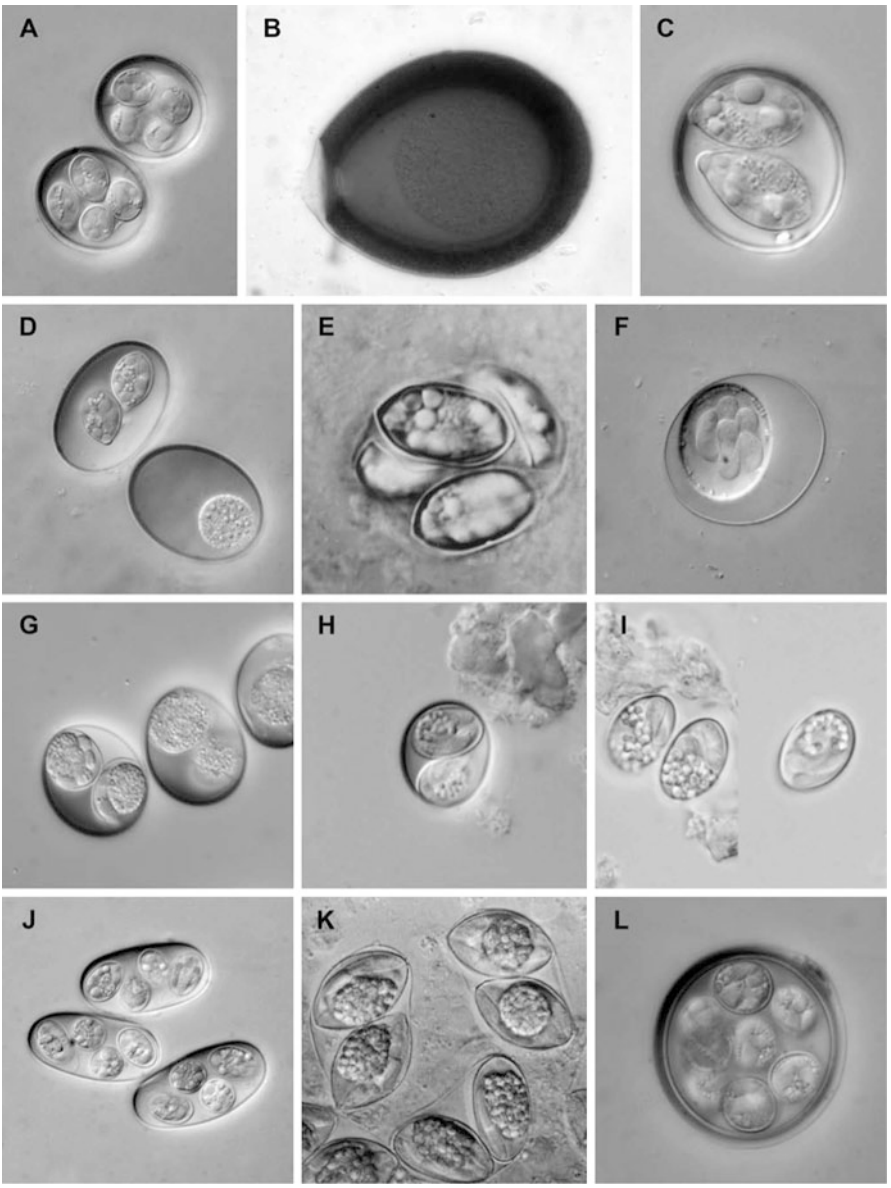

Fig. 15 Representative morphology of sporulated coccidian oocysts from the intestinal content (a–d, f–i, l) or other organs (e, k, j) of various hosts. *Eimeria elephantuli* from a rufous elephant shrew (**a**); giant oocyst of *Eimeria cameli* from a Bactrian camel (**b**); *Isospora* sp. from a passeriform bird (**c**); *Isospora jaracimrmani* from a chameleon (**d**); *Goussia alburni* from the fat body of a perch (**e**); *Caryospora kutzeri* from a kestrel (**f**); *Cystoisospora vulpina* from a fox (**g**); *Toxoplasma gondii* from a domestic cat (**h**); oocyst (*left*) and free sporocyst (*right*) of *Sarcocystis* sp. from a domestic dog (**i**); *Choleoeimeria hirbayah* from the gall bladder of a Yemen chameleon (**j**); *Hyaloklossia lieberkuehni* from the kidney of a green frog (**k**); *Adelina dimidiata* from a centipede of the genus *Scolopendra* (**l**)

Genus *Eimeria*

With ~1,700 described species, this genus is one of the most diversified eukaryotic genera. Traditional definition of the genus is simple and straightforward – it comprises monoxenous coccidians with tetrasporocystic oocysts and dizoic sporocysts (Figs. 7, 8, and 15). However, recent studies based on morphology as well as molecular phylogeny do not support this sensu lato delimitation of monoxenous coccidians. To solve the paraphyly of *Eimeria*, several genera (*Acroeimeria*, *Choleoeimeria*, *Epieimeria*, *Goussia*) have been established. The current view holds that the presence or absence of the Stieda body distinguishes *Eimeria* sensu stricto from other coccidians with *Eimeria*-like oocysts.

The striking diversity of the genus *Eimeria* may be the result of its high host specificity. Poly-infections with several *Eimeria* species are typical for many hosts (ruminants, rodents, lagomorphs, gallinaceous birds), and organ specificity and ecological within-host niche partitioning (Fig. 3) further contribute to the diversity of this genus. Although most *Eimeria* develop in the host intestinal epithelium, bile ducts, kidneys, and even placenta serve as sites of development for some species.

Thanks to features such as direct life cycle, short-generation interval, very high production of oocysts, and intracellular multiplication inside the host, *Eimeria* qualifies as one of the most detrimental parasites of domestic animals. As a result, intensive animal husbandry, especially in the case of domestic fowl, is virtually impossible without efficient control of coccidioses, either by vaccination or anticoccidial medication. However, *Eimeria* has developed drug resistance against most anticoccidials used today which has led to the requirement for an effective vaccine strategy. Attenuated strains of several coccidia were developed and are widely used for vaccination of domestic fowl. Pathogenicity for domestic mammals and birds is mainly caused by high density of animals of the same age in an artificial environment, where the transmission is substantially facilitated, as coccidians of their wild ancestors are usually only mild pathogens.

Other Genera of the Eimeriidae

Monoxenous coccidians of the genera *Caryospora*, *Cyclospora*, *Isospora*, *Tyzzeria*, and *Wenyonella* also exploit vertebrates having life cycle similar to *Eimeria* (Fig. 15). Among them, genus *Isospora,* possessing bisporocystic oocysts with tetrazoic sporocysts and Stieda bodies, is by far the most numerous, comprising ~200 species found mainly avian and reptilian hosts. Exceptionally, some avian *Isospora* (formerly assigned to *Atoxoplasma*) form extraintestinal stages, detectable in the blood cells and parenchymatous organs. In contrast to the simplicity of a typical monoxenous life cycle, some *Caryospora* cycle between snakes and rodents in a rather complicated manner, involving the intestinal merogony and gamogony in the predator and further merogony and gamogony in the connective tissue of the prey.

Despite the fact that many species were described already in the nineteenth century, monoxenous eimeriids of invertebrates (genera *Barrouxia*, *Caryotropha*,

Diaspora, *Dorisa*, *Mantonella*, *Ovivora*) belong to the least known coccidians. So far, no sequences are available from these obscure and neglected organisms.

Family Sarcocystidae Poche, 1913

Traditionally, the family Sarcocystidae comprised heteroxenous coccidians of vertebrates, with the merogony and gamogony located in the intermediate vertebrate prey and final carnivorous predator, respectively. The family accommodates ~350 named species, some of great medical and veterinary significance, with *Sarcocystis* and *Toxoplasma* being the most prominent members. The family is well defined by the unique morphology of its bisporocystous tetrazoic oocysts. The sporocyst wall is composed of four plates joined by sutures that enable the excystation in host's intestine (Fig. 16).

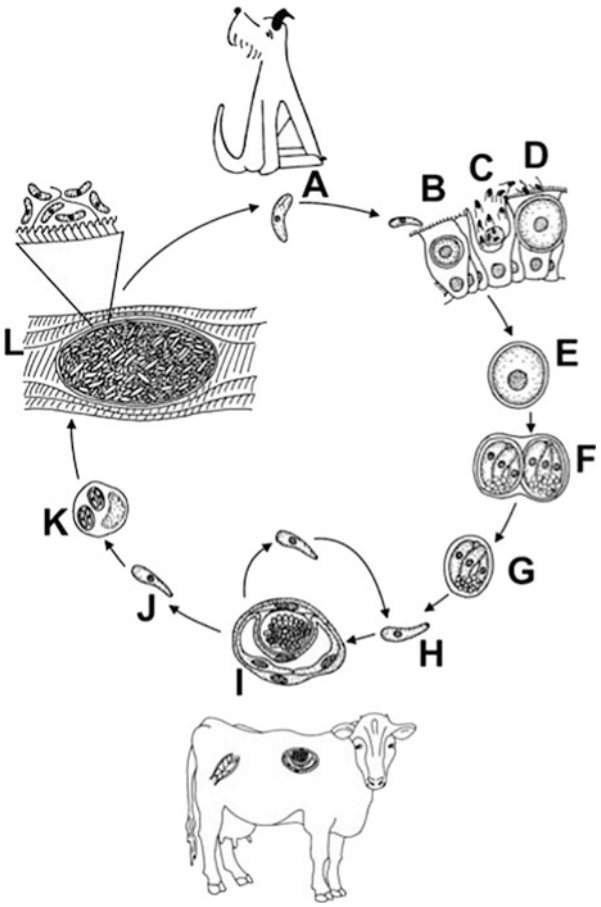

Fig. 16 Schematic drawing of the life cycle of *Sarcocystis cruzi* cycling between cattle and dogs. After ingestion of infected meat by definitive host (dog), cystozoites are released from a tissue cyst during digestion (*A*); cystozoite invades intestinal mucosa, where macrogametocytes (*B*), microgametocytes (*C*), and zygotes (*D*) are formed; unsporulated oocysts (*E*) sporulate in situ (*F*); upon rupture of the oocyst wall, sporocysts are released into the environment and subsequently ingested by the intermediate host (*G*); released sporozoites (*H*) undergo cyclic merogony in endothelial cells (*I*); liberated merozoites (*J*) then spread via macrophages (*K*) to striated muscles, where the tissue cysts develop (*L*); inset shows detail of the cyst wall with invaginations dividing the content into chambers

Phylogenetically, the family is split into two major branches: (i) a well-defined monophyletic assemblage of *Sarcocystis* (including the former genus *Frenkelia*) referred to as Sarcocystidae and (ii) a group consisting of closely related *Toxoplasma*, *Hammondia*, and *Neospora* and somewhat less related *Besnoitia*, *Cystoisospora*, and *Hyaloklossia*. Moreover, recent phylogenetic studies revealed surprisingly close relatedness of some monoxenous coccidians, such as *Cystoisospora* from the intestine of carnivores and *Hyaloklossia* from the kidneys of frogs (Fig. 15), with the above-mentioned heteroxenous genera.

Genus *Sarcocystis*

The most species-rich genus within the Sarcocystidae contains invariably heteroxenous members, cycling between predator (definitive host) and prey (intermediate host). Although the causative agent of macroscopically visible cysts in muscles of various animals was named *Sarcocystis* by Lankester in 1882, the life cycle of these widespread parasites was not deciphered until the 1970s. The definitive host becomes infected by ingestion of meat containing tissue cysts with cystozoites. Directly after that, gamogony takes place in deeper layers of the intestinal mucosa, often close to the lamina propria, and sporulation typically occurs in situ. In most cases, the oocyst wall ruptures in the intestine, and liberated sporocysts are shed in the feces of the definitive host (Fig. 16). Upon ingestion of sporocysts with contaminated food or water by the intermediate host, merogony occurs in its parenchymatous organs, followed by the formation in muscles of tissue cysts, often of macroscopic dimensions and species-specific morphology. Within the cysts, the parasite multiplies by endodyogony or endopolygony, resulting into the formation of metrocytes and later thousands of infectious cystozoites. On the ultrastructural level, the primary wall of the sarcocysts usually bears distinct micro-ornamentation, often with bizarre protrusions (Fig. 17). Numerous invaginations stretching inside the sarcocysts divide its content into chambers, in which cystozoites develop. Cystozoites are characterized by numerous closely packed micronemes (Fig. 17).

The life cycle is based exclusively on predator-prey trophic relationships. The spectrum of definitive hosts comprises carnivorous mammals (especially canids, felids, and marsupials), raptorial birds and owls, and a variety of snakes. Preys of these predators represent intermediate hosts (Fig. 16). For example, dogs (and other canines) are definitive hosts of several *Sarcocystis* species, cycling through goats, sheep, cattle, camels, etc. The so-called dihomoxenous development has been described for *Sarcocystis* affecting lizards in isolated island ecosystems, where the same host species alternatively serves as intermediate and definitive host. In many cases, host specificity of individual *Sarcocystis* species is poorly understood or even unknown. Moreover, more than 50% of species are known only from the intermediate host. At least one species – *Sarcocystis hominis* – is cycling between humans (definitive host) and cattle (intermediate host). Some species possess a remarkable affinity for the central nervous system, where either tissue cysts (species formerly referred to as *Frenkelia*) or meronts (*Sarcocystis neurona* in the brains of its aberrant

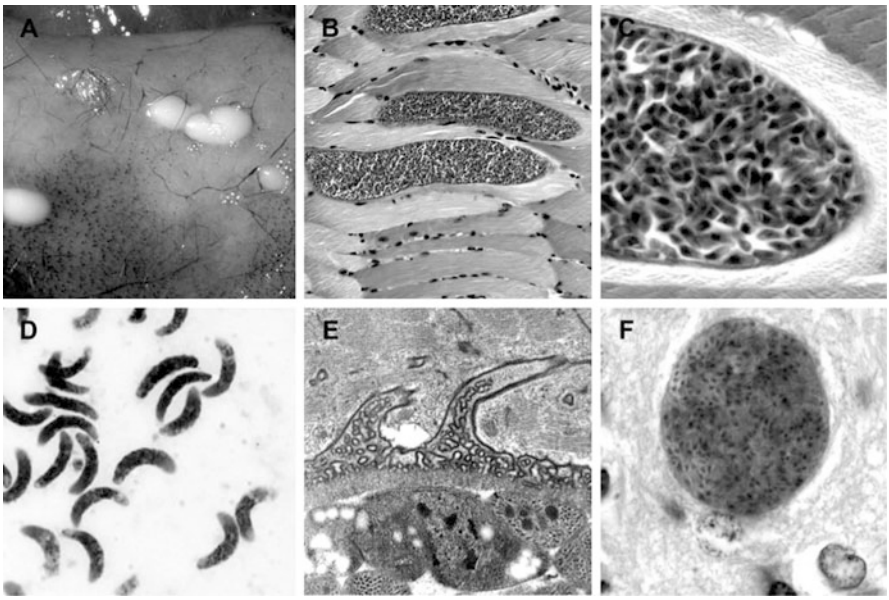

Fig. 17 Representative morphology of sarcosporidian stages in tissues of intermediate hosts. Macroscopically visible cysts of *Sarcocystis dirumpens* from the connective tissue of a rodent (**a**); elongated microscopic cysts of *Sarcocystis dispersa* from the muscles of a mouse (**b**); periphery of mature cyst of *S. dispersa* packed with cystozoites (**c**); cystozoites released from smashed cyst of *Sarcocystis muris* (**d**); species-specific structure of protrusions of primary cyst wall of *Sarcocystis lacertae* from a wall lizard (**e**); characteristic rounded cyst of *Toxoplasma gondii* from brain (**f**). Light microscopy (**a**, **d**), histological sections (**b**, **c**, **f**), and transmission electron microscopy (**e**)

hosts, horses) develop. However, in most cases, clinical significance of *Sarcocystis* infections is generally low both for the definitive and intermediate hosts (Fig. 17).

Genus *Toxoplasma* (and Related Genera)

Since humans are intermediate hosts for *Toxoplasma gondii*, it is understandably the most studied coccidian (Weiss and Kim 2014). The parasite was described already in the beginning of the twentieth century from the brain of a North African rodent (common gundi), but its life cycle remained unknown until 1970, when the domestic cat was identified as its definitive host.

After oral ingestion of sporulated oocysts, asexual multiplication occurs in the intermediate host (Fig. 18). In the so-called "acute" phase, the merogonial development (by endodyogony) occurs in various tissues, leading to the formation of short tachyzoites organized in pseudocysts. This process is repeated many times, ending by the penetration of tachyzoites into the neural (and other) tissues, where cysts are formed. In contrast to the *Sarcocystis* cysts, the tissue cysts of *Toxoplasma* are noticeably smaller and nonseptate (Fig. 17). Inside the cysts, continuous

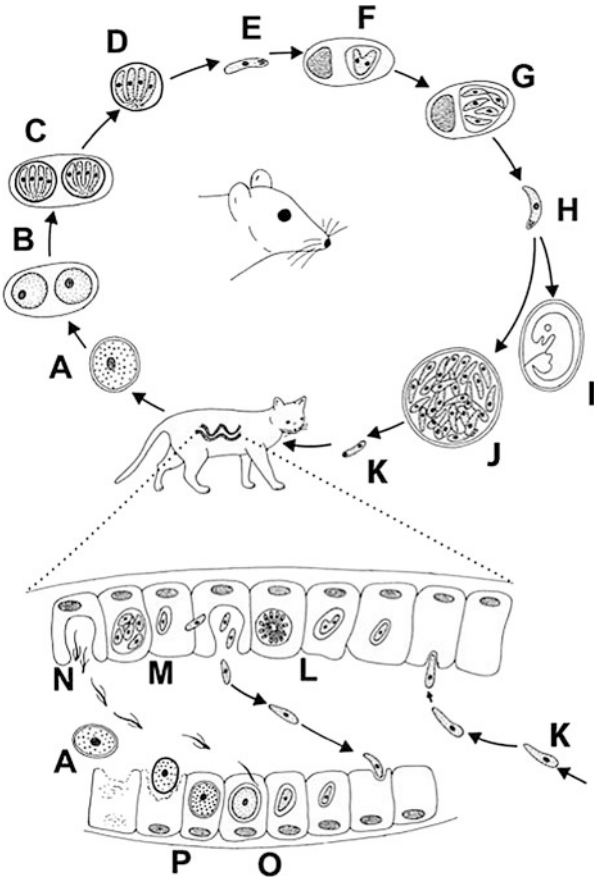

Fig. 18 Schematic drawing of the life cycle of *Toxoplasma gondii* in a mouse and a cat. Unsporulated oocyst in fecal content (*A*); upon sporulation (*B*), two sporocysts each with four sporozoites are formed (*C*); oocyst wall usually ruptures at this stage (*D*); after ingestion by an intermediate host, sporozoites (*E*) invade host cells, where they multiply by endodyogony (*F*), gradually fill the cell (*G*) and form extracellular tachyzoites (*H*); these can be transmitted transplacentally into embryos (*I*); tachyzoites invade new cells and form another generation of tissue cysts (*J*), where bradyzoites are formed (*K*). The inset shows intestinal development infected with bradyzoites (*K*) released from cysts from ingested meal; after several rounds of merogony (*L*, *M*), gamogony takes place (*N*–*P*) and unsporulated oocysts are released from the final host (*A*)

endodyogony occurs, producing prolonged bradyzoites. In this dormant stage, the parasite may survive for years, perhaps even decades. Cat as the definitive host typically acquires the infection by ingesting cysts with bradyzoites in the tissue of the intermediate host. After several merogonial generations in the cat's intestine, gamogony takes place in its intestinal epithelia, and unsporulated oocysts are expelled in feces. Importantly, *T. gondii* can be transmitted among intermediate hosts without involving the definitive one, representing a classical example of opportunism in the transmission mode. For example, humans (as well as any other intermediate host) become infected by several alternative routes: (i) by the ingestion of oocysts from the environment, (ii) by the ingestion of bradyzoites in tissue cysts from meat, (iii) by the transfer of tachyzoites transplacentally, and (iv) rarely by the transmission of tachyzoites in milk (Fig. 18). Along with the domestic cat, wild felids also serve as definitive hosts. When intermediate hosts are concerned, *T. gondii* infects hundreds of mammalian species, less often also birds and rarely some reptiles. Without any doubt, *T. gondii* is the most prevalent parasite of

humankind and one of the most widely distributed parasites of homeotherms in general.

There are two coccidian genera closely related to *Toxoplasma*: *Neospora caninum* exploits dogs as the definitive hosts, while the species of *Hammondia* cycle either through cats or dogs. Only after molecular techniques allowed distinguishing between *T. gondii* and *N. caninum*, the latter turned out to be a potentially serious pathogen of ruminants and dogs. Interestingly, despite its wide distribution and intense research, its life cycle was elucidated only in 1998.

Family Aggregatidae Labbé, 1899

This is a relatively small family (~20 named species) of heteroxenous coccidia from marine invertebrates. The type species *Aggregata eberthi* circulates between crabs and cuttlefish or octopus. Gamogony takes place within the intestine of definitive host (cephalopod), where macroscopically visible oocysts containing thousands of sporocysts are formed. Water contaminated with sporocysts is ingested by crabs, in which extraintestinal merogony occurs. Life cycle is finished by the ingestion of the infected crab by the cephalopod.

Family Lankesterellidae Nöller, 1920

A unique feature of this family is the absence of environmentally resistant oocysts. About 30 named species belonging to the genera *Lankesterella* and *Schellackia* invariably have a heteroxenous life cycle. Frogs and lizards serve as definitive hosts, in the intestine of which gamogony occurs. Oocysts lack sporocysts and harbor variable numbers of sporozoites, which upon exit in situ from the thin-walled oocysts enter the blood cells. The merogony, gamogony, and sporogony of *Lankesterella* occur in the frog's intestine, while sporozoites mature in leeches, which are thought to be principal vectors. *Schellackia* from lizards possesses the same morphological and developmental traits; however, it has only eight sporozoites per oocyst and is transmitted by mosquitoes (Fig. 20).

Haemosporidia

Haemosporidians and piroplasms constitute a phylogenetically well-defined group (e.g., Outlawa and Ricklefs 2011) with obligatory heteroxenous life cycles (Fig. 19). Haemosporidian genera can be distinguished on the basis of the erythrocytic stage morphology, localization of endogenous development in vertebrate host, and the type of invertebrate vector. Merogony of individual species occurs in vertebrate hosts (amphibians, reptiles, birds, and mammals) which serve as intermediate hosts, while sporogony takes place in a broad spectrum of blood-feeding Diptera. Parasites are taken up with the blood meal by the vector, where fertilization occurs and a

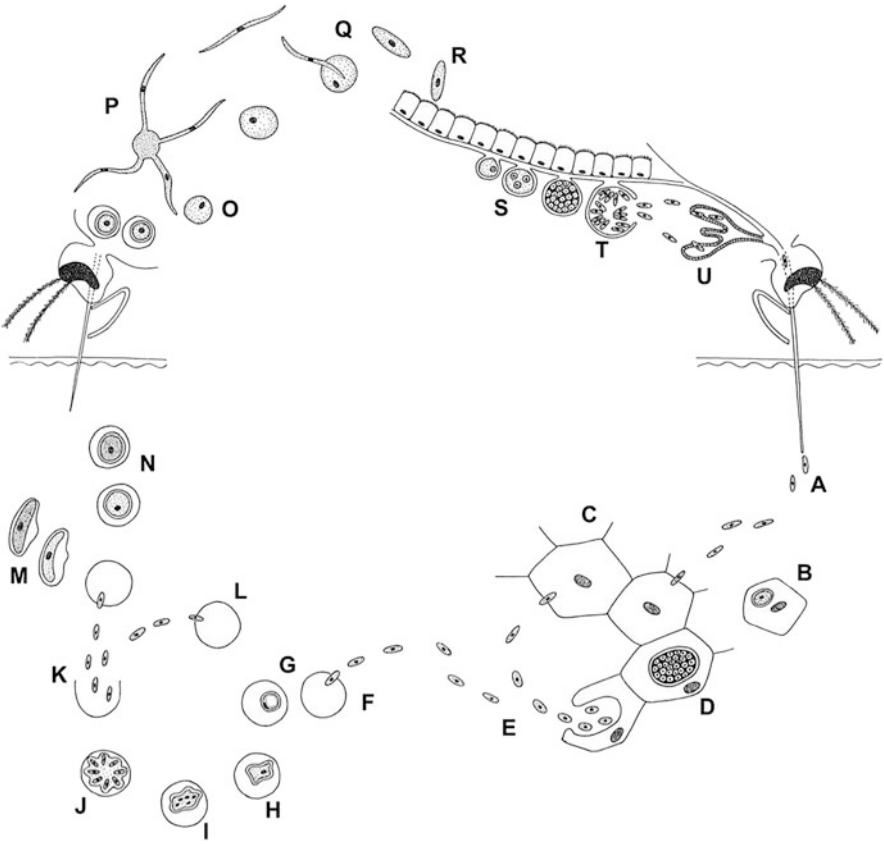

Fig. 19 Schematic drawing of the life cycle of *Plasmodium falciparum* in primate and mosquito hosts. During blood feeding by a mosquito, sporozoites (*A*) are injected into the blood; they enter hepatic cells and either turn into dormozoites (*B*) or active meronts (*C*), which undergo exoerythrocytic merogony (*D*); after release from the liver, merozoites (*E*) invade the red blood cells (*F*); from a characteristic ring stage (*G*), they produce through merogonial division (*H*–*J*), a species-specific number of merozoites (*K*) that either repeat the cycle (*L*) or transfer into gametes; the immature gametes, like other blood stages, have species-specific morphology. Here stages of *Plasmodium falciparum* (*M*) and *Plasmodium malariae* (*N*) are shown; during blood feeding, gametocytes are taken up by another mosquito where they turn into mature macrogametes (*O*) and microgametes (*P*) that copulate (*Q*); the ookinete (*R*) penetrates the intestinal wall and undergoes sporogony (*S*), in the course of which it substantially grows and produces numerous sporozoites (*T*); these invade the salivary glands (*U*) and during the next blood feeding enter another intermediate host

motile zygote (ookinete) is formed. The ookinete actively enters hemocoel by penetrating the midgut wall, rounds up, and transforms into the oocyst. Large oocysts of *Plasmodium* and *Haemoproteus* transmitted by mosquitoes and hippoboscid flies, respectively, subdivide their contents into several sporoblasts, from which hundreds of sporozoites bud off. Haemosporidians with small oocysts

– *Leucocytozoon* (transmitted by black flies) and species of *Parahaemoproteus* (transmitted by biting midges) – produce just one sporoblast with less than a hundred sporozoites. The oocyst ruptures, and the freed naked sporozoites with rudimentary apical complex migrate into salivary glands, where they develop organelles such as rhoptries and micronemes.

