Ciliates have been used in a number of practical applications, ranging from the assessment of water quality to their use as model organisms for assessment of the effects of chemicals on metazoans.

Certain associations of ciliates can be used as complex indicators of the quality of the environment (Bick 1972 in Lynn 2008; Foissner 1988; Foissner et al. 1982) and to reveal the complex effects of pollution on the microbiota (Cairns et al. 1972; Tan et al. 2010). Ciliates play an important, perhaps essential, role in the clarification of water during and after sewage treatment (Curds 1969 in Lynn 2008; Fried et al. 2000 in Lynn 2008; Small 1973 in Lynn 2008).

Protists are becoming increasingly popular as bioassay organisms due in part to rising costs of maintaining laboratory animals and increasing pressure from animal welfare groups (Schultz et al. 1978). Ciliates, in particular the *Tetrahymena*

"pyriformis" species complex and *Colpidium campylum*, have been used in bioassays for protein quality (Rølle 1980; Wang et al. 1980), in bioassays to detect toxic substances in aquatic environments (Gilron and Lynn 1996; Gilron and Lynn 1998; Slabbert et al. 1983) and soils (Forge et al. 1993 in Lynn 2008), and as possible models for mammalian cells in assessing the effects of chemicals (Dayeh et al. 2004).

Habitats and Ecology

The comprehensive bibliography of Finlay and Ochsenbein-Gattlen (1982), while dated, should provide the interested reader with a starting point for the literature. Fenchel (1987) provides another focus with some emphasis on the ciliates while Dolan et al. (2013) have provided a thorough and readable overview of the systematics and ecology of tintinnid ciliates, a conspicuous group in the marine plankton.

Habitats

The four main environments where ciliates are obvious include the benthos, especially the marine littoral, terrestrial soils, the plankton, and certain symbiotic associations. Ciliates are also found in some unusual habitats, which will be described as well.

Benthic Habitats. Benthic ciliates have been studied in freshwater, brackish, and marine habitats where they may be found freely swimming over the substrate or attached to it. The community of microbes in aquatic environments attached to rocks, fallen logs, and the like is called the aufwuchs or biofilm.

One of the earliest studies of the benthic ciliates within sediments was Fauré-Fremiet's study (1950c in Lynn 2008) of the interstitial fauna of sandy beaches; he noted that ciliate species may be free-swimming in the interstices or thigmotactic, crawling on grain surfaces. Others are attached to the grains. The distribution of ciliates is affected both by the compaction and the redox potential of the substrate in marine (Fenchel 1969) and salt marsh sediments (Elliott and Bamforth 1975 in Corliss 1979). Ciliates are particularly conspicuous when fine interstices are present and when oxygen tension is low. Azovsky and Mazei (2013) concluded that ~60% marine benthic ciliates species are endemic. Ciliates are common eukaryotic organisms in sediment trap samples off southern California at depths to 2,000 m and in the deep benthos of the Mediterranean Sea (Hausmann et al. 2002 in Lynn 2008), often conspicuous in deep anoxic regions (Orsi et al. 2012; Takishita et al. 2010). They have been found on rock surfaces as well as on the tubes of vent worms in the 21° N hydrothermal vents at depths up to 2,600 m (Small and Gross 1985).

Terrestrial Soils. Ciliates are often conspicuous in damp soils; they are ubiquitous in soil cultures from all parts of the world (Foissner 1998a in Lynn 2008). However, ciliates are usually outnumbered by the testate amebae (Bamforth 1980 in Lynn 2008). Protists in general constitute a relatively small portion of the total biomass in soil (Adl 2003). The species diversity and abundance of ciliates are functions of

geography, season, moisture content, temperature, pH, organic content, and the degree of compaction and abrasion of the soil environment (Foissner 1987, 1997d in Lynn 2008).