Sporozoites injected into the blood of vertebrate hosts by the vectors transform into the exoerythrocytic meronts (Figs. 19 and 20), known to develop most frequently in the liver but found also in the spleen, lungs, kidneys, heart, skeletal musculature, and endothelium of other organs. The megalomeront stage is characteristic of second-generation merogony of *Leucocytozoon*, *Hepatocystis*, and (*Para*) *Haemoproteus*. The prepatent period varies from 2 to 3 weeks. The process of transformation of sporozoites and exoerythrocytic merozoites into trophozoites inside host cells includes a rapid degeneration of the inner double-membrane layer, subpellicular microtubules, polar rings, rhoptries, and micronemes. Within erythrocytes, trophozoites of *Plasmodium* and (*Para*)*Haemoproteus* are localized in the parasitophorous vacuole and absorb host cell cytoplasmic content via a micropyle. Haemosporidians with the intraerythrocytic development (*Plasmodium* and (*Para*) *Haemoproteus*) turn host hemoglobin into a characteristic pigment hemozoin, easily discernible under the microscope. Rapid growth of trophozoites is finalized by the formation of meronts. Members of the genus *Leucocytozoon* depart from the general scheme, as they infect a significantly wider range of host cells, and when infecting erythrocytes digest hemoglobin without the formation of hemozoin granules. Gametocytes of haemosporidians develop only in the blood cells, and individual human malaria species can be distinguished based on their morphology. The life cycle is closed when the gametocytes enter the appropriate vector during blood feeding, where they undergo fertilization and formation of the ookinete (Figs. 19, 20, and 21).

Genus *Plasmodium*

After injection into host blood, sporozoites rapidly attack cells of various inner organs (e.g., hepatocytes in mammals), where the asexual exoerythrocytic division followed by transformation into merozoites occurs. After penetration into erythrocytes, merozoites initiate erythrocytic merogony and develop into meronts. Even though amplification via asexual reproduction in blood cells is not genetically limited in terms of the number of divisions, in each generation a certain number of merozoites develop into macrogamonts (macrogametocytes) and microgamonts (microgametocytes) after entering new erythrocytes. These stages then await ingestion by a mosquito, where each macrogamont matures into a macrogamete, while each microgamont produces six to eight flagellate microgametes (exflagellation) (Fig. 19).

It is often an overlooked fact that only less than 2% of known *Plasmodium* species infect humans, namely, the relatively rare *P. malariae*, *P. ovale*, and simian *P. knowlesi*, followed by *P. vivax* which is responsible for approximately 20% of human malaria worldwide and by far the most pathogenic species *P. falciparum*, which represents the majority of human cases. All four human *Plasmodium* species

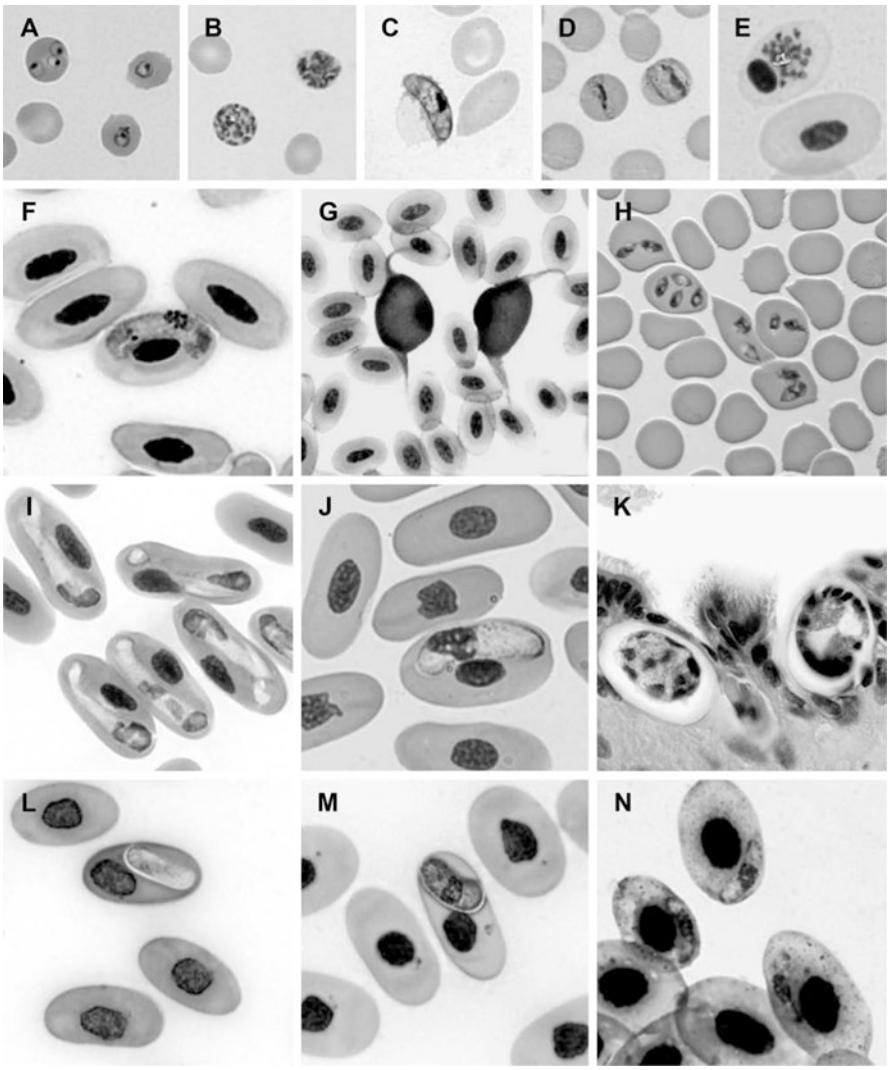

Fig. 20 Representative morphology of apicomplexan stages in the blood cells of vertebrates. are closely related to various simian species, and *P. falciparum* seems to have been acquired by humans from gorillas only relatively recently (Prugnolle et al. 2011). Lately developed amplification of *Plasmodium* DNA from host feces allowed an insight into the diversity of *Plasmodium* species in African and Asian great apes, sharpening significantly the view on evolution of *Plasmodium* in humans and suggesting some level of cross-species transmission between humans and nonhuman primates. Almost 50 other *Plasmodium* species belonging to three subgenera are transmitted exclusively by anopheline mosquitoes (*Anopheles*) to various mammals, mostly rodents and primates. The remaining five subgenera comprise of more than 40 species attacking birds are transmitted mainly by the *Culex* mosquitoes. In general, avian species do not cause serious diseases in their hosts, with highly pathogenic species, such as *P. gallinaceum* in chicken and *P. relictum* in wild birds, being exceptions. With almost hundred species described to date, reptiles (mainly lizards) host about half of all named *Plasmodium* species. Vectors of *Plasmodium* parasitizing cold-blooded vertebrates are mosquitoes (*Culex*, *Aedes*), phlebotomine sand flies (*Phlebotomus*, *Lutzomyia*), and biting midges (*Culicoides*). Interestingly, so far only two species have been described from amphibian hosts.

Members of the genus *Hepatocystis* (25 species) are considered nonpathogenic and are found in reptiles, birds, and mammals, particularly in bats and monkeys. Phylogenetic studies indicate that *Hepatocystis* represents just an internal group among the mammalian plasmodia. Since oocysts of these less studied haemosporidians develop in the head and thorax of biting midges, the transmission is likely mediated by the ingestion of vectors.

Genera *Haemoproteus* and *Leucocytozoon*

Species of both genera undergo development similar to *Plasmodium* with the following exceptions. Asexual reproduction is limited to the exoerythrocytic merogony that occurs in the endothelial cells (*Haemoproteus*) or hepatocytes (*Leucocytozoon*). A unique feature of the life cycle of *Leucocytozoon* is that huge megaloschizonts develop in host macrophages, producing millions of merozoites. The erythrocytic merogony is absent, and merozoites enter erythrocytes (*Haemoproteus*) or leukocytes and immature erythrocytes (*Leucocytozoon*) only to develop into gametocytes (Fig. 20).

The genus *Haemoproteus* includes over 130 morphologically defined species of avian blood parasites (Valkiūnas 2004; Peirce 2005); however, some reptilian blood parasites are also accommodated within this genus. An absolute majority of species infecting birds belongs to the subgenus *Parahaemoproteus* and are transmitted by biting midges (Ceratopogonidae), whereas sporogony of six named species from the subgenus *Haemoproteus* takes place in hippoboscid flies (Hippoboscidae). The genus *Leucocytozoon* is also confined to the avian hosts and is subdivided into the subgenus *Leucocytozoon* with approximately 40 species transmitted by black flies (Simuliidae) and the monospecific subgenus *Aikiba*, the sporogony of which takes place in biting midges (Figs. 19 and 20).

Piroplasmida

This order is a diverse group of haemosporidians (sometimes called piroplasms or piroplasmids), owing their name to pear-shaped (piriform) intracellular stages formed in the host erythrocytes. Unique morphological features of piroplasmids are the absence of conoid and the reduction of the apical complex to the polar ring. Extreme reduction is characteristic for the family Theileriidae, which lacks subpellicular microtubules, the inner membrane complex, as well as the micronemes. After entering the host cell, piroplasms escape from the parasitophorous vacuole and, with few exceptions (*Theileria buffeli*, *T. separata*), digest host hemoglobin without producing any pigment or other visible residues. Heteroxenous life cycle is composed of merogony taking place in a wide range of mammals (to a lesser extent in birds and reptiles), with gamogony and sporogony occurring in the gut and salivary glands of invertebrates, respectively. So far, only hard ticks (Ixodidae) were identified as vectors, although for the majority of species vectors are yet to be found (Fig. 22).

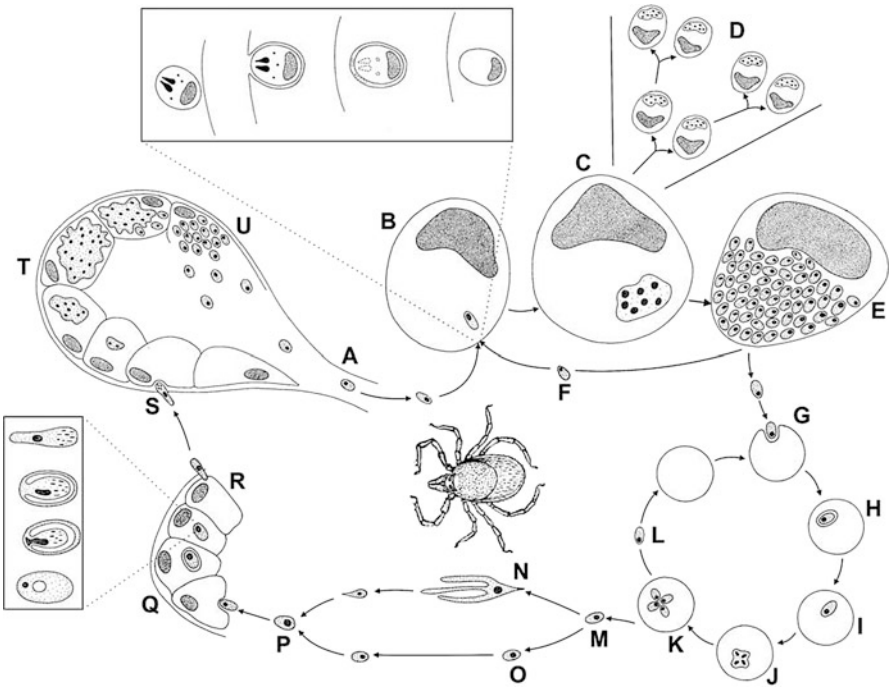

Fig. 22 Schematic drawing of the life cycle of *Theileria annulata* in a cow and a tick. Sporozoite injected with saliva of feeding tick (*A*) in the vertebrate host enters its macrophage (*B*); *inset* shows the invasion process characteristic for *Theileria* without reorientation and escape from the parasitophorous vacuole; merogonial division (*C*) induces a unique clonal expansion of the infected leukocytes (*D*); leukocytes full of merozoites (*E*), although known as Koch's bodies, rupture and released merozoites either repeat the cycle (*F*) or enter erythrocytes (*G*); merozoite also escapes there from the parasitophorous vacuole (*H*, *I*), and multiplication leads to the formation of the Maltese cross composed of four merozoites (*J*, *K*); there can be several merogonial divisions (*L*); upon engorgement during blood feeding by the tick (*M*), gamogony occurs in its intestine, where flagellated microgametocyte (*N*) fuses with macrogametocyte (*O*); motile zygote (*P*) invades epithelial cells, where it transforms into a motile kinete (*Q*); the peculiar transformation is shown in the inset; after traversing, the gut wall (*R*) enters salivary glands (*S*), where sporogony takes place (*T*), producing an enormous number of infectious sporozoites (*U*) terminating the cycle during following blood feeding

Family Babesiidae

In mammalian erythrocytes, trophozoites of the genus *Babesia* usually produce by binary fission two (rarely four) daughter merozoites, which enter new red blood cells (Schnittger et al. 2012). However, development within the invertebrate host is quite complicated and is known for only a few species. After ingestion by a tick, the parasites leave the blood cells and develop into pseudopodia-like gametes (spiky-rayed bodies), which fuse into motile zygote and form a primary kinete. Due to the penetration of the elongated kinetes (vermicules) into numerous internal organs of

the tick, including the ovaries, and in some species, the infection can be passed through transovarial transmission into the next generation, while the ticks can maintain the infection for two or more generations. Further development occurs in the hemocoel and various organs, where *Babesia* produces new secondary kinetes, some of which migrate to the salivary glands. During blood feeding that takes several hours or days, piroplasms rapidly multiply and eventually transform into sporonts and infectious sporozoites. Finally, sporozoites from the tick saliva are injected into the vertebrate host where they directly infect red blood cells and develop into the well-known piriform stages.

The genus *Babesia* contains more than 110 species; several globally distributed species (depending on the range of their tick vectors) are important pathogens of livestock, such as bovines (*B. bovis*, *B. bigemina*, and *B. divergens*), sheep, goats, horses, pigs, dogs (*B. canis*, *B. gibsoni*), cats, and rodents (Uilenberg 2006). Humans can also be accidentally infected with several species (mostly *B. divergens* or *B. microti* of rodents) (Fig. 20). Human babesiosis occurs mainly in the New World where it is a serious disease, especially in immunocompromised and splenectomized persons (Telford et al. 1993; Lobo et al. 2013).

Family Theileriidae

After injection into the vertebrate host, sporozoites enter the T and B lymphocytes or macrophages by a process significantly different from the invasion process known for the other apicomplexans (Fig. 22). Sporozoites as well as merozoites enter into host cells (lymphocytes and erythrocytes) by zippering in from any orientation. Importantly, the invasion does not require reorientation of the parasite's apical end toward the host cell membrane, with the internalization being much slower than in other apicomplexans. The completely surrounded and internalized sporozoites and merozoites release the contents of their secretory organelles (rhoptries and granular bodies), which apparently allows them to escape from the enclosing parasitophorous vacuole into the host cytoplasm. Once established in the host cytoplasm, the parasite grows and differentiates into a multinucleate schizont and, by a remarkable, yet largely unknown mechanism, transforms infected host lymphocytes into immortal cells, which leads to their clonal expansion (Fig. 22). Leukocytes filled with schizonts are called Koch's bodies. The released merozoites invade erythrocytes, where usually another round of division occurs, producing a generation of merozoites, which in turn infect new erythrocytes, particularly in species with limited or missing intralymphocytic multiplication. Multiplication in erythrocytes results in four merozoites forming characteristic tetrads (the Maltese cross), yet some species (*T. parva*) do not multiply in the red blood cells (erythrocytes), their multiple rounds of asexual division being confined only to lymphocytes. Gamogony occurs in the vector's intestine, where gametes fuse to produce a motile zygote. This stage invades epithelial cells, where it transforms into a single motile kinete similar to the haemosporidian ookinetes, and remains there during the development of the tick (trans-stadial transmission). However, unlike in *Babesia*, the kinete does not

multiply and ceases to further develop in the gut but transverses the gut wall and via the celom and hemolymph reaches and consequently penetrates the cells in salivary glands, where sporogony takes place. Feeding of the tick initiates rapid sporozoite development, and in the glandular epithelium, parasites rapidly multiply and produce an enormous number of sporozoites (up to 100,000 per each kinete) that escape into the salivary ducts (Fig. 22).

The two most important species are *T. parva*, which causes the east coast fever in Africa, and *T. annulata*, the causative agents of the tropical or Mediterranean theileriosis (Mans et al. 2015). About 40 *Theileria* species infect mainly ungulates in Africa and Asia but also Australia's marsupials, foxes, and other hosts. Species such as *T. ovis* are pathogenic to sheep and to other small ruminants; *T. equi* is an important pathogen of horses.

The classical difference between the genera *Theileria* and *Babesia* is the absence of extraerythrocytic asexual multiplication (schizogony) in the latter, while schizogony in *Theileria* occurs in lymph nodes and erythrocytes rather than in erythrocytes alone. Despite such a clear distinction, systematic affiliations of several species of piroplasms, even those with economic impact, remain unresolved. Small piroplasms of equines were recently transferred from the genus *Babesia* to the genus *Theileria*. Even more complicated is the case of *Babesia microti*, whose schizogony in lymphocytes and development and transmission in ticks are more similar to *Theileria*. Phylogenetic studies also indicate that the only two named species of the genus *Cytauxzoon* infecting felids including domestic cats represent just an internal group within the *Theileria-Babesia* clades. However, molecular evidence indicates that all these "problematic" parasites differ both from typical *Theileria* and *Babesia*. As in other apicomplexan groups, molecular tools are becoming increasingly important for phylogenetic delineation of the order Piroplasmida (Sivakumar et al. 2014).

Predatory and Photosynthetic Reminiscence of Apicomplexa

Colpodella was first described by Cienkowski in 1865 yet has not found its evolutionary home until the twenty-first century, when insight into its detailed ultrastructure and molecular phylogeny revealed its close relationship with the core Apicomplexa. *Colpodella* is a small (less than 20 μm long; Fig. 23), usually biflagellated free-living predator of other protists and algae, to which it attaches by its anterior tip containing the apical complex, through which it sucks the cellular content of its prey. After feeding, the organism withdraws flagella and forms a cyst. The major component of the apical complex of colpodellids is a pseudo-conoid, composed of an incomplete ring of subpellicular microtubules, micronemes, and elongated organelles reminiscent of rhoptries. All these organelles are considered plesiomorphies common to all apicomplexans. Furthermore, it has been suggested that the gliding motility used by *Colpodella* to penetrate prey cells is very similar to the mode of motility used by apicomplexans to invade host cells (Gubbels and Duraisingh 2012).

Chromerids are photosynthetic algae closely related to apicomplexans, branching in the frame of colpodellids. The group contains just two named species, *Chromera*

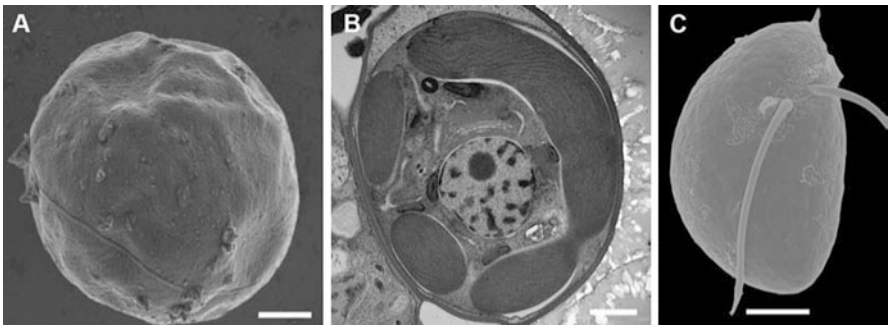

Fig. 23 Morphology of *Chromera velia* and *Colpodella edax*. SEM electromicrograph of *Chromera velia* cell with apparent suture in its cell wall (**a**); TEM electromicrograph of cross-sectioned cell of *C. velia* revealing a giant plastid (**b**); SEM electromicrograph of *Colpodella edax* with two flagella (**c**)

velia and *Vitrella brassicaformis*, isolated from stony corals in Australia (Fig. 23) (Moore et al. 2008; Oborník et al. 2011; Weatherby et al. 2011). The ecology of this organism and the nature of its association with the corals are not fully resolved; however, it has been shown that *C. velia* can infect coral larvae of the genus *Acropora* (Cumbo et al. 2013). The alga hosts a single secondary plastid per cell pigmented by chlorophyll *a*, a novel isoform of isofucoxanthin, and, surprisingly, lacks chlorophyll *c*. Primitive apical complex (pre-conoid) was found in *C. velia*; its presence or absence in *V. brassicaformis* remains to be established (Oborník et al. 2011; Oborník and Lukeš 2013; Portman and Šlapeta 2014; Oborník et al. 2016). Ultrastructural features, noncanonical genetic code in the plastid, and four membranes surrounding the plastid of *Chromera* resembling the non-photosynthetic apicoplast together indicate that *Chromera* possesses characteristics of the relict phototrophic organism leading to the extremely successful phylum Apicomplexa (Fig. 23) (Moore et al. 2008; Janouškovec et al. 2010; Oborník et al. 2016; Woo et al. 2015).

Maintenance and Cultivation

In vitro culture systems represent powerful tools for screening of potential drug candidates. Cultures of apicomplexan parasites such as *Cryptosporidium*, *Eimeria*, *Sarcocystis*, *Neospora*, *Toxoplasma*, *Besnoitia*, *Plasmodium*, *Babesia*, and *Theileria* have been documented, but they are often not productive and capable of sustaining the parasite for only a finite number of replication cycles. The mainstream apicomplexan cell cultures are *Toxoplasma* asexual stages (tachyzoites) in mammalian host tissue cells and *Plasmodium* asexual stages in mammalian red blood cells. The generation of sexual stages is still lacking for *Toxoplasma*, and in vitro animal experimentation is required to fulfill the life cycle (Müller and Hemphill 2013). Cell cultures for *Cryptosporidium* and *Eimeria* remain nonproductive.

Cultivation of any apicomplexan parasite in a good defined cellular system for studies on the proliferative stages is quite complicated because the complex nutritional and environmental characteristics of the host cells are difficult to mimic in vitro. The ultimate goal is to cultivate the parasites in a fully defined medium. In vitro cultivation of apicomplexans is further complicated by the tendencies of most life cycle stages to produce different stages (trophozoites and merozoites transform into merozoites and gamonts, respectively), transfer to a different host, and/or remain as encysted dormant tissue cyst or environmentally resistant oocysts. Only a few examples of life cycle stages have the ability to cycle indefinitely such as those in the mainstream culture systems for *Toxoplasma* and *Plasmodium*.

The availability of cultivation brought many benefits and remains a key research technique for the studies of hematozoans. The asexual stages of *Plasmodium* in the red blood cells are successfully exploited, and a wide array of genetic tools is now available to study malaria in vitro, including stable transfection to study roles of individual genes (de Koning-Ward et al. 2015). Continuous cultivation of *P. falciparum* in a medium containing red blood cells (not fully defined) is fundamental for drug screening and advanced studies of its molecular and cellular biology. Moreover, in 2002, a complete life cycle from sporozoite to sporozoite under in vitro conditions has been achieved for *Plasmodium berghei*, a model malaria species infecting rodents (Al-Olayan et al. 2002; Schuster 2002). Although each parasitic stage requires different cultivation conditions, the tissue culture RPMI-1640 remains the medium of choice, not only for *P. falciparum* and other human malarial parasites but also for piroplasms. However, recent findings have shown that a combination of three commercially available growth media (RPMI-1640, NCTC-135, and IMDM) supplemented with 10% bovine calf serum supports optimally long-term cultivation.

In spite of the fact that certain stages of avian coccidians as well as tachyzoites of *Toxoplasma* or *Neospora* can be readily cultivated in cell cultures, pharmaceutical compounds are still usually tested on parasites collected from experimentally infected hosts that are infected either orally (*Eimeria*), intraperitoneally (*Toxoplasma*), or via arthropod vectors (*Plasmodium*).

Evolutionary History

Origin of Apicomplexa

In the absence of a fossil record, apicomplexan evolution has been inferred from ultrastructural and morphological characters, coevolution with hosts, and molecular phylogenetic analyses. It has been generally supposed that the Apicomplexa first invaded marine invertebrates, as molecular dating places their origin between 600 and 800 million years ago, long before the emergence of vertebrates.

The Apicomplexa belongs to a group named Alveolata, which traditionally consists of three phyla: (i) the almost exclusively parasitic apicomplexans, (ii) the fully heterotrophic ciliates (Ciliophora), and (iii) the facultative photoautotrophic dinoflagellates (Dinophyta), which possess a complex (secondary or tertiary) plastid

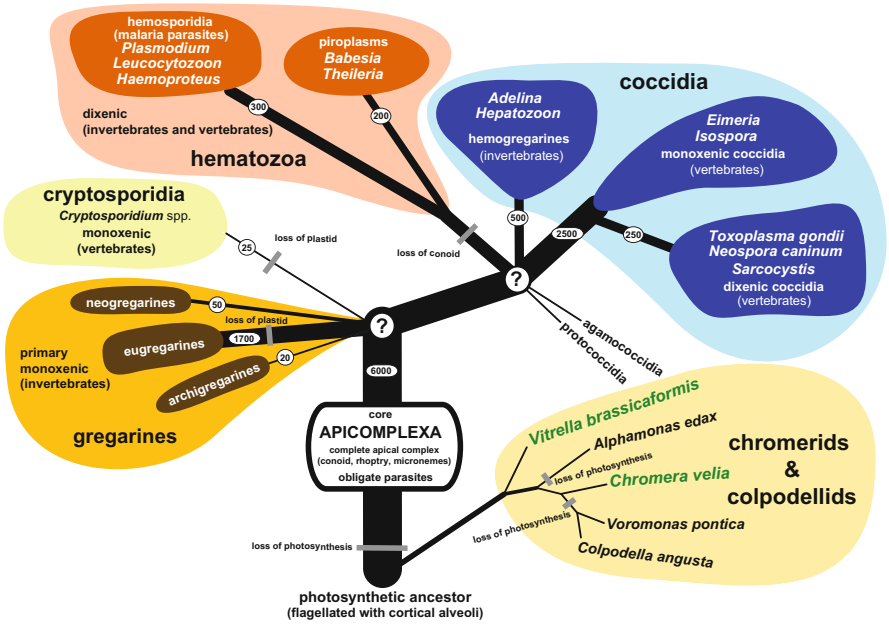

Fig. 24 Hypothetical tree of life of the Apicomplexa. The relationships are derived from morphology, biology, and molecular evolutionary studies based on current state of knowledge. The two major question marks denote the uncertainty of these key radiation events. The key to the common names is provided in Table 1. The branch thickness indicates the relative number of extant species also encircled at the branch

(Fig. 24). From the evolutionary standpoint, the ciliates are early-branching alveolates with the apicomplexans and dinoflagellates constituting an advanced sister groups. Finally, recently discovered chromerids contain coral-associated algae *Chromera velia* (Moore et al. 2008) and *Vitrella brassicaformis* (Oborník et al. 2012) that both appear more closely related to the apicomplexans than to the dinoflagellates (Moore et al. 2008; Janouškovec et al. 2010; Oborník and Lukeš, 2013; Janouškovec et al. 2015; Woo et al. 2015). It has been proposed that the entire group nowadays classified as the supergroup or kingdom SAR (Stramenopila + Alveolata + Rhizaria) (Adl et al. 2012) evolved through secondary and/or tertiary endosymbiotic event(s) between the red alga and a phagotrophic eukaryotic ancestor. However, the exact number of such events remains unknown, with proposals varying from a single endosymbiosis (Cavalier-Smith 1999) to multiple independent endosymbioses for each group of phototrophs (e.g., Falkowski et al. 2004) in the frame of the SAR supergroup. The proposed single secondary endosymbiosis has been dated to ~1.3 billion years ago, about 300–400 million years after the occurrence of the primary endosymbiosis between the heterotrophic eukaryote and cyanobacterium leading to the evolution of the primary plastids known from plants and rhodophytes (Fig. 24).

Although chromerids are closely related to the Apicomplexa, *C. velia* and *V. brassicaformis* do not form sister groups as anticipated but seem to be placed in

unrelated phylogenetic positions in the frame of colpodellids, with *Chromera* being affiliated with the *Colpodella* + *Voromonas* clade, while *Vitrella* is a sister to the genus *Alphamonas* (Gile and Slamovits 2013; Janouškovec et al. 2015; Oborník and Lukeš 2015). This suggests several possible independent losses of photosynthesis in this group. Although chromerids are not as closely related to each other as expected, they are known to possess noncanonical pathway for tetrapyrrole (heme and chlorophyll) synthesis, which is using the heterotrophic C4 route to form aminolevulinate, homologously to apicomplexan parasites and colpodellids (Kořený et al. 2011; Woo et al. 2015; Janouškovec et al. 2015). Since chromerids form relatively long branches, possibly resulting in artifacts in phylogenetic analyses, metabolic synapomorphies in the tetrapyrrole biosynthetic pathway between apicomplexans, colpodellids and chromerids represent one of the most convincing evidence for their common ancestry.

Regardless of the fact that both chromerid algae were isolated from similar environment, they substantially differ in morphology and life cycle. The isolated stage of *C. velia* is a coccoid vegetative cell containing a single large plastid surrounded by four membranes and numerous small mitochondria. Moreover, upon light exposure, large zoosporangia and consequently flagellated zoospores that highly resemble colpodellids are formed in the culture. Autosporangia of *C. velia* contain up to four autospores and zoosporangia up to ten zoospores, whereas the autosporangia and zoosporangia of *V. brassicaformis* are filled with dozens of spores (Oborník et al. 2011, 2012; Oborník and Lukeš 2013). Formation of zoospores in the zoosporangium of *C. velia* ultrastructurally resembles schizogony in Apicomplexa. It represents so far the only known developmental synapomorphy between photosynthetic chromerids and parasitic apicomplexans (Oborník et al. 2016).

Evolutionary Significance of the Apicoplast

The discovery of the apicoplast showed that the evolutionary history of the Apicomplexa is closely associated with the phenomenon of secondary endosymbiosis (Delwiche 1999; Foth and McFadden 2003; Keeling 2013). During this process, a eukaryotic alga was engulfed (or invaded) by a phagotrophic eukaryotic heterotroph and evolved into a multimembraneous complex plastid. Subsequently, this plastid lost its most important function – photosynthesis – and in hematozoans and coccidians, its genome has been reduced to a mere 35 kb circle. At the same time, the ancestral apicomplexan had to switch from autotrophy to heterotrophy, which may have coincided with the evolution of parasitism (Woo et al. 2015). Monophyletic origin of the apicoplast is generally accepted (Denny et al. 1998), yet two distinct lineages that slightly differ in plastid gene order, nucleotide composition, codon usage, and metabolic pathways have been distinguished (Oborník et al. 2002). Secondary endosymbiosis has deeply influenced the apicomplexan evolution by numerous replacements of the secondary host (exosymbiont) nuclear genes by their homologues from all three engulfed algal (endosymbiont) genomes (nuclear,

plastidial, and mitochondrial), likely through endosymbiotic gene transfer. This suggests that a substantial fraction of the apicomplexan genome can be composed of genes obtained from distantly related eukaryotes and their organelles.

However, not all members of the phylum Apicomplexa contain a plastid. This organelle is absent from the genus *Cryptosporidium* (Zhu et al. 2000; Keeling 2004), while its presence in gregarines is yet to be resolved. So far, a multimembraned apicoplast-like structure has been observed in the archigregarine *Selenidium hollandei* (Schrével 1971), whereas the eugregarine *Gregarina niphandrodes* seems to lack both the organelle and its genome (Tosso and Omoto 2007). It is likely that in this group the apicoplast has been lost multiple times, supporting the recent opinion that gregarines form a paraphyletic assembly at the base of the apicomplexan tree. It is plausible that some gregarines and the related genus *Cryptosporidium* lost their apicoplast early in the evolution, well before it became essential, as it is in *Plasmodium* and *Toxoplasma*, where cytosolic pathways were substituted by their plastidial counterparts (Oborník et al. 2009).

Besides predominating parasites, apicomplexans also include free-living marine predators called colpodellids, which use their apical complex for predation instead of parasitism (Leander et al. 2003b). The presence of a plastid in colpodellids has been recently confirmed (Gile and Slamovits 2013). While both photosynthetic alveolates branch within colpodellids, they contain photosynthetic plastids lacking chlorophyll *c*, the hallmark of the chromist and alveolate plastids. Interestingly, the plastid of *C. velia* (but not the one of *V. brassicaformis*) uses the noncanonical UGA triplet to encode tryptophan in the plastid-encoded proteins, which is a synapomorphy with the coccidian apicoplast (Moore et al. 2008). Plastid genomes of both chromerids contain roughly the same number of genes, but they display substantially different sizes and therefore also different levels of genome compaction. While the plastid genome of *C. velia* is linear and ~120 kb long, encoding highly divergent genes, the *V. brassicaformis* plastid genome is circular and compacted into ~80 kb (Janouškovec et al. 2010).

The apicomplexan cell carries unusual mitochondria, which either contain the smallest mitochondrial genome known or lost DNA altogether. While the linear mitochondrial genome of *P. falciparum* is only 5.9 kb long (Suplick et al. 1988; Feagin 1992), the DNA-lacking mitochondrion of *Cryptosporidium* has been reduced to a relic form resembling the mitosomes of microsporidia and diplomonads. Mitochondrial genome of *C. velia* is even smaller than those found in *Plasmodium* and *Toxoplasma*. It contains only two protein-coding genes (conserved *cox1* and highly divergent *cox3*) and fragmented rRNA genes. Consequently, the entire respiratory complex III (ubiquinol: cytochrome *c* oxidoreductase) was lost specifically from *C. velia*; homologously to apicomplexan parasites, *V. brassicaformis* and dinoflagellates, the complex I (NADH: ubiquinone oxidoreductase) is also absent in this chromerid alga. The electron transport function of the complex III is proposed to be substituted by L- and D-lactate cytochrome c oxidoreductases and L-galactono-1,4-lactone dehydrogenase. In contrast to *Chromera*, *Vitrella* still contains complex III; however, the mentioned newly proposed components of the respiratory chain are also present. Phylogenetic analyses showed that

these proteins are mostly of eukaryotic origins and have likely been lost from most of eukaryotic lineages (Flegontov et al. 2015; Oborník and Lukeš 2015).

Nuclear genomes of *C. velia* (194 Mb) and *V. brassicaformis* (73 Mb) were sequenced, and phylogenomic analyses confirmed phylogenetic position of chromerids on the root of Apicomplexa (Woo et al. 2015). It was also shown that massive gene loss (about 3,900 orthogroups) occurred during transition from a phototrophic ancestor to the apicomplexan parasites, while only dozens (80 orthogroups) were acquired. This suggests that the phototrophic ancestor of Apicomplexa already contained most of genes (or their ancestors) which are used for parasitism in apicomplexan parasites (Woo et al. 2015).

Evolutionary Diversity of Apicomplexa

The evolution of the apical complex and gliding motility opened an extremely successful obligatory parasitic niche for the apicomplexans (Portman and Šlapeta 2014; Heintzelman 2015; Keeling and Rayner 2015). The core parasitic Apicomplexa are monophyletic (Fig. 24). There are two alternative schools of thought in respect to relationships among the principal groups. The first school postulates that coccidians represent the ancestral polyphyletic group from which all the other major groups arose independently. This scenario assumes secondary hypertrophy of the gregarine trophozoites, as well as acquisition of extracellularity from primarily intracellular ancestral coccidians. An alternative scenario is that the gregarines are the most ancient paraphyletic group, from which monophyletic hematozoa and coccidia arose. Such a view finds support in the evolutionary relationships with hosts (invertebrates vs. vertebrates) and the complexity of life cycles (single host vs. multiple hosts). Unlike coccidia and hematozoa, gregarines are exclusively parasites of invertebrates and have simple life cycles.

The current knowledge of the gregarine evolution has recently been dramatically challenged by molecular ecology surveys of diverse oceanic and sediment samples (Leander 2008). A large proportion of phylotypes formerly unrelated to any known eukaryotic group have been shown to constitute an assembly of gregarine sequences monophyletic within the Apicomplexa. Their morphological identity remains unknown, but the link between phylotypes represents a challenging issue to be elucidated in the coming decades. Besides these relatively well-defined apicomplexan groups, there is a myriad of organisms of uncertain taxonomic placement, often found in diverse and obscure marine hosts. Organisms classified under agamococcidia (*Rhytidocystis*) from polychetes, protococcidea (*Gemmocystis*) from corals, or even parasites of squids and crabs (*Aggregata*) are just a few examples that challenge even the simplest traditional scenario of apicomplexan evolution.

Due to their effects on human and animal health, members of the monoxenic and cyst-forming coccidia have attracted substantially more attention than the other groups. The evolution of coccidia is traditionally based on the life cycle and number of sporocysts and sporozoites in the environmentally resistant oocysts. Stabilization of the number of sporocysts per oocyst and sporozoites per sporocyst seem to be key

events. However, the modes of excystation are arguably even more informative characters (Jirků et al. 2002). Feline and canine species infecting ruminants as intermediate hosts represent a classical examples of coevolution of the cyst-forming coccidia with their final hosts, where sexual development occurs. The two-host life cycle appears multiple times in coccidian evolution, and it has been hypothesized that homoxeny (single-host cycle) predated heteroxeny (two-host cycle).

The fact that gametogony of hematozoa takes place in vertebrate hosts implies that these parasites have evolved from coccidians of invertebrates rather than vertebrates. The common ancestral host of both avian malarial parasites (*Plasmodium* and *Haemoproteus*) appears to be reptile, and host switches between reptiles and birds are documented quite frequently. By contrast, the host shift from reptiles to mammals was a singular event. On a species level, fascinating recent evolutionary consequences are revealed about malarial parasites affecting humans. It has been postulated that 10,000 years ago a major geographic expansion of malaria took place in Africa. Mechanisms behind this expansion are wide adoption of more efficient agriculture resulting in increased population size and coinciding spread of the *P. falciparum* mosquito vector with climate change in sub-Saharan Africa after the last glacial period. Over the past 40 years, incidence of malaria is rapidly increasing, amplified by the rapid spread of antimalarial resistance, pesticide-resistant mosquitoes, increased population size, poverty, and global warming, all resembling the situation 10,000 years ago. In contrary, recent advances in malaria control led to eradication of significant reduction of impact of malaria in several tropical areas.

Dinoflagellata

17

Juan F. Saldarriaga and F. J. R. 'Max' Taylor

Abstract

Dinoflagellates are a major group of aquatic protists responsible for a major part of marine primary productivity, the creation of coral reefs, marine bioluminescence, and most toxic red tides; indirectly they also cause some human diseases like paralytic shellfish poisoning, ciguatera, etc. They are derived from photosynthetic ancestors and early in their evolutionary history exchanged most of the histones in their nuclei for DVNPs, proteins of putatively viral origin that caused a complete reorganization of chromosomes that includes the loss of the typical eukaryotic nucleosomes and a very marked increase in total amounts of DNA per nucleus. Later on, they acquired other types of DNA-binding proteins, so-called HLPs in at least two waves, possibly lateral transfers from bacteria. Dinoflagellate mitochondrial genomes are some of the smallest known, and the genomes of the ancestral plastid type of the group, the peridinin plastids, are atomized into minicircles with usually one single gene per circle. Roughly half of the dinoflagellates are non-photosynthetic, and the majority of the photosynthetic forms have peridinin plastids. Loss of photosynthesis has occurred repeatedly, but all free-living non-photosynthetic forms remain metabolically dependent on cryptic plastids; complete loss of plastid metabolic activity has only been shown in a few parasitic forms. Several lineages show a marked propensity for reacquisition of photosyn-

thesis, be it in the form of permanent photosynthetic endosymbionts, kleptochloroplasts, or serial secondary and tertiary endosymbioses that produce cells with a wide variety of plastid types. In a few members of the group, peridinin plastids have become the pigment cup/retinoid of complex eyelike structures, so-called ocelli.

Introduction

General Characteristics

Dinoflagellates (Gr. δίνη/díni, to whirl) are an eukaryotic group containing approximately 4,500 species in more than 550 genera, nearly three quarters of the genera and more than half of the species being fossil. Members of the group can be photosynthetic or non-photosynthetic, walled or naked, parasitic or free-living, and very rarely even multicellular. Of the ca. 2,400 living species, 83% are marine, 8% are benthic, 7% are parasitic, and roughly half are photosynthetic (Gómez 2012); several species are also known from snow and sea ice. Numbers of extant species are sure to grow substantially in the future; recent molecular analyses have shown that there are large numbers of undescribed dinoflagellates in environments like marine picoplankton (Moreira and López-García 2002, de Vargas et al. 2015) or as symbionts ("zooxanthellae") in many types of protists and invertebrates like corals or radiolarians (Coffroth and Santos 2005; Brate et al. 2012). The cell periphery, wall, cyst, nuclear, and flagellar features are very distinctive, dinoflagellates show great diversity of form, and some have highly complex internal differentiation.

Occurrence

Dinoflagellates can be found in most aquatic environments, both freshwater and marine, and in intrazoic habitats (see section "Habitats and Ecology"). Principal sources for dinoflagellate cultures include the Provasoli-Guillard National Center for

Culture of Marine Phytoplankton (CCMP, Boothbay Harbor, Maine, USA), the Canadian Center for the Culture of Microorganisms (CCCM, Vancouver, Canada), the CSIRO Collection of Living Microalgae (CSIRO, Hobart, Tasmania, Australia), the Cawthron Institute Culture Collection of Micro-algae (CICCM, Nelson, New Zealand), the Culture Collection of Algae and Protozoa (CCAP, Oban, UK), and the Microbial Culture Collection at the National Institute for Environmental Studies (MCC-NIES, Tsukuba, Japan).

Literature

Because dinoflagellates have been claimed by botanists as algae and by zoologists as protozoa, and the fossil forms by palynologists and micropaleontologists, literature concerning them is widely scattered. The most comprehensive taxonomic reference work is the two-volume contribution by Schiller (1933, 1937, in German) to Rabenhorst's Kryptogamen Flora, although it is now seriously out of date. Examples of more recent English-language taxonomic monographs covering large numbers of species are those by Steidinger and Williams (1970, Gulf of Mexico), Taylor (1976, Indian Ocean), Dodge (1982, British Isles), and Gómez (2003, Mediterranean). The catalogues of genera (Loeblich and Loeblich 1966) and species by Sournia (1973) and Gómez (2005 and 2012) help in tracking down more recently described taxa. The Center for Excellency in Dinoflagellate Taxonomy (CEDiT, http://www.dinophyta.org) provides authoritative information on taxonomic matters; it includes, for example, lists of valid names, sources of first descriptions, etc. The taxonomy of extant and fossil species was unified for the first time by Fensome et al. (1993). A good summary of the biology of the group is presented in Hackett et al. (2004b); papers concerned primarily with the evolution of the whole group include Taylor (2004), Saldarriaga et al. (2004), Zhang et al. (2005), and Bachvaroff et al. (2014).

A small book by Sarjeant (1974) mostly on fossils and volumes edited by Spector (1984) and Taylor (1987) has brought together much general literature. Major reviews have been provided on particular aspects, e.g., Fensome et al. 1993, classification; Granéli and Turner 2006, biology of harmful species; and Coffroth and Santos 2005, zooxanthellae.

History of Knowledge

The largest dinoflagellate, *Noctiluca*, reaches 2 mm in diameter and can be seen with the naked eye as a grayish sphere, luminescent when disturbed. It is not surprising that it was the first dinoflagellate to be described in 1753 by Henry Baker. Several microscopic forms, both freshwater and marine, were discovered by the early Danish microscopist Otto F. Müller in the 1770s and illustrated in 1786. From then on, there was a slow but steady stream of descriptions, most notably by C.G. Ehrenberg who named many protists, particularly those forming microfossils, in the mid-nineteenth

century. Ehrenberg mistakenly believed that they were scaled-down, multicellular animals (the plastids were interpreted to be gonads). Another common misconception was that there was a ring of cilia in the girdle groove (in the position of the transverse flagellum) additional to the trailing longitudinal flagellum, leading to the name "Cilioflagellates" in use until the end of the nineteenth century. The group was first monographed by F.R. von Stein in 1883, at which time 32 genera were recognized (two not attributed to the dinoflagellates today), 26 of which are still in use. He was the first to recognize the taxonomic usefulness of thecal plate patterns in the group. The nomenclatural system for dinoflagellate thecal plates was standardized by C.A. Kofoid in 1907 and 1909, and the "Kofoid System" is still used universally, although its weakness for generic comparisons is becoming recognized (Taylor 1980; Evitt 1985).

Links to marine luminescence were demonstrated by G.A. Michaelis in 1830, and zooxanthellae symbiotic in colonial radiolarians was described and named by Karl Brandt in the 1880s (their dinoflagellate nature was only later recognized by S. Kawaguti in 1944, and they were cultured by H.D. Freudenthal in the 1950s). Parasitic species were studied largely in the early 1900s by Edouard Chatton.

Freshwater species were first monographed by A.J. Schilling at the end of the nineteenth century, with strong contributions on their biology by George Klebs at the turn of the century.

Ecologists gradually became aware of the importance of the photosynthetic members of the group as beneficial, or sometimes harmful, bloom-forming organisms of the phytoplankton. Their frequent causal association with "red tides" became apparent, with massive kills of fish and marine life being recorded with increasing frequency during this century. Their association with paralytic shellfish poisoning (PSP) was recognized by Hermann Sommer and his colleagues in the 1930s, and the link to ciguatera fish poisoning only in the 1970s by T. Yasumoto and colleagues.

The culture of dinoflagellates was pioneered chiefly by Albert Barker in the 1930s. This permitted the physiology and life cycles to be studied more carefully, principally by T. Braarud and his Norwegian colleagues and B.M. Sweeney in America. The latter, together with J.W. Hastings, focused on luminescence and circadian rhythms.

Much of the current ultrastructural knowledge of the group, including the unusual nuclear features, has come from John Dodge in the 1960s and 1970s, with valuable contributions by many others, including J. and M. Cachon, M.-O. Soyer, C. Greuet, K.R. Roberts, G. Hansen, and Ø. Moestrup. Ultrastructural and biochemical data on the dinoflagellate nucleus led to the proposal of the so-called Mesokaryote hypothesis (Dodge 1965), in which dinoflagellates are thought to represent an intermediate kingdom between prokaryotes and eukaryotes. This view was very prevalent until the advent of molecular data.