The Plankton. Ciliates, conspicuous components of planktonic communities at most times of the year, are found in freshwater (Pace and Orcutt 1981 and Porter et al. 1979, both in Finlay and Ochsenbein-Gattlen 1982), neritic (Beaver and Crisman 1989; Leakey et al. 1994 in Lynn 2008), and oceanic environments (Strom et al. 1993 in Lynn 2008). They are found in small, temporary puddles, tide pools, lakes, rivers, and the major oceans of the world. Because standard zooplankton sampling procedures are unsuitable for soft-bodied ciliates their presence, abundance, and diversity were undoubtedly underestimated until the late 1980s when more appropriate sampling techniques, using water bottles, were adopted. Although loricate tintinnids predominate in the plankton literature (Dolan et al. 2013; Kofoid and Campbell 1939; Heinbokel and Beers 1979 in Coats and Heinbokel 1982), it is now clear that nonloricate ciliates are consistently more abundant when other sampling techniques are used (Lynn and Montagnes 1991 in Lynn 2008; Pierce and Turner 1992). Indeed, ciliates are exceedingly abundant in association with the spring phytoplankton bloom in temperate waters and may flourish at other times of the year in short-term blooms. These blooms can lead to spatial patchiness in the distribution of ciliates that may range from 10s to 100s of meters in size (Bulit et al. 2009).

Symbiotic Associations. Ciliates are found as symbionts in association with a wide variety of species (Bradbury 1996 in Hausmann and Bradbury 1996; Lynn 2008). The most thoroughly studied associations include those with ruminant mammals and related herbivores (Hungate 1978 in Kreier 1978), sea urchins (Levine 1972 in Chen 1972), fish (Hoffman 1978 in Kreier 1978), crustaceans (Ferńandez-Leborans 2001 in Lynn 2008), and a variety of molluscan species (for example, Raabe 1972 in Lynn 2008). The symbiotic relationships are generally thought to be commensalistic, either as endo- or ectocommensals, but ruminant ciliates may be mutualistic (Hungate 1978 in Kreier 1978). Some ciliates found in fish and insects can be classified as parasitic (i.e., harmful to their host): they may be histophagous (tissue-eating; necrotrophic) (Alvarez-Pellitero et al. 2004 in Lynn 2008; Batson 1983; Hoffman 1978 in Kreier 1978).

Ciliates host a variety of microorganisms, including bacteria, mastigotes, chlorellae, and other ciliates. Again, the nature of the symbiotic relationships varies from mutualistic, commensalistic, parasitic, or pathogenic (Ball 1969 in Chen 1969; Berninger et al. 1986 in Lynn 2008; Görtz and Dieckmann 1987 in Lynn 2008; Heckmann 1983; Soldo et al. 1974; Weis and Ayala 1979).

Some Unusual Habitats. The ciliates are not as successful as prokaryotes and mastigotes in exploiting extreme habitats. Nevertheless, species have been described from habitats of temperature extremes: from hot thermal springs and waters near the deep-sea hydrothermal vents at a depth of 2,600 m off the California coast (Small and Gross 1985) to the ice and lakes of Antarctica (Christner et al. 2003 in Lynn 2008; Kepner et al. 1999 in Lynn 2008; Laybourn-Parry et al. 2002 in Lynn 2008; Lee and Fenchel 1972 in Lynn 2008).

Ecology

Three aspects of the ecology of ciliates will be discussed below: the role that ciliates have played in models of ecological theory, the ecology of ciliate communities, and the contribution ciliates make to primary and secondary production.

Ecological Models. Protists/protozoa are excellent experimental organisms for the modelling of ecological theory for several important reasons (Montagnes et al. 2012; Salt 1974).

"These are that if a phenomenon is found to occur in protozoa it has a high probability of being a general one, and that the absence of sexes, age classes, and other characteristics of more complex animals permit certain reactions to be seen in protozoa more clearly than in higher animals." (Salt 1974).

Ciliates share with other protists the properties outlined above by Salt (1974). Being small organisms, they have many generations in a short period of time, and the diversity of "functionally" different species can enable the construction of complex communities. Microcosm experiments with ciliates can be replicated with ease and because these are small and manageable "systems" there can be rigorous to complete control of most abiotic factors.