Dinoflagellates were thought by many to be entirely asexual in reproduction. Early observations by E. Zederbauer and Karl Diwald of apparent sexual fusion were discounted, and it was only careful documentation and observations of H.A. von Stosch in the 1960s that established its occurrence unequivocably in *Ceratium*. The first genetic studies followed later in 1974, using *Crypthecodinium cohnii*,

coincidentally in two different laboratories (C.A. Beam and M. Himes in Brooklyn; R.C. Tuttle and A.R. Loeblich III at Harvard).

The study of fossil dinoflagellates (reviewed by Sarjeant 1974) accelerated in the 1920s and 1930s with studies by O. and W. Wetzel (unrelated) and the growing realization that the fossils were actually cysts rather than thecae, for the most part, and that many of the spiny "hystrichospheres," formerly of unknown affinities, may also be dinoflagellates. This was only clearly established by W.R. Evitt, using careful observation and encystment experiments, and with the excystment of cysts collected from natural sediments by D. Wall and B. Dale during the 1960s. The zygotic nature of resting cysts (most readily fossilizable) only become evident in the 1970s. Later studies on dinoflagellate life cycles and cyst biology have been made by K. Steidinger, M. Montresor, and J. Lewis, among others.

Practical Importance

Dinoflagellates are perhaps best known as causers of harmful algal blooms, as roughly 75–80% of toxic phytoplankton species belong to the group (Cembella 2003). They are frequent causes of "red tides" that may kill fish and/or shellfish either because of toxin production (Table 1) or because of nontoxic effects caused by large numbers of cells in the water (clugging of animal gills, oxygen depletion, etc., e.g., Smayda 1997). Dinoflagellate toxins are among the most potent biotoxins known and accumulated in shellfish or fish cause human diseases like paralytic shellfish poisoning (PSP), neurotoxic shellfish poisoning (NSP), diarrheic shellfish poisoning (DSP), and ciguatera (Lehane and Lewis 2000). They also have been linked to major human health concerns, especially in estuarine environments (*Pfiesteria*). This is significant to coastal aquaculture in that they prevent otherwise productive areas of coastline from being fully exploited. Parasitic species of the genus *Amoebophrya* infect other dinoflagellates, often toxic ones, and have a significant role in ending harmful algal blooms (Velo-Suárez et al. 2013). The syndinian genus *Hematodinium* causes bitter crab disease in 25 species of crustaceans. When infected, crab meat acquires an aspirin-like, bitter taste, and this has large repercussions for crab fisheries (e.g., Meyers et al. 1987; Stentiford and Shields 2005).

Some dinoflagellates (e.g., *Akashiwo sanguinea*) have been used in aquaculture as a preferred food source for larval fish, for example, for anchovies, because they have a higher caloric content per cell than diatoms. Unfortunately they are sensitive to stirring and bubbling, and this, combined with relatively slow division rates (often 0.5 cell divisions or fewer per day), makes them useful only in special cases.

The main ecological importance of dinoflagellates lies elsewhere, though. They are second only to diatoms as marine primary producers, and so are responsible for a very major fraction of marine primary production worldwide. As phagotrophic organisms, they are also important components of the microbial loop in the oceans and help channel significant amounts of energy into planktonic food webs that would otherwise get lost. Dinoflagellates also have a pivotal role in the biology of reef-

building corals: as zooxanthellae, they build symbioses with corals and other animals and protists, and by removing CO_2 from the medium for photosynthesis, they facilitate the deposition of calcium carbonate.

Habitats and Ecology

Dinoflagellates can be found in most aquatic environments including snow, freshwater, marine, or intrazoic habitats.

Comprehensive treatments of their ecology include the chapters by Taylor and Pollingher in Taylor (1987). Reviews on toxic dinoflagellate blooms (e.g., Lundholm and Moestrup 2006) contain numerous references of ecological interest. Pross et al. (2004) provide a good review on palaeobiogeography based on fossil dinoflagellate cysts.

Nutrition

Roughly half the dinoflagellate species are photosynthetic, but completely autotrophic species are very rare (Gaines and Elbrächter 1987; Schnepf and Elbrächter 1992). Photosynthetic dinoflagellates are generally mixotrophic and rely on a combination of photosynthesis and heterotrophic nutrition; the relative importance of the uptake of dissolved organic nutrients, feeding, and photosynthesis for the nutrition of members of the group is unknown. Non-photosynthetic forms can be either free-living or parasitic, and they rely on both osmotrohy and phagotrophy. Prey capture mechanisms in phagotrophic forms vary greatly. Direct phagocytosis occurs in several species. A distinct cell mouth (cytostome) is present in several large phagotrophic genera (e.g., *Oxyrrhis*, *Noctiluca*, *Kofoidinium*, *Erythropsidinium*, *Gyrodinium s.s.*). Other forms, for example, *Protoperidinium*, extend a delicate, pseudopodial "feeding veil" with which they surround portions of diatom chains and other large prey. Digestion then occurs outside of the theca, and only digested material is taken up; the veil is retracted afterward (Gaines and Taylor 1984; Jacobson and Anderson 1992). A third form of feeding, myzocytosis (e.g., in *Paulsenella* spp., "*Katodinium*" *fungiforme*), involves piercing the cell membrane of prey items with a special organelle, the peduncle, and somehow "sucking" the prey cell's contents as if through a straw (Schnepf and Elbrächter 1992). Peduncles, also present in some photosynthetic species, are c shaped in cross section; the details of the mechanism that underlies this mode of feeding are unknown. Parasitic forms can be intra- or extracellular, and they take up nutrients from their host directly.

Only relatively few non-photosynthetic dinoflagellates have been studied in detail using transmission electron microscopy, and several ostensibly non-photosynthetic species have been shown to carry cryptic plastids (e.g., Sparmann et al. 2008). The ratio of photosynthetic versus non-photosynthetic forms in dinoflagellates may well change in the future as more species are investigated in this regard.

Dinoflagellate Phytoplankton

Dinoflagellates are generally considered second only to diatoms in their importance as primary producers among marine plankton. A deceptive impression has built up in the literature that diatoms predominate in colder, and dinoflagellates in warmer, water. A more accurate picture is that diatoms predominate in coastal waters during the most productive periods and also in open waters of high latitudes (arctic, subarctic, circumantarctic). In the nutrient-poor temperate and tropical oceanic regions, all types of plankton are impoverished, with coccolithophorids less so in the former and dinoflagellates less so in the latter. In fact, the greatest concentrations of dinoflagellates (10^7–10^8/l) occur in temperate coastal waters subject to transient periods of vertical stability (Taylor et al. 2008).

Many photosynthetic dinoflagellates behave as annual species. They are generally ecophysiologically diverse and tend to be more specialized to particular habitats/hydrographic regimes than diatoms, for example. For this reason, dinoflagellate blooms tend to be monospecific (Smayda and Reynolds 2003).

Polar waters have relatively few photosynthetic dinoflagellate species (e.g., McMinn and Scot 2005). In temperate coastal and also in freshwaters, dinoflagellates usually bloom in mid- to late summer when sunshine and vertical stability allow strong aggregations to develop at vertical and/or horizontal discontinuities, referred to as clines (e.g., thermocline, nutricline) or fronts. The swimming abilities of the cells (maximum approximately 1 m/h) allow them to resist moderate downward water movements and to occupy compromise positions in the water column relative to light (maximum upward) and inorganic nutrients (maximum downward; Cullen and MacIntyre 1998 and references therein). Subsurface maxima may occur at 1% surface light levels or even less (Anderson and Stolzenbach 1985). In ice-covered lakes, dinoflagellates can accumulate just under the ice if it is not too thick and may bloom early in the season or even in winter.

Daily patterns of vertical migrations are also seen, with the cells rising as far toward the surface as the nutrients allow during the day and downward at night (e.g., *Lingulodinium polyedrum* and *Akashiwo sanguinea* off California or *Ceratium hirundinella* and *Peridinium cinctum* in lakes; Cullen and MacIntyre 1998). *Prorocentrum* spp., *Ceratium fusus*, and *C. furca* tend to predominate in estuarine water. Several of the coastal bloom formers are harmful to marine life or humans when in high concentrations ("red tides"): see Table 1. In higher latitudes (but not polar), the summer community is generally similar but of shorter duration than in warmer temperate waters (e.g., the Bering Sea/Gulf of Alaska relative to southern California or southern Chile compared with Peru; Taylor et al. 2008). Many of the bloom formers overwinter as benthic cysts.

In temperate lakes, the dominants in summer can vary considerably according to many factors, including degree of eutrophy (nutrient level), pH, depth, and surrounding vegetation. Dinoflagellates are represented chiefly by *Ceratium* spp. (especially *C. hirundinella*), when grazing is intense, or *Peridinium* and "*Gymnodinium*" spp. when it is not. In tropical lakes, other protist groups usually predominate, but

Table 1 Examples of toxic dinoflagellates

Species	Toxin	Effect
Alexandrium spp.	Saxitoxins	PSP
Amphidoma spp.	Azaspiracid	Azaspiracid poisoning
Azadinium spp.	Azaspiracid	Azaspiracid poisoning
Cochlodinium polykrikoides	Unknown	Fish kills, smothered corals
Coolia monotis	Cooliatoxin	
Dinophysis spp.	Dinophysistoxin	DSP
Gambierdiscus toxicus	Maitotoxin, ciguatoxin	Ciguatera
Gymnodinium catenatum	Saxitoxins	PSP
Karenia spp.	Brevetoxins	NSP, fish kills
Karlodinium veneficum	Brevetoxins	NSP
Lingulodinium polyedrum	Yessotoxin	
Ostreopsis spp.	Ostreotoxin	
Pfiesteria spp.	*Pfiesteria* toxin	Possible estuary-associated syndrome (PEAS)
Prorocentrum spp.	Okadaic acid, dinophysistoxin	DSP
Protoceratium reticulatum	Yessotoxin	
Pyrodinium bahamense	Saxitoxins	PSP
Takayama spp.	Brevetoxins	NSP
Vulcanodinium rugosum	Pinnatoxins	

Peridinium gatunense is a major dominant in Lake Kinneret, Israel, where it "oversummers" as a benthic cyst (Pollingher 1987).

Tropical nearshore waters are usually diatom dominated, but brief dinoflagellate blooms may occur, and some tropical Atlantic mangrove-lined bays have become famous for persistent blooms of the bioluminescent species *Pyrodinium bahamense* var. *bahamense*; with the development of the shoreline, these blooms have been greatly reduced. Several toxic species bloom in tropical coastal waters. In the oceanic tropics, although a great variety of *Ceratium* spp. are most obviously present, they are not abundant; *Pyrocystis* spp. and in the nanoplankton size range (<20 μm) *Oxytoxum* spp. are usually more abundant.

Dinoflagellate Microzooplankton

Non-photosynthetic forms depend on the presence of their food for nutrition; as might be expected, they are most abundant at the end of blooms of their prey organisms. *Protoperidinium* spp. and *Noctiluca scintillans*, for example, typically

follow diatom blooms. From a biogeographic standpoint, they are most abundant where the latter are. Species of *Protoperidinium* are important in polar waters and are generally coastal in distribution. The effect of non-photosynthetic dinoflagellates on marine (or freshwater) ecosystems is very understudied, but at least in coastal food webs, it can be very large (e.g., Lessard and Swift 1985).

Benthic Dinoflagellates

Dinoflagellates (both photosynthetic and non-photosynthetic) are common inhabitants of benthic sediment habitats, but details of their biology are scarce (Hoppenrath et al. 2014). Early data suggests that benthic marine communities are remarkably similar across locations of similar latitudes, but investigations are too few and geographically restricted to allow for generalized biogeographic conclusions so far. Photosynthetic forms can bloom in benthic habitats; several *Amphidinium* and *Prorocentrum* species may discolor marine sand flats. *Crypthecodinium cohnii* and *Oxyrrhis marina* are often associated with seaweed (brown and green algae, respectively), and the latter also forms intense pink tide-pool blooms. On tropical, bushy seaweeds several toxic species occur, e.g., *Gambierdiscus toxicus*, which adheres to the surface of the weeds and is the ultimate cause of ciguatera (Anderson and Lobel 1987).

Symbioses

Mutualistic Associations

Most zooxanthellae (golden-brown endosymbionts of marine animals and protists) are dinoflagellates. The association between dinoflagellates and reef-building corals was mentioned above, but dinoflagellate endosymbionts inhabit a great number of other invertebrates and protists, for example, many sea anemones, jellyfish, nudibranchs, the giant clam *Tridacna*, and several species of radiolarians and foraminiferans (for a review, see, e.g., Trench 1997). The effect that these associations have on organisms and ecosystems can be massive. They use waste products of their host (e.g., waste nitrogen and phosphorus compounds) as nutrients and release up to 40% or more (possibly more than 90%) of their photosynthate to their hosts, chiefly in the form of glycerol, with smaller amounts as sugars and amino acids. Furthermore, by taking CO_2 from the water for photosynthesis, zooxanthellae facilitate the deposition of calcium carbonate (Marshall 1996) and the production of coral reefs, large foraminiferal skeletons, the massive shells of *Tridacna*, etc.

Dinoflagellate zooxanthellae often belong to the genus *Symbiodinium*, which divides in the coccoid stage and has very transient flagellated stages. But at least seven dinoflagellate genera from four orders have been found in symbiotic associations (Banaszak et al. 1993). For a long time, *Symbiodinium* was considered to be a monospecific genus, but now it is clear that it contains a large cryptic diversity. Coral bleaching is the expulsion/digestion of zooxanthellae in temperature-stressed corals.

Dinoflagellates can also function as hosts of mutualistic symbioses. They may, for example, carry extracellular cyanobacteria ("phaeosomes") that may help fix nitrogen in nutrient-poor oceanic regions, e.g., the dinophysoids *Ornithocercus*, *Histioneis*, and *Citharistes*; other endosymbiotic bacteria are not at all uncommon: Sinophysis and Triposolenia contain for example cyanobacterial endosymbionts. Eukaryotic endosymbionts are also found in many dinoflagellates. *Noctiluca scintillans*, for example, exists in the Pacific in at least two populations: one of them always harbors *Protoeuglena*, a green alga, as an endosymbiont and the other one never seems to contain them. Other noctilucales, for example, *Spatulodinium*, and at least one *Kofoidinium*-like species also contain green endosymbionts (Gómez and Furuya 2007). Two other such endosymbioses that may well be permanent (definitive proof is lacking at the moment) are the genus *Amphisolenia*, which always seems to contain pelagophyte endosymbionts (Daugbjerg et al. 2013), and *Podolampas bipes*, which seems to contain a pedinellid dictyochophyte (Schweikert and Elbrächter 2004). Diatom-carrying dinoflagellates (so-called dinotoms, *Kryptoperidinium*, *Durinskia*, *Dinothrix*, *Galeidinium*, "*Peridinium*" *quinquecorne*, "*Peridiniopsis*" sp.) show a similar situation; they contain (almost) complete diatom endosymbionts and are thus binucleated. Molecular phylogenetic trees put all dinotoms in a clade, and this would seem to suggest that the diatom endosymbiosis occurred before the divergence of the different species. However, things are not that simple: the type of diatom endosymbiont (pennate vs. centric) is different in the different genera (Takano et al. 2008). This situation is very close to being a true tertiary endosymbiosis, but no diatom genes seem to have moved to the dinoflagellate nucleus. True tertiary endosymbioses do exist in dinoflagellates; they involve plastids of haptophyte origin (Patron et al. 2006; Nosenko et al. 2006) and will be discussed in the plastid section below.

Parasitism

Many extant dinoflagellates are parasites (here defined as organisms that eat their prey from the inside, i.e., endoparasites, or that remain attached to their prey for longer periods of time, i.e., ectoparasites), and of those, a majority branch early in the dinoflagellate molecular tree. Syndinians, early-branching parasitic dinoflagellates, are characterized by a plasmodial (multinucleate) stage (references in Cachon and Cachon 1987; Fensome et al. 1993). Core-dinoflagellate parasites on the other hand seem to have originated repeatedly from within the group, and their trophic stages are generally much easier to relate morphologically to the flagellated stages from which they arise. Dinoflagellates can parasitize animal or protist hosts. Ectoparasitic forms show the least modification; they attach to and penetrate the host by a stalklike projection from the sulcus, probably homologous to the peduncle of motile forms. *Chytriodinium* actively penetrates the chorion of crustacean eggs by extraordinary rapid "drilling" movements with its extensible hyposome, while the motile stages of parasites on fish, such as *Piscinoodinium*, *Amyloodinium*, and *Crepidoodinium*, have a pedunclelike organelle with which they penetrate the host. *Blastodinium* inhabits the gut of copepods, maintaining its position by rows of small spines. *Protoodinium*, *Crepidoodinium*, *Piscinoodinium*, and *Blastodinium* retain their plastids while feeding on their zooplanktonic or fish hosts.

Circadian Rhythms

In a number of species, many cellular phenomena are rhythmic, exhibiting daily (circadian) differences. Processes such as bioluminescence, photosynthesis, cell division, and motility have been studied intensively, especially in *Lingulodinium polyedrum* (Sweeney 1987; Akimoto et al. 2004), but it is likely that many other cellular processes are under circadian control and that this cellular "clock" occurs in many – possibly all – dinoflagellates. A key feature of the circadian (about 1 day) control is that the mechanism responsible is endogenous, not directly dependent upon the light-dark cycles, which, however, serve to confer phase to the system (Johnson and Hastings 1986).

Toxins

The toxic species that have caused illness or death of humans or marine fauna, as listed in Table 1, produce two principal types of toxins: (a) water-soluble, small molecular weight substances that block the entry of sodium into the nerves of some animal groups, including humans, and (b) larger, water-, or lipid-soluble compounds that increase membrane permeability to various ions, including sodium and/or calcium. Additionally, there are a few toxic substances such as cholinesterase-like compounds in *Amphidinium carterae* known only from laboratory testing. Toxins in the first group include the saxitoxin complex (saxitoxins, neosaxitoxin, gonyautoxins), heterocyclic guanidines produced by *Alexandrium* species, *Pyrodinium bahamense*, and *Gymnodinium catenatum*, which produce paralytic shellfish poisoning. Saxitoxin, by mass, is 1,000 times more potent than cyanide and 50 times more toxic than curare (Sako et al. 2001). Toxins in the second group are polyether compounds. They include the brevetoxin complex from *Karenia brevis* which kills fish and causes neurotoxic shellfish poisoning, okadaic acid from tropical *Prorocentrum lima*, ciguatoxin and maitotoxin from *Gambierdiscus toxicus*, the dinophysistoxins from *Dinophysis* and *Prorocentrum* spp., pectenotoxin from *Dinophysis*, yessotoxin from *Protoceratium reticulatum* and *Lingulodinium polyedrum*, and azaspiracid from Azadinium spp. and Amphidoma spp. (Van Dolah 2000). They cause ciguatera (Lehane and Lewis 2000), diarrheic shellfish poisoning, and azaspiracid shellfish poisoning. Maitotoxin is one of the most potent biogenic toxins known (Terao et al. 1989).

The functions of the toxins are presently unknown. They do not prevent predation on the producers, and most of their grazers, such as copepods, pteropods, or bivalve mollusks, remain unharmed. However, they can cause massive kills of fish and other marine life (dolphins, manatees, birds, etc.). Toxins produced by benthic dinoflagellates that do not often bloom generally do not cause fish kills: the toxin is taken orally by the fish with its food and is accumulated in the animal's tissues (mostly the liver) where it causes comparatively little damage. Toxins produced by blooming, planktonic dinoflagellates are much more likely to cause fish kills. When the blooms end and the cells die, toxins are released into the water, and fish take the toxin via their

gills, a much more direct way into their bloodstream. In these cases, the effects of the toxin are much more severe. Both brevetoxin and maitotoxin have been shown to accumulate in fish tissues if taken orally, but brevetoxin is more likely to cause fish kills because of the ecology of its producing organism.

Most toxin producers are photosynthetic, but *Protoperidinium crassipes*, producer of azaspiracid, is an exception. Toxicity in benthic coral reef dinoflagellates is a common occurrence (Anderson and Lobel 1987); this is not the case in planktonic dinoflagellates.

Characterization and Recognition

The typical dinoflagellate is a biflagellated eukaryotic unicell, between 10 and 100 μm in length (the extreme range is 2–2,000 μm). One ribbonlike flagellum, the transverse, winds to the left around the cell causing it to turn as well as providing forward thrust. The second flagellum, the longitudinal, beats posteriorly. Although providing some forward thrust (Gaines and Taylor 1985), its principal function seems to be directional (an exception is *Ceratium*). Cell shape is highly variable but is often pyriform.

In most dinoflagellates, the two flagella arise from the side (designated as ventral) and lie in surface grooves: the transverse in the girdle (or cingulum) and the longitudinal in the sulcus (Fig. 1), although its distal portion projects freely behind the cell. This is known as the dinokont condition. If the distal and proximal ends of the girdle do not meet at an equal level at the sulcus, they are said to be displaced. Displacement may be left handed (the most common condition), in which the proximal (left) end is more anterior, or right handed, and the degree is measured in girdle widths, given from the upper edges.

The girdle divides the cell into an anterior body portion, the episome (or epicone), and a posterior hyposome (hypocone). The sulcal groove stops at the posterior of the cell. In athecate (wall-less) cells, there is a thin, anterior extension of the sulcus, the acrobase, which reaches the cell's apex. Acrobases can be straight, sigmoid, or form loops around the apex of the cell.

In a few genera, most notably *Prorocentrum*, the two flagella arise from the anterior (apex) of the cell and are not associated with grooves, although they are differentiated as in dinokonts and beat differently. This is the desmokont condition (Fig. 2).

Flagella

The longitudinal flagellum is relatively conventional in appearance, with few or no hairs (mastigonemes). It may be ribbonlike, and in some, e.g., *Ceratium* (in which it is the main propulsive unit) and *Oxyrrhis*, an accessory fibrillar band may be present, running parallel to the axoneme. It beats with only one or two periods to its wave. In *Ceratium*, it can contract rapidly up to the body.

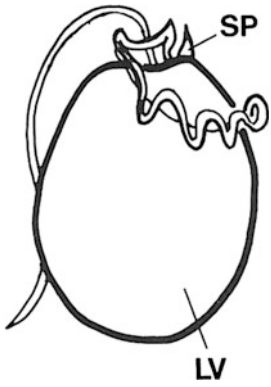

Fig. 2 Flagellar arrangement of *Prorocentrum*. *LV* left valve; *SP* spine

The transverse flagellum (Fig. 3) is generally a wavy ribbon in which only the outer edge undulates from base to tip, due to the action of the axoneme which runs along it. The beat of the axoneme is approximately spiral, but because the ribbon is anchored on its inner edge by an accessory fibrillar band, the striated strand, the

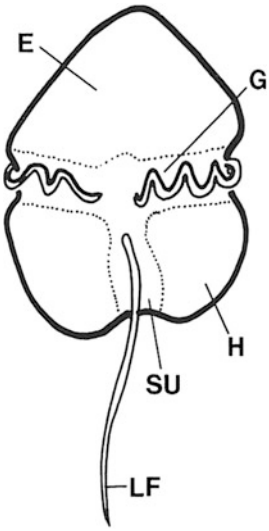

Fig. 3 Flagellar arrangement in a dinokont dinoflagellate seen from the ventral side. *E* episome; *G* girdle (=cingulum); *H* hyposome; *LF* longitudinal flagellum; *SU* sulcus

ribbon forms a travelling ruffle rather than a spiral, the outer advancing faces being inclined forward and downward. The axonemal edge has simple hairs, which can be of varying length. The form of the ruffle as it beats and the hairs act in such a way that there is forward propulsion and also a turning force. Curiously, the cells rotate in the direction of the wave, i.e., always to the cell's left (Gaines and Taylor 1985). Early-branching dinoflagellates (*Oxyrrhis*, the syndinians, and *Noctiluca*) do not seem to have a striated strand in their transverse flagellum.

Amphiesma (Cortex)

The cells may be naked (athecate) or possess a wall (thecate, pelliculate). In a few species of *Oxyrrhis*, *Heterocapsa*, and *Lepidodinium*, very small delicate, star-, or basketlike organic scales occur external to the cell membrane, but in walled dinoflagellates, the close-fitting cellulosic plates which together form the theca are intracellular.

The organization of the outer cortical region of the cell is distinctive. This entire structural complex, regardless of the presence or absence of cellulose plates, is the amphiesma (Morrill and Loeblich 1983; also known as the cortex; Netzel and Dürr 1984). Beneath the cell membrane of the motile cell, a single layer of vesicles is usually present, the alveolae (Fig. 4; the term "alveolus" comes from the ciliate literature, but it is starting to be used in dinoflagellates and apicomplexans to underline the homologous nature of these structures in the three groups). It is within these alveolae (traditionally called amphiesmal vesicles) that the cellulose plates are formed, one per vesicle in thecate (= armored) dinoflagellates. In

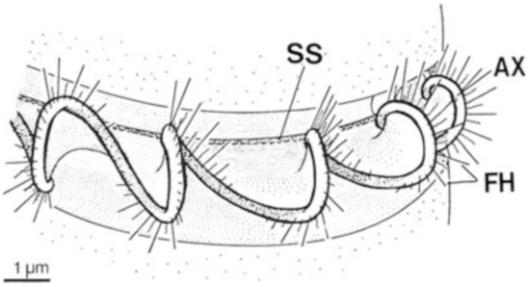

Fig. 4 Detail of the transverse flagellum, modified from Gaines and Taylor (1985). *AX* axoneme; *FH* flagellar hairs; *SS* striated strand

athecate (= naked) species, the vesicles are either empty or contain amorphous material, and the vesicles themselves play a structural role. In some species of *Gymnodinium*, there is a very thin "membrane" within the vesicles that resembles the membranous layer that acts as a plate precursor in *Ceratium* and other more heavily thecate species. The thecal plates usually fit tightly together, the margins often overlapping in a predictable way (imbrication pattern). There is a general trend to overlap from dorsal to ventral and from girdle to pole. The boundaries of the plates are the sutures. Cell growth is permitted by the addition of wall material along some of the margins of the thecal plates. These growth zones, often striated, are termed intercalary bands. In gonyaulacoids, plate growth is usually along only one margin of the suture, whereas it is on both in peridinioids. Pores do not usually occur in the intercalary growth zones. The patterns formed by the thecal plates (tabulation) are of critical importance in taxonomy and are discussed here following the description of other internal components, life cycles, and cysts. Recent molecular phylogenetic trees suggest that thecate dinoflagellates are monophyletic (Janouškovec et al. 2016).

Throughout part or all of the life cycle in some species, there may be a thin continuous fibrous layer, the pellicle, usually lying internally to the alveolae. It consists of cellulose, usually with sporopollenin added to varying degrees. It may form the principal strengthening layer of the amphiesma of athecate genera such as *Ptychodiscus*, *Balechina*, *Sclerodinium*, and *Kofoidinium*. In thecate genera such as *Alexandrium* or *Scrippsiella*, it is present beneath the theca for much of the life cycle and forms the wall of temporary cysts, which are formed rapidly and asexually by the shedding of the theca (ecdysis). Athecate cells with a well-developed pellicle are here termed pelliculate.

Microtubules are also usually present below the vesicles of both thecate and athecate forms, presumably adding some strength to the latter and aiding in morphogenesis. Both microtubular and fibrous (banded, rhizoplast) flagellar roots (portions of kinetids) are present, with sphincterlike collars around the flagellar insertion pockets. Peduncles are tubular structures through which food may be drawn, e.g., in "*Katodinium*" *fungiforme*, *Paulsenella*, *Pfiesteria*, etc.

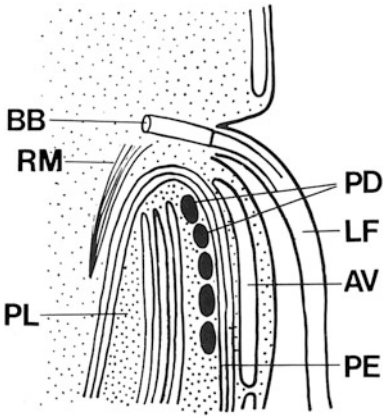

Fig. 5 A typical eyespot, located beneath the longitudinal flagellum (drawn from micrographs by Dodge 1973). *AV* amphiesmal vesicle; *BB* basal body (=centriole); *LF* longitudinal flagellum; *PD* pigment droplets; *PE* plastid envelope; *PL* plastid; *RM* microtubular root

In addition to cholesterol, most dinoflagellate membranes contain a rare 4α,23,24 (R)-trimethyl-5α-cholest-22-en-3-ol, so-called dinosterol, a fossilizing biomarker (Alam et al. 1979); the abundance of dinoflagellate fossils from the Mesozoic onward correlates with levels of derivatives of dinosterols. Early-branching dinoflagellates like syndinians, *Noctiluca*, *Amphidinium*, *Gyrodinium*, and the Kareniaceae lack dinosterol, but the Gymnodiniaceae, *Akashiwo*, and all thecates seem to be able to produce it (Janouškovec et al. 2016).

Ejectile Bodies (Extrusomes)

The most common type of extrusome, of almost universal occurrence in the motile phase, is trichocysts: rod-shaped bodies (Fig. 5) which, when mature, usually lie in the amphiesma perpendicular to the cell membrane. The shaft is a paracrystalline, proteinaceous rod a few micrometers in length, rectangular in cross section. At its distal end, it extends as a group of twisted fibers. The whole is enclosed within a membranous sac, and there is a sheathing material between the rod and the membrane (Livolant 1982a, b). The tip of the sac is in contact with the cell membrane, passing through the amphiesmal vesicles (and thecal plates, if present). The exact mechanism of extrusion is unknown, but it is suspected that the sac ruptures at the contact point at the cell surface, and water entering causes a change in the polymerization of the rod, resulting in an elongation of eight times or more. Trichocysts are formed in the vicinity of the Golgi apparatus (Bouck and Sweeney 1966) and subsequently move to the cell periphery. It appears that most pores in the thecal plates are associated with trichocysts, but this is difficult to establish. Their function is unknown but is assumed to be defensive, excretory, or both. They are most similar to those of ciliates. A less ordered type of extrusome in dinoflagellates is the mucocyst, a simple sac with granular contents, associated with the release of mucoid material.

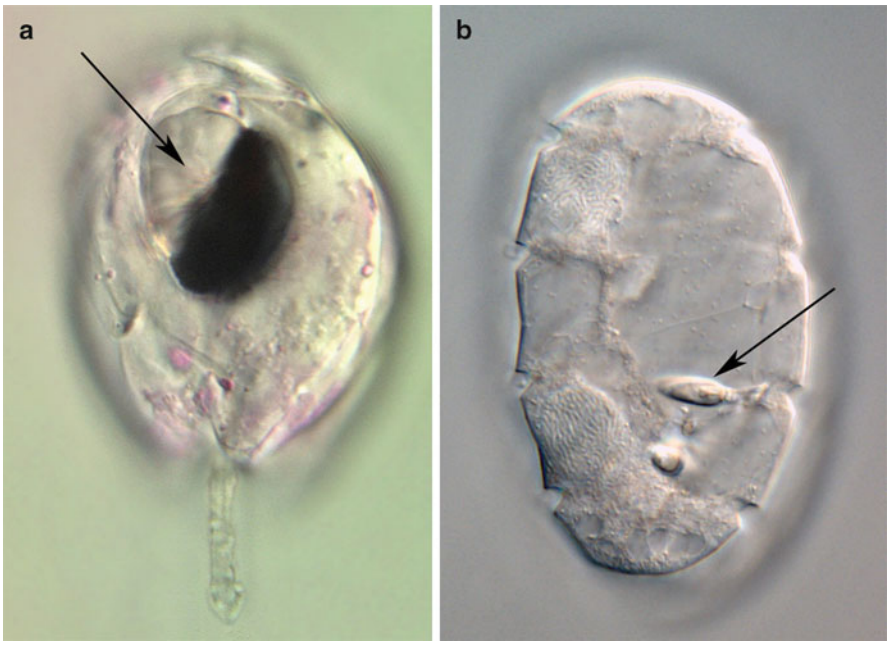

Fig. 6 (**a**) Light micrograph of *Erythropsidinium* sp. *Arrow*: Ocelloid. (**b**) Light micrograph of *Polykrikos kofoidii*. *Arrow*: Nematocyst (Courtesy of Greg Gavelis, Arizona State University)

Much more elaborate extrusomes are found in polykrikoids and warnowiids. These are nematocysts (Fig. 6), named for their resemblance to the stinging organelles of cnidarians (also known as cnidocysts), although their ontogeny differs in a few details (Westfall et al. 1983). Nematocysts are larger than trichocysts and can reach 20 μm in length. They are conical, fluid-filled sacs with a capitate blunt end. Most of the body consists of a large posterior chamber, supported by longitudinal ribs in *Nematodinium*, from which a smaller anterior chamber is isolated; the whole structure is capped by a lidlike operculum. A sharp stylet in the anterior chamber is connected to a tubular filament in the posterior chamber. In *Polykrikos*, it is coiled much like those in cnidarians, and the nematocysts fire by inversion, the stylet driving through the operculum. In *P. schwartzii*, two other structures are invariably associated with the nematocysts: a taeniocyst, which resembles a trichocyst in that it is a solid rod but with more elaborate differentiation (Fig. 6), and a chute with chute organelles, which appears to act as a safe conduit to the exterior when the complex discharges (Westfall et al. 1983). The taeniocyst projects from the cell surface near the kinetosomes. The whole complex originates by coordinated, linked differentiation from Golgi complexes near the nucleus, the primordial forms (anlage) being referred to as the nematogene and taeniogene.

Mitochondria, Golgi Bodies, and Microbodies

Dinoflagellate mitochondria have tubular cristae constricted at the base and arising from the inner membrane. Their genomes are highly unusual (Waller and Jackson 2009): like those of their close relatives, for example, apicomplexans, they encode for only three proteins: cytochrome oxidase 1 (cox1), cytochrome oxidase 3 (cox3), and cytochrome b (cob) as well as ribosomal RNA genes that are fragmented into separate pieces. In dinoflagellates, however, the modification of mitochondrial genomes has gone further than in apicomplexans. For example, all dinoflagellate mitochondrial transcripts need to be edited extensively before translation, and transcripts for at least cox3 need to be trans-spliced (Lin et al. 2002, Zhang and Lin 2005).

Golgi bodies are common, usually near the nucleus; and they may play a role in mitosis, surrounding the zones from which the spindle arises. They give rise to extrusomes. Microbodies are usually present, and some of them seem to be linked with bioluminescence (see below).

Plastids

All dinoflagellates arose from photosynthetic ancestors, and the plastids of a large majority of the photosynthetic members of the group share genetic similarities to the apicomplexan apicoplast and the plastids of chrompodellids like *Chromera* and *Vitrella* (Janouškovec et al. 2015). These so-called peridinin plastids are characterized by triple-membraned (sometimes double-membraned) envelopes, the lack of a girdle lamella, thylakoids usually in groups of unappressed threes, and various types of pyrenoids (Schnepf and Elbrächter 1999). They contain chlorophyll a and c_2 as well as peridinin (a type of carotenoid only found in dinoflagellates), β-carotene, and small amounts of diadinoxathin and dinoxanthin (Jeffrey et al. 1975). DNA-containing areas may be single or multiple, sometimes in prominent "nucleoid-like" regions; they never form a peripheral ring like in some heterokonts (Dodge 1973). In these peridinin-containing plastids, genes appear to exist as minicircles with usually one gene per circle (but two to four in a circle also exist) flanked by a variety of noncoding sequences (Zhang et al. 1999; review in Howe et al. 2008). The absolute number of genes coded in the dinoflagellate peridinin plastids also seems to be much lower than in other algae: while the plastid of cryptomonads, diatoms, and other photosynthetic chromalveolates codes for around 165–185 genes, no more than 16 genes have ever been found in any dinoflagellate peridinin plastid (Green 2004; Nisbet et al. 2004). Some of the missing genes appear to have been moved to the nucleus of the organisms involved (e.g., Hackett et al. 2004a; Bachvaroff et al. 2004), but there are still a number of them that are missing altogether. There are data that suggest that in at least some species, these minicircles may be located in the nucleus, not in the plastids (Laatsch et al. 2004). Peridinin plastids have a bacterial

type of rubisco (evidently a lateral gene transfer) that has a much lower specificity for CO_2 over O_2 when compared to the more common "eukaryotic" rubisco found in other algae (Whitney et al. 1995; Morse et al. 1995). The usual storage products in peridinin dinoflagellates are starch, produced exterior to the plastid, and oils.

In spite of their photosynthetic ancestry, not all dinoflagellates are photosynthetic: roughly half of the members of the group have secondarily lost the ability to photosynthesize and may or may not contain traces of the ancestral plastid. *Oxyrrhis*, *Noctiluca*, and *Crypthecodinium*, for example, contain plastid-targeted proteins even if an organellar plastidial remnant has not been identified, but the syndinian *Hematodinium* appears to have lost all traces of a plastid (Gornik et al. 2015; Janouškovec et al. 2016).

The diversity in types of photosynthesis that exists within dinoflagellates is unparalleled within any group of eukaryotes (Schnepf and Elbrächter 1999), but in this group, it is not always easy to distinguish between true plastids (here defined as organelles that include proteins encoded in their host's nucleus), endosymbionts that have not transferred genes to the host's nucleus but that nevertheless may well be permanent, and other phenomena related to photosynthesis acquisition, for example, kleptoplastidy. The green symbionts in *Noctiluca*, diatoms in the dinotom clade, pelagophytes in *Amphisolenia*, and dictyochophytes in *Podolampas* are (probably) examples of endosymbioses with no genetic transfer to the nucleus (only the dinotoms have been studied in detail in this respect, E. Hehenberger, pers. comm.); at least in dinotoms, this endosymbiosis seems to be permanent. Genetic transfers to the host's nucleus seem to have occurred in at least two lineages that have replaced their peridinin plastids for plastids with completely different origins: the Kareniaceae (*Karenia*, *Karlodinium*, and *Takayama*), which have obtained a haptophyte-derived plastid through tertiary endosymbiosis (Ishida and Green 2002; Patron et al. 2006; Nosenko et al. 2006), and the gymodiniacean genus *Lepidodinium*, which has a plastid derived from a green alga (Watanabe et al. 1991; Minge et al. 2010).

In addition to permanent plastid replacements, non-photosynthetic dinoflagellates may reacquire photosynthesis through the temporary use of plastids from their prey, so-called kleptochloroplasts (stolen chloroplasts; Schnepf and Elbrächter 1999; Janson 2004). Plastids acquired in this way are either eventually digested or lost because of imperfect distribution to daughter cells following division. This is not a rare phenomenon; it has been shown to occur in several eukaryotic lineages like foraminiferans, ciliates, katablepharids, and even animals (sea slugs). In dinoflagellates, kleptochloroplasts have been found in several lineages, for example, *Dinophysis*/*Phalacroma*, *Amylax*, and *Nusuttodinium*, and in an undescribed member of the Kareniaceae, but details are different in the different lineages. *Nusuttodinium* and the undescribed kareniacean use plastids that they take directly from their prey, cryptomonads, and the haptophyte genus *Phaeocystis*, respectively (Onuma and Horiguchi 2015; Sellers et al. 2014). In *Nusuttodinium aeruginosum*, the prey's nucleus and nucleomorph are retained together with the plastid, but as the dinoflagellate lacks the mechanism to initiate the cryptomonad nucleus' division, this is only passed on to one daughter cell after the dinoflagellate's cell division.

Dinoflagellate daughter cells containing cryptomonad nuclei have large, healthy kleptochloroplasts, but in the ones that lack it, the plastids start to degenerate (Onuma and Horiguchi 2015). *Dinophysis* and *Amylax* also have cryptomonad-derived kleptochloroplasts, but they acquire them indirectly by feeding on another kleptoplastidic organism, the ciliate *Mesodinium rubrum*. However, while *Amylax*, like *Mesodinium*, retains the cryptomonad's nucleus and nucleomorph as well as the plastid (Kim et al. 2014), *Dinophysis* seems to digest the cryptomonad nucleus and nucleomorph and retains only the plastid itself. In spite of this, *Dinophysis* kleptochloroplasts can remain viable for at least 10 weeks, a similar amount of time to what is observed in *Mesodinium rubrum*. One possible reason for this is that the *Dinophysis* nucleus contains plastid-targeted genes that may help keep the plastid active; while some of these genes seem to be remnants of the original peridinin plastid of dinoflagellates, others seem to have been obtained from cryptomonads, haptophytes, and other algae (Wisecaver and Hackett 2010). At least one species of *Dinophysis*, *D. mitra*, contains kleptochloroplasts of haptophyte origin (Koike et al. 2005) that may be obtained by preying on kleptoplastidic ciliates like *Tontonia*, *Laboea*, or *Strombidium* (Nishitani et al. 2012).

Eyespots and Ocelloids

No protist group displays so many eyespot types as dinoflagellates (Hansen et al. 2007). Four types (not including ocelloids; see below) have been distinguished, all situated in the sulcal area close to the flagellar roots where they are likely to be shadowed by the proximal part of the longitudinal flagellum. In many dinoflagellates, like in many photosynthetic heterokonts, eyespots consist of osmiophilic, carotene-containing globules inside the plastid, usually as a single or double layer between the plastid envelope and the outermost thylakoids. In some groups, an elongated vacuole that contains brick-like vesicles is located in front of the eyespot but outside the plastid (e.g., the *Borghiella*/*Baldinia* clade; Hansen et al. 2007; Moestrup et al. 2008). In suessialean dinoflagellates, these brick-like vesicles form multiple layers. Another type of eyespot, found in genera like *Esoptrodinium*, *Jadwigia*, *and Tovellia*, consists of osmiophilic globules not bounded by any membrane, floating free in the cytoplasm. And in dinotoms osmiophilic granules are surrounded by three membranes, a situation that has given rise to the hypothesis that this organelle represents the remnant of the original peridinin-containing plastid (see section on "Evolutionary History"). The detailed structure of the eyespot in other dinoflagellates, for example, in non-photosynthetic species like *Oxyphysis oxytoxoides*, is unknown. In *Protoperidinium* species, numerous large carotenoid-like masses occur throughout the cell periphery prior to cyst formation and may act as a reserve material for the wall or for metabolism.

The ocelloid (ocellus) found in the seven genera of the warnowiaceans is a complex organelle showing extraordinary resemblances to metazoan eyes, but at a subcellular level and without any neurological connection to a brain. It consists of four primary components: a darkly pigmented cup called the retinal body; a lenslike,

refractile hyalosome; iris-like rings; and a transparent, cornea-like layer over the lens. The lens is constructed of secretions of unknown material within endoplasmic reticulum and is surrounded by constricting fibers that have been suggested to change the shape of the lens (Greuet 1978, but experimental proof of this is lacking). The "cornea," a transparent layer covering the lens, is composed of mitochondria that extend into a network in the surrounding cytoplasm (Gavelis et al. 2015). The retinal body consists of a cuplike structure containing very precisely aligned membranes backed by a layer of reddish brown to black pigment droplets (Greuet 1978). This retinal body turns out to be a heavily modified plastid: it contains DNA that encodes plastidial genes and dedifferentiates into a plastid of more standard morphology at the end of interphase. The outer membrane of the retinal body of *Nematodinium* is contiguous with that of peridinin plastids that also exist in this cell, and so appears to be a part of a larger netlike plastid. At least some warnowiaceans (e.g., *Nematodinium*) feed on other dinoflagellates, and because the dinoflagellate dinokaryon polarizes light, it has been suggested that function of the ocellus may be to recognize polarized light (Gavelis et al. 2015).

Pusules

In the motile cell, there are usually two specialized vacuoles that arise from ducts that open at the flagellar bases, in addition to the generalized cell vacuolar system (vacuome). These pusules are particularly large in *Protoperidinium*, where they are differentiated into a sac pusule, which can occupy a third or more of the episome, and a collecting pusule, which resembles a cluster of grapes. Each has evaginations, which can be highly elaborate, running close to the vacuome membrane where exchange presumably takes place. Although they resemble water-regulating vacuoles, they do not behave like them. They are most developed in non-photosynthetic marine species. They may be for excretion, uptake, or both (one for each). They do not participate in phagotrophic ingestion, and large particles are usually absent from them. At the ultrastructural level, a flaky material may coat the surface of one of them.

Luminous Organelles

Marine dinoflagellates in at least 18 genera have been documented as being capable of bioluminescence (Poupin et al. 1999); they account for much of the planktonic bioluminescence in oceans. *Pyrocystis noctiluca* and *Noctiluca scintillans* are particularly important in oceanic tropical and coastal temperate regions, respectively. The luminescence occurs as a brief (0.1 s) blue flash (max 476 nm) when stimulated, usually by mechanical disturbance. Flashes have been seen to emanate from individual cytoplasmic bodies ca. 0.5 μm in diameter distributed mainly in the cortical region of the cell (Johnson et al. 1985; Hastings 1986) as pockets that protrude into the main cell vacuole. These so-called scintillons contain luciferase, the main

enzyme involved in dinoflagellate bioluminescence (Nicolas et al. 1985), and luciferin, a tetrapyrrole ring structurally similar to chlorophyll that acts as the substrate to the light-producing reaction. At physiological pHs, (pH 7–8), luciferase is inactive, and luciferin is bound to a protein. Light generation occurs when the pH in the scintillon is lowered to about pH 6, the luciferin is released, and the luciferase takes its active conformation (Hastings 1996). The triggering mechanism for the whole reaction is most commonly mechanical: shearing pressure deforms the cell's plasma membrane, where mechanoreceptors signal a release of calcium ions into the cytoplasm. This forms an action potential across vacuolar membranes in the cell and causes the opening of proton channels in the membrane that release hydrogen ions into the cytoplasm and into the scintillons. The consequent lowering of the pH in the scintillons triggers the light-producing reaction. Luciferin production probably occurs in plastids (cryptic ones in non-photosynthetic dinoflagellates) from precursors repurposed from heme and chlorophyll production (Janouškovec et al. 2016).

Predation on zooplankton by fish and cephalopods is facilitated by dinoflagellate luminescence (Mensinger and Case 1992; Fleischer and Case 1995). The idea proposed to explain this, the so-called burglar-alarm hypothesis, postulates that shearing stress caused by copepod feeding currents trigger dinoflagellate bioluminescence and that this bioluminescence is then used by visual predators like fish and squid to find their zooplankton prey. This, in the end, benefits the dinoflagellates. An alternative possibility is that bioluminescence may startle predators and discourage their feeding (Buskey and Swift 1983).

Luminescent and nonluminescent strains can occur in the same species, e.g., *Alexandrium tamarensis* and *Noctiluca scintillans*.

Dinoflagellate bioluminescence is controlled by circadian rhythms and only occurs at night (e.g., Knaust et al. 1998)

Skeleton

Internal skeletal elements, siliceous in some species, are known in genera of the actiniscaceans and dicroerismaceans. In *Dicroerisma*, there is a single, branching skeleton in the shape of an inverted Y. In *Actiniscus*, the siliceous internal elements are also paired and are star shaped. Basketlike peripheral skeletons are present in *Achradina* and *Monaster*.

Nucleus

The dinoflagellate nucleus is so different from that of typical eukaryotes that it is usually given its own name, the dinokaryon; in the 1960s, the ultrastructural and biochemical differences between dinokarya and typical eukaryotic nuclei were deemed to be important enough to warrant the establishment of an intermediate kingdom between prokaryotes and eukaryotes, the so-called Mesokaryota (Dodge 1965). This view was subsequently disproved by molecular data.

Dinoflagellate nuclei lack nucleosomes (e.g., Rizzo 1991), and the ratio of basic proteins to DNA in them is much lower than in any other eukaryotes (1:10 in dinoflagellates, as opposed to the equimolar ratios found in other eukaryotes). The main basic components in dinoflagellate nuclei are not histones but other types of basic proteins that interact with DNA: so-called DVNP's (dinoflagellate/viral nucleoproteins) that are otherwise only known from a group of large algal viruses (Gornik et al. 2012) and HLPs (histone-like proteins, Wong et al. 2003), which seem to have entered dinoflagellates in two separate waves of lateral transfer from bacterial sources (Janouškovec et al. 2016). Dinoflagellates also contain very high amounts of DNA per cell: 3,000–215,000 Mbp weighing up to 250 pg in a haploid nucleus (in humans those numbers are 2,900 Mbp DNA/cell and 3 pg in a haploid cell). Chromosomes remain continuously condensed and visible during interphase and mitosis, but whereas syndinians have few chromosomes (four in *Syndinium*, Ris and Kubai 1974), some species may have up to 143 (*Alexandrium fundyense*, Oakley and Dodge 1974).

In the so-called core dinoflagellates, chromosomes appear fibrillar, the 3–6 nm fibrils being packed in a highly ordered state (up to six levels of coiling), consisting of arches and whorls (e.g., Dodge 1966; Spector et al. 1981). A prominent nucleolus is also persistent. In those species investigated, there is an unusual substitution (12–68%) of the base thymine by 5-hydroxymethyluracil (Rae 1976).