Gause (1934) was the first to take advantage of the protists in testing and modelling ecological phenomena, both in his studies of predator–prey modelling using *Paramecium caudatum* and *Didinium nasutum* and in his studies of competitive exclusion using *Paramecium aurelia*, *Paramecium caudatum*, and *Stylonychia mytilus*.

Over 30 years later, Salt (1967) modelled the predator–prey interaction between *Woodruffia metabolica* and *Paramecium aurelia*, discovering, among other things, that the predator exhibited a threshold response to prey density rather than a proportional response and that the escape from predation of a portion of the prey population was a result of innate behavioral characteristics of the predator. Salt (1974, 1975 in Salt 1979) investigated predator–prey interactions between two species used by Gause (1934), *Didinium* and *Paramecium*. In these studies, Salt (1974) found that both predator and prey density can act as controls on the capture rate of the predator, that as predator density increases, the size of individual *Didinium* increases while prey capture and/or food intake rates decline (Salt 1975 in Salt 1979), and that "*Didinium* at higher densities are more efficient in the utilization of energy than are those at low densities" (Salt 1979). Li and Montagnes (2015) have used these two species to more deeply explore predator–prey models, concluding predator conversion efficiency and predator mortality, two key model components, can depend upon prey abundance. Luckinbill (1973 in Lynn 2008) concentrated on the prolonged coexistence of predator and prey also using *Didinium* and *Paramecium*. Whereas Gause (1934) and Cooper et al. (2012) found that the prey needed physical refuges or habitat fragmentation to prolong the interaction, Luckinbill (1973 in Lynn 2008) prolonged coexistence by providing a physically homogeneous environment using methyl cellulose to slow both predator and prey locomotion; in this system, if prey growth is restricted and if prey can maintain adequate numbers for survival while simultaneously remaining at low enough

densities to avoid capture, a cycling of the predator and prey populations is achieved. Luckinbill and Fenton (1978) have further explored the relationship between intrinsic rates of increase, frequency of environmental perturbation, and population cycling in bacterivorous ciliates. They demonstrated that populations of fast-growing species track environmental variations more closely and become extinct more quickly than populations of slower growing species.

Gause's initial experiments on competitive ability have been explored in more detail. Natural, rather than experimental, populations of *Paramecium aurelia* were studied in a woodland seepage area (Gill and Hairston, in Gill 1972). Although one stock of *P. aurelia* was apparently competitively excluded, evidence suggests that it was not well adapted to the marginal, highly unpredictable habitat used for the experiments. Further investigating the relationships between intrinsic rates of increase r, saturation densities K, and competitive ability of experimental populations of *Paramecium aurelia*, Gill (1972) concluded that there was "no consistent relationship between r and K and competitive ability, and that simple environmental changes affect competitive ability much less than they affect either r or K." On the other hand, Luckinbill (1979) showed that selection for increased r also increased K of several stocks of *Paramecium primaurelia*. In over six species of bacterivorous ciliates, estimates of r_m (the maximum rate of increase) were also positively correlated with K and negatively correlated with competitive ability (Luckinbill 1979).

Several examples in the recent literature have used ciliates and other protists as model organisms to explore and illuminate aspects of biodiversity and ecosystem function (Giller et al. 2004). Morin and McGrady-Steed (2004) concluded that there was an inverse relationship between species richness and the carbon dioxide flux in microcosms featuring protists, primarily ciliates. Food web diversity and productivity can also strongly influence the composition of bacterial communities in model ecosystems of microbial eukaryotes and thus ultimately influence decomposition rates (Krumins et al. 2006). As a third example, Fukami and Morin (2003) demonstrated that the order in which the ciliate community was assembled had significant impacts on the productivity-diversity relationship. Finally, Limberger and Wickham (2012) showed that diversities and differences among habitats of low connectivity persisted longer compared to habitats with medium and high connectivities.