All nuclear-encoded messenger RNAs investigated in a wide diversity of members of the dinoflagellate lineage (including *Perkinsus marinus*) have been recently shown to be trans-spliced to a universally conserved 22 base pair fragment that is added to their 5′ end (Zhang et al. 2007; Lidie and Van Dolah 2007). In core dinoflagellates, many highly expressed genes are arranged in tandem arrays, a feature that is very rare in eukaryotes (Bachvaroff and Place 2008).

Mitosis

Dinoflagellate mitosis is also unusual. The nuclear envelope persists during mitosis ("closed"), as it does in many other eukaryotes (Raikov 1994). However, with the exception of *Oxyrrhis marina* and several species of the genus *Amoebophrya* (Triemer 1982; Moon et al. 2015), the mitotic spindle is extranuclear and passes through furrows and tunnels that form in the nucleus at prophase (Dodge 1987 and references therein). With the exception of the centrioles in *Syndinium*, there are no obvious spindle pole bodies other than concentric aggregations of Golgi bodies ("archoplasmic spheres"). Some microtubules contact the nuclear envelope, lining the tunnels at points where the chromosomes also contact. The chromosomes usually have differentiated, dense regions inserted into the envelope.

Cytokinesis

The plane of cell cleavage is typically oblique between anterosinistral and posterodextral moieties, passing through the kinetid. In thecate species, the theca may be

shared by the offspring, with synthesis of the missing components (desmoschisis), or the parent theca may be cast off, each offspring forming a complete new theca (eleutheroschisis).

In photosynthetic forms, the time of division is phased; this is controlled by an endogenous (circadian) mechanism (see below). Division typically occurs near the end of the dark period, but in several species, it is phased at other times (Hastings and Sweeney 1964). Division rates are usually relatively slow, many species dividing only once every 2 or more days. *Amphidinium carterae* can divide twice in 1 day. The non-photosynthetic species *Crypthecodinium cohnii* is the most rapidly reproducing dinoflagellate known, dividing three times per day, although parasites may divide faster during sporogenesis via palintomy.

Life Cycle

Most dinoflagellates appear to be haploid, with post-zygotic meiosis. Clearly established sexual fusion is known for only a few species, but, because of its cryptic nature (gametes grossly resembling regular motile cells, slow fusion, occurring at night in photosynthetic species), it is probably widespread.

Syngamy may involve equal (isogamy) or unequal (anisogamy) motile gametes (see Fig. 7). Both heterothallism (no fusion in clonal strains) and homothallism are known. The product of fusion is a tri- or quadriflagellate planozygote (later biflagellate in some), which may remain motile for hours or days. Eventually a nonmotile resting cyst (hypnospore) is formed. After a varying length of time (see section "Cysts" below), excystment occurs. Meiosis, heralded by a peculiar churning and rotation of the nucleus termed nuclear cyclosis, associated with the pairing of homologous chromosomes, may precede or follow excystment and may be accomplished in two conventional, successive divisions (e.g., *Ceratium cornutum*) or possibly one (*Crypthecodinium cohnii*). In some species, the planozygote that emerges from the cyst may again be tri- or quadriflagellate.

In most dinoflagellates, the motile phase (mastigote) is dominant, but in some, most of their life cycle is spent in a coccoid or other nonmotile form. Those living as intracellular symbionts (e.g., *Symbiodinium)* are photosynthetically and reproductively active in the coccoid state (vegetative cyst: see section "Cysts" below). Some marine planktonic forms, such as *Pyrocystis*, live predominantly as greatly inflated trophic cysts, as do the benthic phases of genera like *Halostylodinium*, *Spiniferodinium*, *Cystodinium*, etc. *Thoracosphaera* and *Pfiesteria* are other genera that can divide in the cyst stage. These coccoid life stages usually lack amphiesmal vesicles, trichocysts, and pusules, as well as flagella, and as a consequence are often difficult to identify as dinoflagellates. A continuous, fibrous wall that may be greatly reduced in the symbionts appears to be homologous with the pellicular layer and cyst wall. In the broadest sense, they represent cysts that are metabolically active rather than dormant. Transient mastigote phases occur in these species; they are suspected to be gametes, although no fusion has been seen.

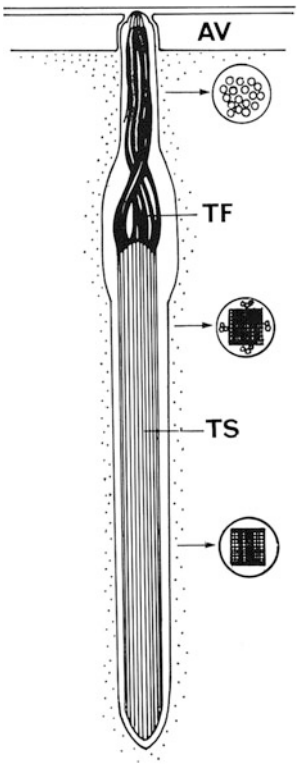

Fig. 7 Longitudinal section of a trichocyst (redrawn from Bouck and Sweeney 1966). *AV* amphiesmal vesicle, *TF* trichocyst fibers, *TS* trichocyst shaft.

Cysts

In dinoflagellates the protozoological term cyst, rather than the approximately equivalent botanical term spore, has been used for nonmotile, continuous walled stages. Fewer than 15% of the living forms are known to form cysts, although the figure is climbing steadily; virtually all fossils appear to be cyst stages; see below. Dale (1983) has reviewed cyst biology, and Fensome et al. 1993 has unified the classification of extant and fossil dinoflagellates.

Cysts can be of several types, according to their roles in the life cycle, and the literature may be confusing because of earlier lack of awareness of this and the lack of standardization of terms. Here, the following are recognized:

1. Resting cyst (resting spore, hypnozygote) –
   A dormant stage, generally resistant to adverse conditions. In several instances (see above), these result from sexual fusion, but it is not known if this applies to most of them. The wall may contain a sporopollenin-like material, additional to cellulose and/or gelatinous material, and may be of several layers. Internally, the contents often shrink (due to loss of water), storage products become polymerized (oils, starch), photosynthetic pigments are gradually reduced, and a large, red-pigmented body is often formed.

2. Temporary cyst (pellicle cyst, ecdysal cyst) –
   In those thecate species with a well-developed pellicular layer (e.g., *Alexandrium* and *Scrippsiella* spp.), the cell may respond to rapid adverse changes by shedding the theca (*ecdysis*), including the outer amphiesmal layers and axonemes, the pellicular layer becoming the cyst wall. In *Pyrophacus* and *Protoperidinium*, this accompanies eleutheroschisis.
3. Trophic cyst (coccoid cells) –
   Nonmotile, usually photosynthetic cells that are metabolically and reproductively active in this phase. Surrounded by a continuous wall homologous with the pellicle (e.g., *Symbiodinium*, *Pyrocystis*, *Spiniferodinium*, *Thoracosphaera*).
4. Digestion cyst –
   This type, in which the organism encysts after feeding, is common in some phagotrophic protist groups but is rare in dinoflagellates. "*Katodinium*" *fungiforme* is an example.

In the first two types, encystment, or the sexual events leading to it, can be triggered by nutrient stress (e.g., nitrogen starvation, the most common experimental method used) or changes in light intensity, photoperiod, or temperature (von Stosch 1964), but other factors are probably also involved. Cyst formation is most commonly observed toward the end of blooms or in the senescent phase of batch cultures.

In many cases, cysts "reflect" the tabulation of the motile cells that gave rise to them by way of ridges or other features like spines, processes, the shape of excystment apertures (archeopyles), etc., that mark the position of thecal boundaries in the motile cells (Fig. 7). This "pseudotabulation" is critical for the taxonomy of fossil taxa.

Excystment will occur after a relatively fixed period at constant temperature. Lower temperature generally prolongs the period. A rapid rise in temperature often triggers excystment. Light may or may not be required. Anaerobic conditions inhibit excystment (see Dale 1983; Pfiester and Anderson 1987 for further details). A residual body, dark brown in color, is often left behind in the empty cyst. It may correspond to an accumulation body or the red body of the cyst (Fig. 8).

Thecal Patterns (Tabulation)

The tabulational patterns formed by the alveolae and the thecal plates contained in them have been used in taxonomy for more than 100 years. Six fundamental types can be recognized (Fig. 9):

1. *Gymnodinoid*. Alveolae are numerous and often hexagonal, the girdle and sulcus being the only clearly distinguishable series. The plates may be too delicate to see or entirely absent. Gymnodinoid tabulations are present in the gymnodiniales and in some members of the distantly related Symbiodiniaceae and Borghiellaceae.

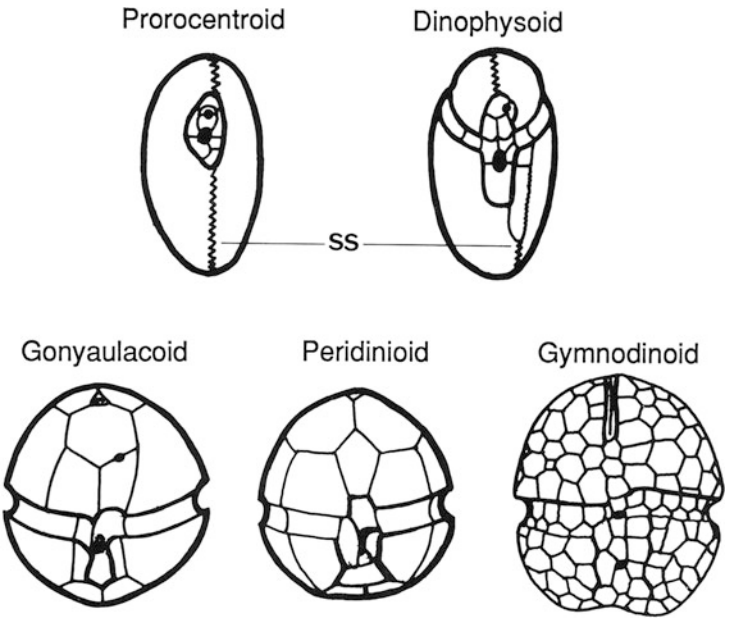

Fig. 8 Basic thecal organizational types (From Fensome et al. 1999)

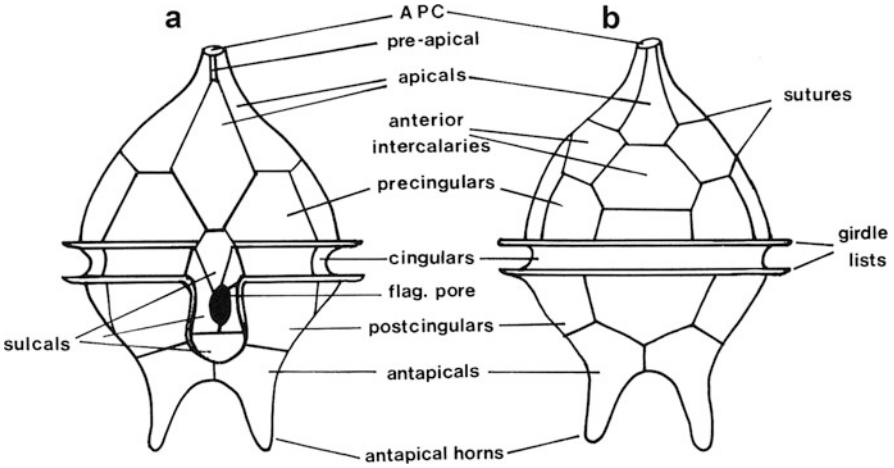

Fig. 9 Thecal plate terminology for a peridinioid or gonyaulacoid taxon. (**a**) ventral view. (**b**) dorsal view

2. *Suessioid*. Amphiesmal vesicles arranged in 6–11 latitudinal series. The number of plates per series, or even the number of series, varies with species. The cingulum is well marked, and it may contain one or two rows of plates. Named after the fossil genus *Suessia*. Extant genera with a suessioid tabulation include

Symbiodinium and *Polarella*, but recent data suggest that fossil Suessiales are not related to *Symbiodinium* and its relatives (Janouškovec et al. 2016).

3. *Peridinioid and Gonyaulacoid*. In these there are five distinct primary latitudinal series termed from apex to antapex/posterior the apicals, precingulars, cingulars (girdle), postcingulars, and antapicals. Plates lying between these series are termed *intercalaries* (anterior or posterior on the epi- or hypotheca, respectively), and those lying within the sulcus are *sulcals*. The midventral epithecal plate often spans both the precingular and apical series. By convention it has been termed the first apical plate (1′). At the apex, an apical pore complex (APC) is often present, consisting of an outer (Po) and inner (Pi) pore plate, and a small pre-apical platelet (Pp) is often present in peridinioids. Apical plates are those that contact the APC. Peridinioid tabulations are defined by a more-or-less symmetrical first apical plate and by the presence of two antapical plates; in gonyaulacoid tabulations, the first apical plate is asymmetrical; and there are two to four fundital plates.
4. *Nannoceratopsioid (fossil only)*. Laterally-flattened cells with a reduced episome. Only cysts are known, and they reflect a sagittal suture dividing the hyposome into right and left halves, like in dinophysoid tabulations. Episomes, however, reflect a gonyaulacoid-peridinioid type of tabulation.
5. *Dinophysoid*. The theca is fundamentally divisible into two halves by a vertical sagittal suture, but a girdle and sulcus are "superimposed" on it, separating an epitheca and hypotheca, and there are small plates on the ventral surface of the epitheca, hypotheca, and in the sulcus around the single large flagellar pore. A simple apical pore is located on the ventral side of the epitheca. The arrangement of the plates varies little within the group, with 18 or 19 being the usual number. Lists (ridges or extensions of the edge of thecal plates) along the girdle and sulcus edges may be prominent and developed to an extraordinary degree in some genera (e.g., *Ornithocercus*, *Histioneis*, and *Citharistes)*, producing bizarre forms, some forming a "phaeosome chamber" from the girdle lists in which extracellular coccoid cyanobacteria occur.
6. *Prorocentroid*. The theca is composed of two large plates, the valves, which join along a toothed margin, the sagittal suture (Figs. 2 and 6). An apical cluster of small platelets of regular arrangement, 8–12 in number (nomenclature in Hoppenrath et al. 2013), surrounds the two pores from which the desmokont flagella arise. The periflagellar platelets lie principally in an excavation of the right valve. A small spine often arises from the periflagellar plate designated as "a" (Taylor 1980).

The plates in each latitudinal series are numbered from the cell's left to right, beginning with the plate closest to the midventral position. This convention, the "Kofoid System," is currently in universal use (Fig. 10). It also uses a notation to designate the series, using primes to indicate the apical (′), precingular (″), postcingular (‴), and antapical (⁗) plates, both when labelling plates on figures and when producing a plate formula. The latter is a listing of the total plates in each series for a species or genus. Thus *Gonyaulax* is represented by Po, Pi, 3′, 2a, 6″, 6C + t, 6S, 6‴, 1p, 1⁗, and *Peridinium* by OP, 4′, 3a, 7″, 5C + t, 6S, 5‴, 2⁗. Cingulars (C),

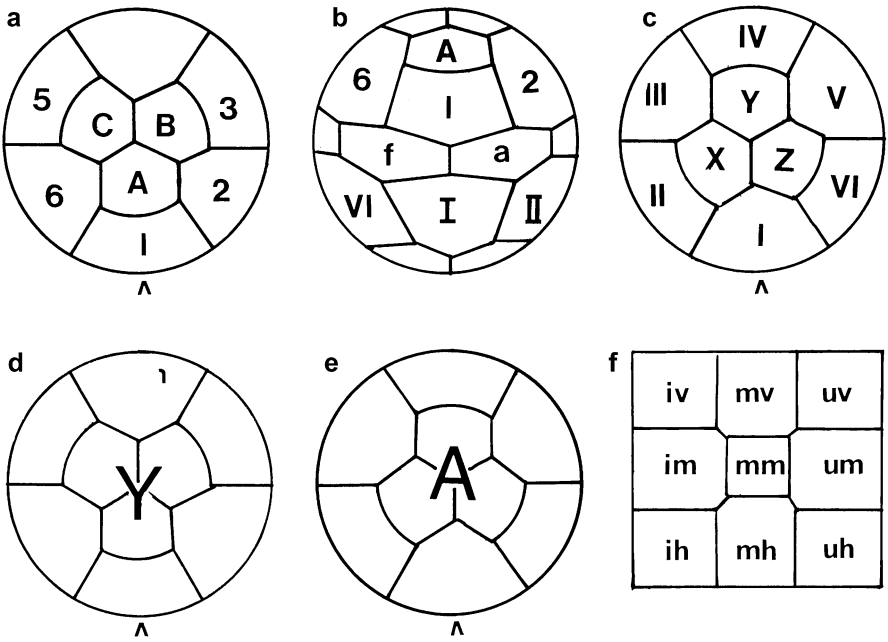

Fig. 10 Model and plate designation used in the Taylor homology system (from Taylor 1980, with modifications by Evitt 1985). (**a**) Polar view; (**b**) ventral view; (**c**) antapical polar view; (**d**) the "Y" arrangement of polar plates relative to the flagellar insertion; (**e**) the "A" arrangement; (**f**) designations for subdivision of a primary plate area (maximum subdivision) using Evitt's modification; *i* initialis; *u* ulter; *m* medialis; *v* vorner; *h* hinter (the latter selected because they are not letters used for whole plates in either system)

sulcals (S), anterior intercalaries (a), and posterior intercalaries (p) are designated by letters. The *t* plate is a small transitional plate between the cingulars and the sulcals at the proximal end of the girdle in peridinioids and at the distal end in gonyaulacoids. Other distinctions between gonyaulacoids and peridinioids include the common occurrence of 6″, 6‴, 1p, and 1⁗ in the former and 2–3a, 7″, 5‴, and 2⁗ in the latter (exceptions being due to apparent suture loss or plate subdivisions); intercalary growth from the overlapping plate margin only in gonyaulacoids versus both sides of a suture; and basic symmetry: the former showing evident torsion, the latter tending to bilateral symmetry.

Although the Kofoid System is usually easy to apply, ambiguities in the attribution of some plates to one series or another can cause problems, resolved by following consensus. This, combined with the mechanical, consecutive numbering, renders the system poor for intergeneric comparisons. Taylor (1980) has introduced a basic model (Figs. 9 and 10) elaborated on by Evitt (1985), consisting of three epithecal polar (A–C), six pre-equatorial (1–6), six equatorial (a–f), six post-equatorial (I–VI), and three hypothecal polar (X–Z) sectors, which represent hypothetical primary plates from which homologous plates can be recognized by

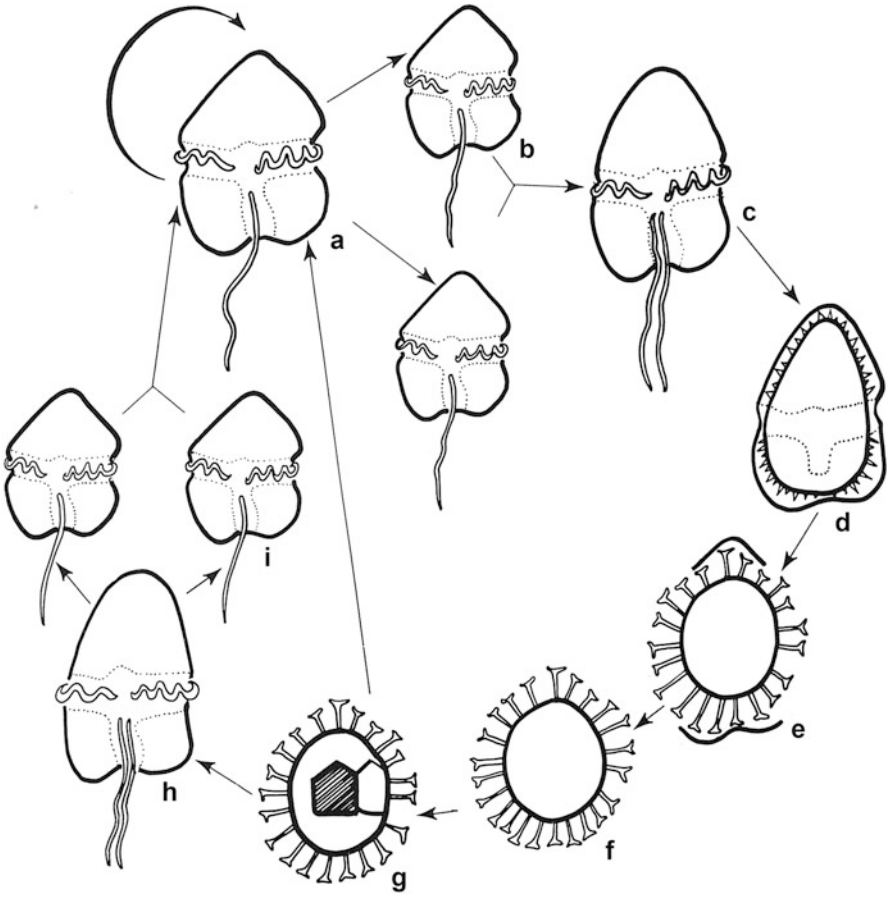

Fig. 11 Common dinoflagellate life cycle (modified from Dale 1983). (**a**) Asexually reproducing motile cell (mastigote); (**b**) gametes (can be iso- or anisogametes); (**c**) planozygote; (**d**) hypnocyst (resting cyst) formation within the theca; (**e**) theca discarded (cysts may be smooth, rigid or spiny); (**f**) dormancy; (**g**) excystment through the archaeopyle; (**h**) meiocytic planozygote; (**i**) meiotic division (**h** and **i** may take place in the cyst and meiosis may involve one or two divisions). Not shown: temporary cysts may be asexually produced from asexually reproducing motile cells (**a**). Pyrocystis and other photosynthetically active amastigotes may be in sexually or asexually produced, pellicle-surrounded "cysts"

assuming subdivisions, suture losses, and plate size and position changes. The first step is to normalize the cell to a sphere, removing obvious plate distortions. Then the primary plates and their sutures are determined by studying the relationships of the plates to each other (see examples given by Evitt 1985).

Cyst walls often exhibit patterns of ridges, spines, or other surface ornamentation, which correspond to the tabulation of the parent theca, although some sutures are often not reflected on the cyst. The pattern discernable on the cyst wall is termed paratabulation and is used extensively in fossil cyst taxonomy (Figs. 11 and 12).

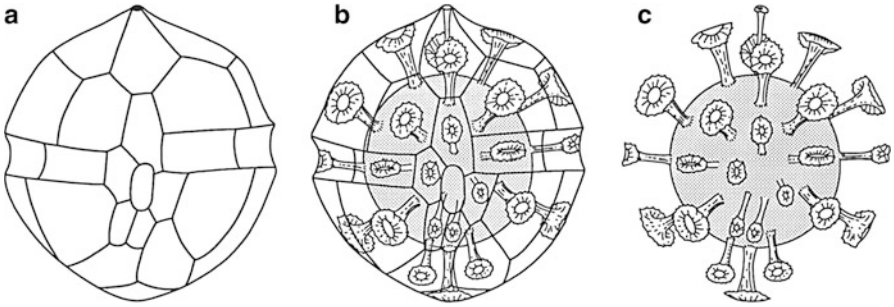

Fig. 12 Development of the fossil cyst species *Hystrichosphaeridium tubiferum* from a hypothetical parent theca. Central body of cyst is shaded (Adapted from Evitt (1985), Fensome et al. (1993). Copyright Micropaleontology Press)

Fossils

If one disregards acritarchs (microfossils with ambiguous morphologies that may or may not be of dinoflagellate origin), a large majority of dinoflagellate fossils consist of cyst stages of forms with gonyaulacoid or peridinoid tabulations (Fensome et al. 1999). Dinoflagellate fossils of other types are rare; they include, for example, suessialean forms, forms with possible dinophysoid affinities (*Nannoceratopsis*), a few Cenozoic gymnodinoid cysts, and fossil chemical traces like dinosterols. In a few cases, some otherwise ambiguous cyst morphologies have been shown to be of dinoflagellate origin through the study of cyst stages of extant forms.

About 15% of extant dinoflagellates produce fossilizable cysts (Head 1996). This does not mean that that was the case in the geologic past, but it does seem to be clear that the fossil record of dinoflagellates is highly incomplete. Nevertheless, certain patterns regarding the evolutionary history of the group can still be recognized.

Fossil dinoflagellates are controversial or absent in strata prior to the early Mesozoic, but quantities of dinosteranes (derivatives of dinosterols, chemical compounds as of yet associated almost exclusively with dinoflagellates) correlate well with some acritarch species' abundance in the Paleozoic (Moldowan and Talyzina 1998). Nevertheless, pre-Mesozoic dinosteranes are unlikely to have originated from dinoflagellates: in extant dinoflagellates, dinosterol is only produced by thecate dinoflagellates and a few of their closest athecate relatives (Janouškovec et al. 2016), and the earliest confirmed (thecate) dinoflagellate fossil is from the mid-Triassic (Fensome et al. 1999). Dinosteranes in early Triassic sediments could be derived from athecate relatives of the thecate clade, but it is unlikely that dinosterol-producing dinoflagellates were present earlier than that. After the mid-Triassic, species diversity increases steadily until the early Cenozoic, and then it declines toward the present day (MacRae et al. 1996). By the mid-Jurassic, practically all major morphological variations of peridinioid and gonyaulacoid forms were already present, and late innovations are very minor. *Nannoceratopsis*, a striking "missing link" between peridinioids and dinophysoids, lived also in the

early Jurassic, as did forms with a suessialean tabulation (already there since the mid-Triassic). Paleontological evidence points to an evolutionary radiation of thecate, cyst-forming dinoflagellates in the late Triassic/early Jurassic that involved early experimentation, stabilization later, and the early presence of "missing links." Whether this evolutionary radiation involved fossil-poor gymnodinoid forms cannot be determined by paleontological data alone.

Maintenance and Cultivation

Dinoflagellates are usually grown in enriched, filtered, and sterilized marine or freshwater. The methods and the media used have been described in detail by Guillard and Keller (1984). The most commonly used media for photosynthetic marine forms are dilutions of Guillard's *f* medium or modifications of Provasoli's *ES*, with Chu's no. 10 for freshwater species. Totally artificial media rarely support vigorous growth, and agar is not suitable for most species. Dinoflagellates are inhibited by strong agitation and prefer light/dark cycles (typically 14:10) to continuous illumination. Many are difficult or impossible to grow axenically (bacteria-free) at present.

Phagotrophic non-photosynthetic species are usually fed smaller, photosynthetic flagellates, with precautions to avoid overgrowth by the latter. Organism-free organic media have been developed for *Oxyrrhis marina* and *Crypthecodinium cohnii*.

Evolutionary History

Molecular evidence shows that the closest relatives of dinoflagellates are apicomplexans and ciliates. These three eukaryotic clades, together with the paraphyletic group that includes their ancestors, the protalveolates (perkinsids, *Colponema*, etc.), form the so-called Alveolates (Cavalier-Smith 1991), one of the best-supported groupings that have emerged from the analysis of molecular phylogenetic data in eukaryotes (e.g., Fast et al. 2002; Cavalier-Smith and Chao 2004 and many others). Morphological data also strongly supports this clade (e.g., Taylor 2004). The closest relatives of alveolates are the stramenopiles (also called heterokonts), the grouping that contains oomycetes, labyrinthulids, opalinids, chrysophytes, diatoms, and brown algae, among others. The relationship between alveolates and stramenopiles is also very well supported with molecular data (e.g., Fast et al. 2001; Harper and Keeling 2003; Hackett et al. 2004a).

The question of whether dinoflagellates evolved from photosynthetic ancestors was answered by the discovery of *Chromera*, a photosynthetic endosymbiont of corals that in phylogenetic trees branches at the base of the apicomplexans (Moore et al. 2008) and whose plastid genes strongly resemble those of the apicomplexans' apicoplast and the peridinin plastids of dinoflagellates (Janouškovec et al. 2010). *Chromera* is only one member of a clade that contains several photosynthetic and many non-photosynthetic members, the so-called chrompodellids, and by comparing

the patterns of the presence, absence, and localization of metabolic pathways involving plastidial elements in chrompodellids, apicomplexans, and dinoflagellates, it was possible to explain the presence of photosynthetic plastids in some members of these groups and not others (Janouškovec et al. 2015). Some non-photosynthetic members of the dinoflagellate lineage have now been shown to contain either plastid-targeted genes or major plastid-associated biosynthetic pathways, e.g., the perkinsozoan *Perkinsus marinus* (Stelter et al. 2007; Matsuzaki et al. 2008; review in Fernández Robledo et al. 2011), *Oxyrrhis marina* (Slamovits and Keeling 2008), *Noctiluca scintillans* (Janouškovec et al. 2016), and *Crypthecodinium cohnii* (Sánchez-Puerta et al. 2007), but in the syndinians, plastids appear to be completely lost (Gornik et al. 2015).

Initially dinoflagellate phylogenetic trees had backbones that were poorly resolved, and so it was difficult to determine phylogenetic relationships of large groups to each other based on this kind of data alone (Daugbjerg et al. 2000; Saldarriaga et al. 2004; Orr et al. 2012); the main value of molecular phylogenetic data was to clarify in-group phylogenies, for example, within groups like calciodinellids, pfiesteriaceans, polykrikoids, or the genera *Symbiodinium* or *Alexandrium*, as well as to underline the differences between groupings of gymnodinoids. More recent phylogenetic studies based on large concatenations of protein sequences (101 genes in Janouškovec et al. 2016) have started to produce phylogenetic trees with better resolved backbones. They suggest that *Oxyrrhis marina* is the earliest branch of the dinoflagellates, followed by the syndinians; whether the Syndiniales are a monophyletic or a paraphyletic group is still unclear. The next group to branch off are the Noctilucales, and the Gymnodiniales build a paraphyletic group that gave rise to thecate dinoflagellates, which are monophyletic. Only a few gymnodinialean lineages are as of yet present in large protein-based trees, but it looks like *Amphidinium* makes the earliest branch after the Noctilucales, followed by the Kareniaceae, the *Gymnodinium* group of families (a single clade that includes *Gymnodinium*, *Togula*, and *Polykrikos*), and *Akashiwo*, the sister group to thecates. The branching order of the thecate groups is not yet clear, but the group includes the Symbiodiniaceae; it looks like the suessioid and gymnodinoid tabulations of the Symbiodiniaceae and Borghiellaceae represent secondary losses of theca (Janouškovec et al. 2016).

Morphological data and palaeontological "missing links" do suggest a close relationship between the four thecate dinoflagellate groups: one theory (unsupported as of yet by molecular data) suggests that the more-or-less symmetric peridinioids arose from gymnodinoids and constitute a paraphyletic grouping that gave rise certainly to the (much more asymmetric) gonyaulacoids, as well as to the *Symbiodinium* group and the dinophysioids (Taylor 2004). The fossil genus *Nannoceratopsis* is a morphological intermediate between peridinioids and dinophysioids (Fensome et al. 1993). The sixth thecate group, the prorocentroids, may have originated from dinophysioid ancestors (Taylor 1980).

A recent study using large phylogenies has suggested that dinoflagellates are primarily a marine group and that transitions to freshwater environments have only happened in a small fraction of the marine lineages (Logares et al. 2007).

Classification

Dinoflagellates have been studied and classified by botanists, zoologists, and paleontologists, and this has resulted in differing taxonomic practices and dual (or even triple) classification schemes. Fensome et al. (1993) unified dinoflagellate classification, and their system builds the scaffolding of the classification system that is presented below. One recent (and very welcome) trend has been the reinvestigation of the type species of large, polyphyletic genera of gymnodinoid dinoflagellates like *Gymnodinium*, *Gyrodinium*, *Amphidinium*, etc., with both ultrastructural and molecular methods (e.g., Daugbjerg et al. 2000; Hansen and Daugbjerg 2004; Flø-Jørgensen et al. 2004). This has enabled a more phylogenetically accurate circumscription of those large genera and has caused a flood of description of new gymnodinoid genera that are not particularly closely related to those types (e.g., *Karenia*, *Karlodinium*, *Takayama*, *Togula*, *Testudodinium*, *Prosoaulax*, *Apicoporus*, *Tovellia*, *Borghiella*, *Baldinia*, *Jadwigia*, etc.). It should be noted, however, that *Gymnodinium*, *Gyrodinium*, *Amphidinium*, etc., are formally still polyphyletic; they contain many species that have not been reinvestigated recently or that have not yet been given new taxonomic placements. Recent papers have used the terms sensu lato and sensu stricto to distinguish between the polyphyletic and the newly defined versions of these genera. In the case of *Gymnodinium*, even the "sensu stricto" version of the genus is still paraphyletic; it has been shown that entire families of dinoflagellates (Polykrikaceae, Warnowiaceae, Actiniscaceae) are descended from it (Hoppenrath and Leander 2007); the corresponding taxonomic changes have not yet been made. In this work, as in much of the primary literature, when there is reason to belive that a species is misclassified into a certain genus, that generic name is given inside apostrophes (e.g., "*Amphidinium*" *longum*).

The classification presented below includes many temporary names and unnamed clades, something that reflects the instability of dinoflagellate classification at the moment. For a more formal classification of the group, see Fensome et al. 1993.

Annex

An informal, annotated classification of living dinoflagellate genera based primarily on molecular data, but using Fensome et al.'s (1993) classification when sequencing data is not available. Note that dinoflagellate classification is currently very unstable, mostly because phylogenies based on small subunit ribosomal genes lack support in many crucial branches.

Perkinsids: Apparently paraphyletic ancestral group to the dinoflagellates. Motile stages have a conoid, micronemes, and rhoptries. External mitotic spindle. Trans-spliced leaders in RNAs from nuclear genes (Zhang et al. 2007), transversal flagellum present in the motile stage of *Parvilucifera prorocentri* (Leander and Hoppenrath 2008). Ancestrally photosynthetic. Inclusion of *Psammosa* in the group seems to render perkinsids paraphyletic, but confirmation of this needs further study (Okamoto et al. 2012).

Perkinsus, *Parvilucifera*, *Psammosa*, *Xcellia*, *Gadixcellia*, *Rastrimonas*?

Dinoflagellates: Eukaryotes lacking nucleosomes and in which histones have been replaced to a large degree by dinoflagellate/viral nucleoproteins (DVNPs); DNA content much higher than in other eukaryotes, chromosomes condensed throughout the life cycle. Ancestrally photosynthetic, with dinokont flagellation (one flagellum takes a transversal orientation), added trans-spliced leaders to nuclear transcripts (Zhang et al. 2007), and an external mitotic spindle (but reversions back to an internal one exist in *Oxyrrhis* and in some species of *Amoebophrya*, Moon et al. 2015).

1. Oxyrrhids: Free-living dinoflagellates with an internal mitotic spindle. Chromosomes continuously condensed, but lacking the fibrillar appearance of core dinoflagellate chromosomes. Molecular data suggests that this monotypic group may be drastically underclassified (Lowe et al. 2005).

Oxyrrhis

2. Syndinians: Parasitic dinoflagellates with at least two life cycle stages: a plasmodial (multinucleate) trophont, and motile, dinokont stages. At least one species has lost all traces of a plastid (*Hematodinium* sp., Gornik et al. 2015); all other described ones are non-photosynthetic. Syndinians may be paraphyletic, but the issue needs more research.

2.1. Ellobiopsids: Trophonts are plasmodial ectoparasites of crustacean zooplankton attached to the host by a nutrient-absorbing rhizoid. Motile stages appear to have dinokont flagella, but this has not been studied in detail. Not always considered to be dinoflagellates; tentatively treated as such here in the absence of nuclear data because of the plasmodial nature of the vegetative stages, because of the apparently dinokont condition of the motile stages, and because molecular data puts the genus *Thalassomyces* within the alveolates with good support, where it weakly clusters with dinoflagellates (Silberman et al. 2004).

Ellobiopsis, *Thalassomyces*, *Parallobiopsis*, *Ellobiocystis*, *Rhizellobiopsis*

2.2. Eduboscquellids and other group 1 alveolates: Most of the members of this group are known only as environmental molecular sequences from the picoplankton of virtually all the world's oceans (de Vargas et al. 2015). Recent data has shown that at least one member of this clade is the genus *Eduboscquella*, a syndinian characterized by a trophont that only becomes multinucleate (i.e., plasmodial) late in its development (as *Duboscquella* in Harada et al. 2007, nomenclatural change in Coats et al. 2012). The fish-egg parasite *Ichthyodinium* also seems to be a member of this group (Skovgaard et al. 2009). Whether the environmental sequences obtained correspond to free-living organisms or to the motile stages of parasites is unknown at present.

Ichthyodinium, *Eduboscquella*, *Dogelodinium*, *Keppenodinium*, symbionts/parasites of radiolarians and phaeodarians (Dolven et al. 2007), and many undescribed species with picoplanktonic life stages in both aerobic and anaerobic environments (Takishita et al. 2007).

2.3. Syndinids and other group 2 alveolates: Another clade whose members are known mostly as environmental sequences from marine picoplankton. A riboclade at the moment, morphological synapomorphies for the group have not been discovered. In molecular trees, there seem to be two distinct groups that correspond to families; a third family exists for which no molecular data has been obtained. Syndinids can be either intracellular or extracellular parasites of copepods, appendicularians, crabs, radiolarians, or other dinoflagellates.

2.3.1. Syndiniaceae: Syndinids in which the trophont consists of a plasmodium with no fixed shape and no internal cavities.

Syndinium, *Hematodinium*, *Merodinium*, *Solenodinium*, *Trypanodinium*

2.3.2. Amoebophryaceae: Syndinids with a wormlike multiflagellated swimming stage, the vermiform.

Amoebophrya

2.3.3. Sphaeriparaceae: Syndinids in which the plasmodial trophont is organized into two segments separated by a sharp constriction, forming an anterior, episome-like region, and a posterior basal disc. Parasitic on appendicularians and radiolarians. No molecular data is available for members of this family.

Atlanticellodinium

2.3.4. Syndinians incertae sedis: *Atelodinium*, *Coccidinium*

3. Core dinoflagellates: Dinoflagellates in which chromosomes are fibrillar in appearance. Mostly free-living, but a few parasitic forms are also known.

3.1. Noctilucales: Dinoflagellates in which trophonts are large and inflated by vacuoles. Only the gametes have a dinokont flagellation and the fibrillar chromosomes that are typical for core dinoflagellates.

Noctiluca, *Kofoidinium*, *Pomatodinium*, *Spatulodinium*, *Leptodiscus*, *Abedinium*, *Cachonodinium*, *Craspedotella*, *Cymbodinium*, *Petalodinium*, *Scaphodinium*

3.2. Gymnodiniales: Paraphyletic group of core dinoflagellates with numerous amphiesmal vesicles arranged non-serially (gymnodinoid alveolar arrangement). Amphiesmal vesicles do not contain thecal plates. Several genera of

this group (e.g., *Gymnodinium*, *Gyrodinium*, *Amphidinium*, *Katodinium*, *Woloszynskia*, *Cochlodinium*) are large and polyphyletic as defined traditionally and are in the process of being reclassified; the classification below only refers to those genera in sensu stricto.

3.2.1. Amphidiniaceans: Benthic or endosymbiotic dinoflagellates with small triangular- or crescent-shaped epicones deflected to the left. Cells dorsoventrally flattened may or may not have chloroplasts.

Amphidinium

3.2.2. Kareniaceans, the "haptophore" lineage: Dinoflagellates with haptophyte-derived plastids and kleptochloroplasts.

Karlodinium, *Karenia*, *Takayama*, *Brachydinium*, *Asterodinium*, *Microceratium*, and the Ross Sea dinoflagellate, an as yet unnamed species from Antarctic ice with haptophyte-derived kleptochloroplasts. *Apicoporus* is related to this clade and may have plastids of very variable sizes, some being not much more than pigmented granules (Sparmann et al. 2008; some cells are entirely unpigmented). These are thought to be peridinin plastids, but no molecular data exists on this.

3.2.3. The *Gyrodinium* s.s. clade: Gymnodinialeans with surface ridges and an elliptical, bisected apical groove. Vesicular chambers around the nucleus. In many species of *Gyrodinium*, there is a tough nuclear capsule either outside of the nuclear envelope or between its two membranes.

Gyrodinium s.s.

3.2.4. Torodiniales: Gymnodinoids in which the episome is much larger than the hyposome and has a hat- or bill-like apical projection. Cells striated longitudinally, vesicular chambers around the nucleus.

3.2.4.1. Kapelodiniaceans: Non-photosynthetic torodiniales with a cap-like apical projection and three rows of vesicles under the rim of the cap.

Kapelodinium

3.2.4.2. Torodiniaceans: Photosynthetic torodiniales with a bill-like apical projection on top of which lies a structure shaped like a counterclockwise inward spiral.

Torodinium

3.2.5. The *Gymnodinium* family group: Molecularly defined grouping of gymnodinoids; many groups have a horseshoe-shaped apical groove running

in an anticlockwise direction and vesicular chambers around the nucleus. Originally conceived as the genus *Gymnodinium* sensu stricto, it later turned out that several families of naked dinoflagellates are contained in the group.

3.2.5.1. Gymnodiniaceans: Paraphyletic family, only definable in a negative way: naked dinoflagellates with no internal skeletons, surface ridges, nematocysts, or ocelli. As defined here, gymnodiniaceans have given rise to polykrikaceans, warnowiaceans, and actiniscaceans.

Gymnodinium s.s., *Paragymnodinium*, *Gyrodiniellum*, *Levanderina*, *Barrufeta*, *Gymnoxanthella*, *Dissodinium*, *Chytriodinium*, *Lepidodinium*, *SpiniferodiniumNusuttodinium*, *Pellucidodinium*, *Pheopolykrikos*, *Togula*, *Syltodinium*/"*Gyrodinium*" *undulans*, "*Cochlodinium*" *polykrikoides*/"*Cochlodinium*" *fulvescens*

3.2.5.2. Polykrikaceans: Pseudocolonial dinoflagellates with half (or a quarter) as many nuclei as zooids. They have the ability to dissociate into pseudocolonies with fewer zooids and just one nucleus. Nematocyst complexes are present. The genus *Pheopolykrikos* is also pseudocolonial (same number of zooids and nuclei), but it is not related to *Polykrikos* in molecular trees (Hoppenrath and Leander 2007).

Polykrikos

3.2.5.3. Warnowiaceans: Dinoflagellates with ocelli, i.e., elaborate light-receiving organelles. Nematocysts also commonly present.

Warnowia, *Erythropsidinium*, *Greuetodinium*, *Nematodinium*, *Nematopsides*, *Proterythropsis*, *Protopsis*

3.2.5.4. Actiniscaceans: Gymnodinialeans with an internal skeleton.

Actiniscus, *Diaster*, *Dicroerisma*

3.2.5.5. Ptychodiscaceans: Naked dinoflagellates in which the pellicle is strongly developed and is the principal structural element in the amphiesma of the motile cell. Few ultrastructural studies, for example, of the nucleus. Probably polyphyletic: *Ceratoperidinium* branches close to the *Gymnodinium* family group in molecular trees, but it is unclear whether the other ptychodiscaceans are related to it.

Tovellia, *Jadwigia*, *Esoptrodinium*, *Opisthoaulax*

3.2.6. Haplozoaceans: Ribbonlike, multicellular dinoflagellates parasitic in appendicularians and polychaetes.

Haplozoon

– Gymnodiniales incertae sedis:
  (a) Genera with uncertain positions in molecular-based phylogenetc trees or whose familiar relationships are unclear: *Akashiwo*, *Ankistrodinium*, *Bispinodinium*, *Moestrupia*, *Testudodinium*. In addition "*Cochlodinium*" *convolutum*/"*Gyrodinium*" *falcatum* makes clades in molecular trees that may represent an undescribed genus.
  (b) Putatively polyphyletic genera with understudied type species: *Cochlodinium*, *Katodinium*, *Woloszynskia*
  (c) Gymnodiniales for which no molecular data exist: *Bernardinium*, *Crepidoodinium*, *Filodinium*, *Gynogonadinium*, *Pavillardia*, *Pyramidodinium*, *Schizochytriodinium*

3.3. Thecates: Dinoflagellates with cellulosic plates inside the alveolae. Primarily with alveolae in a pattern of five or six latitudinal plate series, but these increase in the suessiales and decrease in dinophysiales and prorocentrales.

3.3.1. Gonyaulacales: Thecates in which the first apical plate is asymmetrical and in which there are two to four (usually three) fundital plates (Fig. 10)

3.3.1.1. Cladopyxineans: Gonyaulacales with a partiform tabulation pattern, that is, the first antapical homologue ("Y" plate) contacts the distalmost postcingular plate and in which the posterior sulcal homologue ("Z") is within the sulcus and extends further to the anterior than the posterior intercalary homologue ("X"), thus contacting the first postcingular homologue (Fig. 10). Molecular data are not available for the group.

Cladopyxis, *Acanthodinium*, *Palaeophalacroma*, *Sinodinium*

3.3.1.2. Gonyaulacineans: Gonyaulacales with a sexiform tabulation pattern (Fig. 10), that is, the first antapical homologue ("Y" plate) contacts the distalmost postcingular plate and in which the posterior intercalary homologue ("X") extends further to the anterior than the posterior sulcal homologue ("Z").

3.3.1.2.1. Gonyaulacaceans: Gonyaulacineans with six precingular plates in which the sulcus is more-or-less midventral (may be straight, oblique, or sigmoideal). The antapical outline is more-or-less symmetrical, no dorsoventral compression.

Protoceratium, *Lingulodinium*, *Gonyaulax*, *Acanthogonyaulax*, *Amylax*, *Spiraulax*, *Ataxiodinium*, *Bitectatodinium*, *Halostylodinium*, *Impagidinium*, *Pentadinium*, *Schuettiella*

3.3.1.2.2. Ceratocoryaceans: Gonyaulacineans with five precingular plates and a midventral, L-type sulcus. There is a strong dextral torsion.

Ceratocorys

3.3.1.3. Ceratiineans: Gonyaulacales with at least three horns and in which the first antapical plate ("Y") contacts six or seven adjacent plates including the distalmost postcingular.

Ceratium, *Tripos*

3.3.1.4. "Goniodomineans": Gonyaulacales with a quinqueform tabulation pattern, that is, the first antapical homologue ("Y" plate) does not contact the distalmost postcingular plate. Plate growth occurs only at overlapping plate margins. Note: because of multiple taxonomic and nomenclatural problems (Kretschmann et al. 2015), the generic name *Goniodoma* has been replaced by *Pyrrhotriadinium*. Suprageneric taxon names based on *Goniodoma* (e.g., Goniodomineans, Goniodomaceans, etc.) have not yet followed suit and are given here in quotation marks.

3.3.1.4.1. "Goniodomaceans": "Goniodomineans" in which the principal life-cycle stage is a motile thecate cell.

3.3.1.4.1.1. "Goniodomoideans": "Goniodomaceans" in which the posterior sulcal homologue ("Z") is external to the sulcus and cells are not anteroposteriorly compressed. Dinosporin cysts. Molecular data are not available for the group.

Pyrrhotriadinium, *Pachydinium*

3.3.1.4.1.2. Gambierdiscoideans: "Goniodomaceans" in which the posterior sulcal homologue ("Z") is external to the sulcus and cells anteroposteriorly compressed. No ventral pore.

Gambierdiscus, *Fukuyoa*, *Coolia*, *Ostreopsis*

3.3.1.4.1.3. Helgolandinioideans: "Goniodomaceans" with either of the following characters: tabulation has more than the typical number of plates in at least two plate series or the presence of a smooth cellulosic cyst in the life cycle.

Helgolandinium, *Alexandrium*, *Fragilidium*, *Pyrophacus*

3.3.1.4.1.4. Pyrodinioideans: "Goniodomaceans" in which the posterior sulcal homologue ("Z") and right sulcal homologue are within the sulcus.

Pyrodinium

3.3.1.4.2. Pyrocystaceans: "Goniodomineans" in which the principal life cycle stage is a nonmotile vegetative cyst.

Pyrocystis

3.3.1.5. Gonyaulacales incertae sedis: *Adenoides*, *Heterodinium*, *Crypthecodinium*, *Centrodinium*, *Dolichodinium*, *Goniodinium*, *Peridiniella*, *Planodinium*, *Thecadiniopsis*, *Thecadinium*, *Pseudothecadinium*, *Stylodinium*, *Pseudadenoides*

3.3.2. Dinophysiales: Dinoflagellates with a sulcus, a cingulum, and a sagittal suture that extends the entire length of the cell

3.3.2.1. Dinophysiaceans: Dinophysiales in which the motile cell is never more than three times as long as it is broad. Ventral pore on the ventral episome, and flagellar pore immediately posterior to the cingulum.

Dinophysis, *Phalacroma*, *Citharistes*, *Dinofurcula*, *Latifascia*, *Histioneis*, *Histiophysis*, *Metadinophysis*, *Metaphalacroma*, *Ornithocercus*, *Pseudophalacroma*, *Sinophysis*, *Thaumatodinium*, *Oxyphysis*

3.3.2.2. Amphisoleniaceans: Dinophysiales in which the motile cell is more than four times as long as it is wide. The ventral pore is on the ventral episome, and the flagellar pore is significantly posterior to the cingulum.

Amphisolenia, *Triposolenia*

3.3.3. Prorocentrales: Dinoflagellates with no sulcus or cingulum, apically inserted flagella.

Prorocentrum, *Mesoporos*

3.3.4. The *Symbiodinium* order ("Symbiodiniales," once the taxon is described formally): *Symbiodinium* and several fossil genera have motile stages with seven latitudinal series of amphiesmal vesicles, i.e., a suessioid tabulation, and this feature was used in the past to define the order Suessiales. Nevertheless, the fossil genus *Suessia* has morphological features that distinguish it from extant Symbiodiniaceae (and Borghiellaceae), and is now thought that the two groups are not related (Janouškovec et al. 2016). The term Suessiales should be used for the group that includes *Suessia* and its fossil relatives, not *Symbiodinium*. Several dinoflagellates with a typically gymnodinoid tabulation group strongly with *Symbiodinium* in molecular trees, there is obviously a strong trend within the group to

increase the number of alveolae and reduce the theca. Eyespots in members of this group are associated with one or more rows of brick-like vesicles.

3.3.4.1. Borghiellaceans: Eyespot consists of rows of globules arranged in a single layer within the chloroplast, and a large, narrow vesicle containing a single layer of translucent bricklike structures.

Borghiella, *Baldinia*, "*Woloszynskia*" *pesheri*

3.3.4.2. Symbiodinaceans: Eyespot contains many layers of brick-like structures. No globules inside a chloroplast.

Symbiodinium, *Polarella*, *Protodinium*, *Prosoaulax*, *Pelagodinium*, *Biecheleria*, *Biecheleriopsis*, *Piscinoodinium*, *Haidadinium*, *Ansanella*, *Asulcocephalium*, *Leiocephalium*, "*Gymnodinium*" *natalense*, "*Gymnodinium*" *linucheae*, "*Katodinium*" *fungiforme*

3.3.4.3. "Symbiodiniales" incertae sedis: *Sphaerodinium*

3.3.5. Peridiniales: Thecates in which the first apical plate is roughly symmetrical, and that have two antapical plates placed more-or-less symmetrically about the midventral/middorsal plane (may be fused or subdivided secondarily).

3.3.5.1. Amphidomataceans: Molecularly-defined clade, six or four apical plates.

Amphidoma, *Azadinium*

3.3.5.2. Heterocapsids: Peridiniales with five apical plates, not laterally compressed.

Heterocapsa

3.3.5.3. Glenodinoids: Peridiniales with four apical plates and six postcingular plates.

Glenodinium, *Glenodiniopsis*, "*Gymnodinium*" *impatiens*

3.3.5.4. Peridiniineans: Peridiniales with three or four apical plates and five postcingular plates.

3.3.5.4.1. Peridiniaceans: Peridiniineans with a distinct cingulum of four to six cingular plates (exclusive of a transitional plate that is sometimes present) and with at least one intercingular boundary on the dorsal surface.

3.3.5.4.1.1. Peridinioideans: Peridiniaceans with seven precingular plates and peridinin-containing plastids, and without calcareous cysts (often build cysts of dinosporin). In all likelihood paraphyletic. The apical pore complex may be absent.

Peridinium, *Vulcanodinium*

3.3.5.4.1.2. Dinotoms: Peridiniaceans with diatom-derived plastids

Kryptoperidinium, *Durinskia*, *Dinothrix*, *Galeidinium*, "*Peridinium*" *quinquecorne*, "*Gymnodinium*" *quadrilobatum*, "*Peridiniopsis*" *penardii*, "*Peridiniopsis*" cf. *kevei*

3.3.5.4.1.3. The *Zooxanthella* clade: Symbionts in radiolarians and hydrozoans

Zooxanthella

3.3.5.4.1.4. Endodiniaceans: Endosymbionts in the cnidarian *Velella velella*.

Endodinium

3.3.5.4.1.5. Thoracosphaeraceans: Peridiniaceans with five or six precingular plates that often form calcareous cysts. Preliminary data suggest that they may be paraphyletic, having given rise to the blastodinioids.

Pentapharsodinium, *Duboscquella*, *Duboscquodinium*, *Ensiculifera*, *Calcicarpinum*, *Pernambugia*, *Scrippsiella*, *Brandtodinium*, *Calciodinellum*, *Calcigonellum*, *Calciperidinium*, *Caracomia*, *Follisdinellum*, *Fuettererella*, *Lebessphaera*, *Pentadinellum*, *Praecalcigonellum*, *Wallidinellum*, *Leonella*, *Melodomuncula*, *Posoniella*, *Thoracosphaera*, *Bysmatrum*, *Chimonodinium*, *Theleodinium*, *Bicarinellum*, *Tintinnophagus*, *Aduncodinium*, *Stoeckeria*, *Paulsenella*, *Pfiesteria*, *Cryptoperidiniopsis*, *Luciella*, *Amyloodinium*, *Tyrannodinium*, *Naiadinium*, "*Peridinium*" *aciculiferum*/"*Scrippsiella*" *hangoei*/ "*Peridinium*" *baicalense*/"*Peridinium*" *euryceps*, "*Peridiniopsis*" *niei*, "*Peridiniopsis*" *penardii*

3.3.5.4.1.6. Blastodinioids: Parasitic dinoflagellates living unattached in the gut of copepods and producing a very distinctive trophont. Only the motile stages have an obvious dinokaryon.

Blastodinium

3.3.5.4.1.7. Peridiniopsids: A group of fresh-water dinoflagellates with rDNA sequences similar to those of *Peridiniopsis borgei* from brackish/limnic habitats (Logares et al. 2007).

Peridiniopsis, *Palatinus*, "*Peridinium*" *umbonatum*, "*Peridinium*" *inconspicuum*, "*Peridinium*" *centenniale*

3.3.5.4.1.8. Peridiniaceans incertae sedis: *Ailadinium*, *Amphidiniella*, *Kansodinium*, *Madanidinium*, *Pileidinium*

3.3.5.4.2. Protoperidiniaceans: Peridiniineans with a well-imprinted cingulum with three cingular plates excluding a transitional plate; there are no intracingular boundaries on the dorsal surface.

3.3.5.4.2.1. Protoperidinioideans: Protoperidiniaceans with two antapical plates.

Protoperidinium, *Congruentidium*, *Archaeperidinium*, *Amphidiniopsis*, *Glochidinium*, *Brigantedinium*, *Echinidinium*, *Herdmania*, *Islandinium*, *Minuscula*, *Multispinula*, *Quinquecuspis*, *Stelladinium*, *Trinovantedinium*, *Votadinium*, *Xandarodinium*

3.3.5.4.2.2. Diplopsaloids: Protoperidiniaceans with six precingular and one antapical (=fundital) plate.

Diplopsalis, *Kolkwitziella*, *Boreadinium*, *Diplopelta*, *Diplopsalopsis*, *Dissodium*, *Dubridinium*, *Gotoius*, *Oblea*, *Preperidinium*, *Zygabikodinium*, *Niea*, *Qia*, "*Protoperidinium*" *depressum*/"*Protoperidinium*" *claudicans*

3.3.5.4.2.3. The *Lessardia/Roscoffia* clade: Protoperidiniaceans with five precingular plates.

Lessardia, *Roscoffia*, *Rhinodinium*, *Cabra*

3.3.5.4.3. Podolampaceans: Peridiniineans in which the cingulum is not indented, but is composed of three cingular plates.

Podolampas, *Blepharocysta*, *Gaarderiella*, *Heterobractum*, *Lissodinium*, *Mysticella*

3.3.5.5. Peridiniales incertae sedis: *Chalubinskia*, *Hemidinium*, *Heteraulacus*, *Nephrodinium*, *Oodinium*, *Plagiodinium*, *Protoodinium*, *Sabulodinium*, *Staszicella*, *Thaurilens*

3.3.6. Thecates incertae sedis: *Archaeosphaerodiniopsis*, *Dinosphaera*, *Melanodinium*, *Oxytoxum*, *Thompsodinium*

3.4. Core dinoflagellates incertae sedis: *Actinodinium*, *Adinimonas*, *Apodinium*, *Bargoniella*, *Cachonella*, *Caryotoma*, *Cystodinedria*, *Cystodinium*, *Desmocapsa*, *Desmomastix*, *Dinamoebidium*, *Dinastridium*, *Dinoclonium*, *Dinococcus*, *Geodinium*, *Gloeodinium*, *Glenoaulax*, *Halophilodinium*,

Hypnodinium, *Micracanthodinium*, *Myxodinium*, *Oodinioides*, *Parapodinium*, *Phytodinium*, *Pleromonas*, *Proaulax*, *Pseliodinium*, *Rhizodinium*, *Rufusiella*, *Schizodinium*, *Tetradinium*
Ptychodiscus, *Balechina*, *Berghiella*, *Ceratoperidinium*, *Lissaiella*, *Lophodinium*, *Sclerodinium*, *Amphitholus*, *Achradina*, *Monaster*

Tovelliaceans: Dinoflagellates with a thin theca and an eyespot composed of pigment globules not bound by membranes and not located in a chloroplast. Members of this group also have an apical line of narrow plates, i.e., a small number of narrow thecal plates arranged in a row, level with the cell surface and lined on each side by another row of wider plates.

Genera in dinoflagellate species lists that are not considered to be dinoflagellates by Fensome et al. (1993): *Chilodinium*, *Entomosigma*, *Glyphidium*, *Pelagorhynchus*, *Pronoctiluca* (see Gawryluk et al. 2016), *Protodinifer*

Genera considered to be taxonomic junior synonyms by Fensome et al. (1993), but that have not been formally transferred: *Amphiceratium*, *Aureodinium*, *Biceratium*, *Bourrelyella*, *Branchiophilus*, *Cachonina*, *Caledonidinium*, *Ceratodinium*, *Clathrocysta*, *Clipeodinium*, *Corythodinium*, *Dimastigoaulax*, *Dinoceras*, *Dinopodiella*, *Dinopyxis*, *Discodinium*, *Epiperidinium*, *Exuviaella*, *Gessnerium*, *Gymnocystodinium*, *Hemicystodinium*, *Heteroceras*, *Hirundinella*, *Hyalosaccus*, *Latifascia*, *Lebouraia*, *Leptospathium*, *Manchudinium*, *Melodinium*, *Microtaeniella*, *Murracystis*, *Nectocystis*, *Parahistioneis*, *Parelion*, *Parrocelia*, *Pavillardinium*, *Pentadinium*, *Philozoon*, *Photocystis*, *Phyllodinium*, *Phytodinedria*, *Planinosphaeridium*, *Plectodinium*, *Polysphaeridium*, *Poroceratium*, *Prorocentrum*, *Prodinophysis*, *Proheteroschisma*, *Properidinium*, *Protogonyaulax*, *Pseudoactiniscus*, *Roulea*, *Schillingia*, *Spiraulaxina*, *Sporodinium*, *Steiniella*, *Trochodinium*, *Tuberculodinium*

Ciliophora

18

Denis H. Lynn

Abstract

The ciliated protists (Phylum Ciliophora) are typically longer than 50 μm in body length and so are conspicuous microbial eukaryotes. There are over 8,000 species of these usually quickly moving protists, which locomote using files of cilia organized on the cell surface. In addition to the files of cilia or kineties on the cell surface, ciliates are also characterized by nuclear dimorphism or the possession of two kinds of nuclei: (1) the micronucleus, which is not transcriptionally active and which is considered the equivalent of the germ line in multicellular organisms and (2) a macronucleus, which is transcriptionally active and which is typically a developmental product of the amplification of the micronuclear or germ-line DNA. The micronucleus participates in conjugation, which is the sexual process of ciliates, and the third major feature to characterize this phylum. Ciliates as large cells are the top predators or heterotrophs in microbial food webs when metazoans are absent. As heterotrophs, they feed upon bacteria, smaller protists, and even other ciliates in ecosystems from the poles to the tropics and from terrestrial soils to the sediments around deep-sea hydrothermal vents. The genus *Mesodinium* includes the only "autotrophic" ciliate species, but many species are mixotrophic, capturing the chloroplasts of prey or hosting autotrophic protists as endosymbionts. Ciliates can also be symbionts of other organisms, ranging from commensals found in the stomachs of ruminants to parasites of fish. Ciliates, such as *Tetrahymena* and *Paramecium*, whose genomes have been sequenced, serve as model organisms for cell and molecular biology.

Introduction

General Characteristics

The ciliates are undoubtedly one of the easiest groups of protists for the nonspecialist to identify since their typical feature is the presence of files or rows of cilia, known as kineties, on the cell surface. Most also have a cytostome or "cell mouth" around which oral cilia are arranged. Ciliates also exhibit nuclear dualism in which the relatively larger macronucleus is physiologically active, containing thousands of copies of genes, while the relatively smaller, diploid micronucleus is the germ nucleus whose meiotic products are exchanged during conjugation. These general features are found together in no other group of protists. *Stephanopogon* was a disturbingly exceptional ciliate as it appeared to have files of cilia on the cell surface but lacked nuclear dualism, but we now know that *Stephanopogon* is an example of presumed phylogenetic affinity that turned out to be convergence when inspected more closely: its kinetid does not have any typical ciliate fibrillar associates (i.e., no transverse microtubular ribbon, no postciliary microtubular ribbon, no kinetodesmal fiber) (Patterson and Brugerolle 1988; see ▶ Heterolobosea). There are over 1,100 ciliate genera and over 8,000 species included in these genera (Lynn 2008), although some argue that this diversity may represent only 10% of the actual diversity of species (Foissner et al. 2008).

Occurrence

Most species are free-living and found in ponds, lakes, estuaries, saltmarshes, and oceans. They have been collected in almost every conceivable aqueous habitat from Antarctica (Kepner et al. 1999 in Lynn 2008; Song and Wilbert 2000 in Lynn 2008) to hot springs; from small, temporary puddles to lakes and oceans (Kofoid and Campbell 1939); from slightly moistened soils (Foissner 1988a in Lynn 2008) to fresh waters (Beaver and Crisman 1989) and saline waters (Pierce and Turner 1992); and from streams (Cleven 2004 in Lynn 2008) to sewage treatment plants (Curds 1975b in Lynn 2008).

A variety of species is available from culture collections and biological supply houses (Table 1). Those strains kept in culture collections are most likely to have a certified pedigree and should be chosen for experimental work.

Literature

The nonspecialist is advised to consult introductory protozoology books, such as Hausmann et al. (2003), although there is still much of value in older texts, for example, Grell (1973) or Sleigh (1989). Having established an appreciation for the

Species[a]	Source[b]	Species	Source
Blepharisma americanum CCAP		*Paramecium tredecaurelia* ATCC	
Blepharisma hyalinum CCAP		*Paramecium triaurelia* ATCC	
Blepharisma stoltei ATCC		*Paramecium undecaurelia* ATCC	
		Parauronema acutum ATCC	
Bursaria truncatella BS		*Plagiopyla nasuta* CCAP	
		Potomacus pottsi ATCC	
Cinetochilum margaritaceum ATCC		*Prodiscophrya collini* CCAP	
Chilodonella uncinata ATCC			
Cohnilembus reniformis CCAP		*Sorogena stoianovitchae* ATCC	
Coleps hirtus CCAP		*Spirostomum ambiguum* CCAP	
Colpidium striatum CCAP		*Stentor coeruleus* BS	
Colpoda cavicola ATCC			
Colpoda cucullus ATCC		*Tetrahymena americanis* ATCC, CCAP	
Colpoda inflata ATCC, CCAP		*Tetrahymena asiatica* ATCC	
Colpoda magna ATCC			
Colpoda maupasi ATCC		*Tetrahymena australis* ATCC	
		Tetrahymena bergeri ATCC	
Colpoda steinii ATCC, CCAP		*Tetrahymena borealis* ATCC, CCAP	
Cyclidium glaucoma ATCC, CCAP		*Tetrahymena canadensis* ATCC, CCAP	
Dexiostoma campyla ATCC, CCAP			
Didinium nasutum ATCC, BS		*Tetrahymena capricornis* ATCC	
		Tetrahymena cosmopolitanis ATCC *Tetrahymena corlissi* ATCC	
Euplotes gracilis ATCC		*Tetrahymena elliotti* ATCC	
		Tetrahymena farleyi ATCC	
Euplotes vannus CCAP		*Tetrahymena furgasoni* ATCC	
Euplotes raikovi ATCC		*Tetrahymena hegewischi* ATCC	
Heliophrya sp. ATCC		*Tetrahymena hyperangularis* ATCC	
Ilsiella palustris CCAP		*Tetrahymena limacis* ATCC, CCAP	
Mesanophrys chesapeakensis ATCC		*Tetrahymena lwoffi* CCAP	
Meseres corlissi CCAP		*Tetrahymena malaccensis* ATCC	
Metopus es CCAP		*Tetrahymena nanneyi* ATCC	
Nassula sorex CCAP		*Tetrahymena nipissingi* ATCC	
Opisthonecta henneguyi ATCC		*Tetrahymena paravorax* ATCC	
		Tetrahymena patula ATCC, CCAP	
Paramecium biaurelia ATCC, CCAP		*Tetrahymena pigmentosa* ATCC, CCAP	
Paramecium bursaria CCAP, BS		*Tetrahymena pyriformis* ATCC, CCAP	
Paramecium caudatum BS		*Tetrahymena rostrata* ATCC	
Paramecium decaurelia ATCC		*Tetrahymena setosa* ATCC	
Paramecium dodecaurelia ATCC		*Tetrahymena shanghaiensis* ATCC	
Paramecium jenningsi ATCC			
Paramecium multimicronucleatum ATCC, BS		*Tetrahymena sonneborni* ATCC

general biology of the phylum, the reader may choose to read Grassé (1984), Hausmann and Bradbury (1996), Jones (1974), and Matthes and Wenzel (1966) or to specialize in any of a number of areas. Lynn (2008) provides a comprehensive account of the literature and the history of ciliatology, and the present chapter is largely a précis of Lynn's monographic work.

More detailed descriptions of particular genera are provided in books on the biology of: *Blepharisma* (Giese 1973); *Paramecium* (Beale and Preer 2008; Görtz 1988); *Stentor* (Tartar 1961); and *Tetrahymena* (Asai and Forney 2000; Collins 2012; Elliott 1973). Details of the physiology and biochemistry of *Tetrahymena* can be found in Hill (1972) and of the developmental biology and genetics of *Paramecium, Tetrahymena, Euplotes*, and other ciliates in Nanney (1980), Frankel (1989), and Beale and Preer (2008).

Several monographs contain review papers that include chapters specifically devoted to the ciliates. These include the general biology of ciliates (Grassé 1984), their systematics (Lynn 2008; de Puytorac 1994), chemical aspects of protozoan biology (Kidder 1967), aspects of the biochemistry and physiology of protozoa (Hutner 1964; Hutner and Lwoff 1955; Levandowsky and Hutner 1980; Lwoff 1951), and selected topics on a wide range of protozoan research topics (Chen 1967–1972).

Specific topics in ciliate biology have been reviewed: extrusive organelles (extrusomes) (Hausmann 1978; Rosati and Modeo 2003 in Lynn 2008); membrane trafficking (Allen and Fok 2000); contractile vacuoles (Allen 2000; Patterson 1980); evolution of cortical microtubular structures (Lynn 1981); somatic function of the micronucleus (Ng 1986); genetics and aging (Smith-Sonneborn 1981); and endosymbionts of *Euplotes* (Heckmann 1983).

Some specific mention should be made of publications on the systematics and ecology of ciliates. Foissner et al. (1994), for example, have published useful keys for freshwater ciliates found in activated sludge plants and other anoxic environments. For a key to species used as biological indicators, see Bick (1972). Curds (1982) and Curds et al. (1983) have provided comprehensive keys to the genera of freshwater ciliates from Britain and other regions. For families of marine ciliates of the northeastern United States see Borror (1973). Foissner et al. (1999) have published a key to limnetic ciliates. Lynn and Small (2002) have provided a broader key to representative genera and species of free-living and symbiotic as well as freshwater and marine ciliates while Jankowski (2007) has reviewed all genera. Berger (2011) is an example of his taxonomic treatments of hypotrich groups while Vd'ačný and Foissner (2012) continue the taxonomic monographs published by the Foissner lab.

History of Knowledge

Antony von Leeuwenhoek was probably the first to observe ciliates. Until the mid-nineteenth century, ciliates were called Infusoria because of their prominence in infusions of vegetation. The early years were spent mainly in descriptive taxonomy. In the nineteenth century, taxonomic research on the protists was expanded by such men as Bütschli, Claparède, Dujardin, Kent, Lachmann, Maupas, and Stein. Stein (1859, 1867 in Corliss 1979) carefully and precisely used the variations in the ciliature of oral and somatic regions of the cortex to establish affinities among taxa. Bütschli (1887–1889 in Lynn 2008) published a comprehensive monograph on the ciliates in which he modified Stein's scheme of classification. Bütschli's classification scheme of the Class INFUSORIA dominated until well into the twentieth century (see Corliss 1974a in Lynn 2008). Kahl (1930–1935) monographed the ciliates, primarily of northern Europe. His encyclopedic work is still authoritative. The name CILIOPHORA was originally proposed by Doflein in 1901. In the mid-1930s, Chatton and Lwoff perfected the "wet" silver impregnation technique, which revealed the pattern of surface and subsurface kinetosomes (basal bodies). The "Chatton-Lwoff" technique revealed details of the cortical patterns and provided information for Fauré-Fremiet's (1950a in Lynn 2008) next revision of ciliate classification, formalized by Corliss (1956, 1961 in Lynn 2008). Basing his analysis primarily on details of the cortex revealed by light microscopy, Jankowski (1967 in Lynn 2008) recognized even more diversity and elevated the number of ciliate orders. The development and use of electron microscopy during the next decade revealed an even more complex picture to systematists (Lynn 2008).

Building on Jankowski's ideas and new ultrastructural information, de Puytorac et al. (1974 in Lynn 2008) and Corliss (1974a, b in Lynn 2008) presented a further revision of what is now recognized as the Phylum CILIOPHORA. Small and Lynn (1981 in Lynn 2008) argued: (1) that these revisions of ciliate classification had been presented with inadequate consideration of their conceptual bases and (2) that more

weight must be placed on the ultrastructural features of the cortex, especially the somatic kinetid (Lynn 1981; Lynn and Small 1981 in Lynn 2008), if phylogenetic affinity was to be recognized. Small and Lynn (1981 in Lynn 2008) proposed a radically new classification system that formed the basis of the revised classifications presented by Lynn and Small (1997, 2002 in Lynn 2008; see section below on "Characterization and Recognition"). Jankowski (2007) has presented a revised system. See Corliss (1979, 1986) and Lynn (2008) for more detailed historical accounts of ciliate systematics.

Practical Importance

The agricultural and medical importance of ciliates relates to their associations with mammals. Large populations of particular species of symbiotic ciliates are found in the digestive tracts of sheep, goats, cattle, pigs, and horses. Although their presence is not essential for the growth of the herbivores, the ciliates most likely stabilize the cellulolytic bacterial populations (Bonhomme 1990 in Lynn 2008; Coleman 1989 in Lynn 2008; Dehority 1993 in Kreier and Baker 1993).

A wide variety of ciliates exploit both freshwater and marine fishes (Basson and Van As 2006 in Woo 2006; Burgess and Matthews 1995b in Lynn 2008; Dickerson 2006 in Woo 2006; Bradbury 1994 in Kreier 1994; Iglesias et al. 2001 in Lynn 2008), presenting economic problems in aquaculture operations only when present in large numbers (Harikrishnan et al. 2010). *Balantidium,* the only endoparasitic ciliate of man, has been reported to cause gastrointestinal infections. These often occur in places where people and pigs cohabit (Schuster and Ramirez-Avila 2008; Zaman 1993 in Kreier and Baker 1993). Numerous ciliates are parasites of invertebrate marine animals (Bradbury 1994 in Kreier 1994). Their effect, from the human perspective, can be defined as harmful, when, for example, populations of the commercially important Dungeness crab are infected (Morado and Small 1995) or rearing of snails for human consumption (Segade et al. 2009) or beneficial, when the infected hosts are the larvae and adults of insects that are vectors of human parasites (Barros et al. 2006 in Lynn 2008; Batson 1983 and references cited therein; Washburn et al. 1988 in Lynn 2008).