Assemblages and Communities. Assemblages of ciliates are characteristic, not only of certain habitats but also within the same habitat where predictable assemblages seem to occur at specific seasons or under specific conditions related to biotic and abiotic factors (Bick 1972 in Lynn 2008; Grolière 1978). The apparent predictability of these assemblages has led some investigators to suppose that the many different species have dependent interactions (Cairns and Yongue 1977) although Dolan et al. (2007) concluded that the neutral theory of random colonization could explain the structure of tintinnid communities. There is certainly variability in the appearance of these assemblages both in time (Goulder 1980 in Lynn 2008) and in space (Bulit et al. 2009; Taylor and Berger 1980), driven primarily by resource availability (Galbraith and Burns 2010).

Ciliates are heterotrophs, being either phagotrophs or osmotrophs. Various species can be categorized as bacterivorous, algivorous, carnivorous (Elliott and Bamforth 1975 in Corliss 1979; Fenchel 1968 in Fenchel 1969; Noland and Gojdics 1967 in Chen 1967), or histophagous. Ciliates perform a similar role in soils and aquatic sediments. By grazing on bacterial populations and ingesting plant residues ciliates increase rates of decay and mineral cycling (Fenchel and Harrison 1976; Krumins et al. 2006). Some ciliates in both marine and freshwater habitats can be classified as "autotrophic" or mixotrophic: in these cases they contain algal symbionts or they somehow "steal" the chloroplasts of their algal prey – a phenomenon called kleptoplasty (Johnson 2011; Perriss et al. 1994; Stoecker et al. 1989). Mixotrophy may enable survival in habitats that would be marginal for an obligate heterotroph (Esteban et al. 2010).

In planktonic communities, ciliates are links in the food chains (Sanders and Wickham 1993; Sherr and Sherr 1988). In marine "snow," ciliates are a part of the decomposition food web (Caron et al. 1982). In oceanic regions, perhaps more than 90% of the carbon may be cycled through the protists, including ciliates such as tintinnids and oligotrichs (Lynn and Montagnes 1991 in Lynn 2008). In planktonic food webs, ciliates may be important in the regeneration of some nutrients (Garst and Horstmann 1983; Johannes 1965 in Corliss 1979) but not others (Taylor and Lean 1981 in Garst and Horstmann 1983). In coastal regions, a few ciliates, such as the autotrophic *Mesodinium rubrum*, may even contribute substantially to primary production (Smith and Barber 1979 in Lynn 2008). As links, ciliates are consumed by a variety of other organisms: in the pelagic realm, copepods, jellyfish, and larval fish have been recorded as predators (de Figueiredo et al. 2007; Stoecker and Sanders 1985 in Lynn 2008; Stoecker et al. 1987 in Lynn 2008).

Production. Production is defined as the amount of biomass generated per unit time. There are now many estimates of the contribution ciliates make to both primary and secondary production of biomass. For example, ciliates in littoral sand sediments representing 0.05% of the biomass are estimated to have contributed 15% to the secondary production of the zoobenthos (Burkovsky 1978). In sediments from a freshwater lake, Finlay (1978 in Finlay and Ochsenbein-Gattlen 1982) concluded that production and consumption by benthic ciliates are significant components of the energy flow through the benthos. Tintinnids may constitute more than 25% of the secondary production at certain times of the year (Middlebrook et al. 1987 in Lynn 2008). However, the nonloricate oligotrich ciliates typically "out-produce" tintinnids in a variety of ecosystems (Gilron et al. 1991 in Lynn 2008; Lynn et al. 1991a in Lynn 2008; Montagnes et al. 1988 in Lynn 2008). The record for contribution to **primary** production (as well as high speed swimming) is held by the autotrophic ciliate *Mesodinium rubrum*, which harbors a symbiotic photosynthetic cryptomonad and its chloroplasts (Lindholm 1985). Smith and Barber (1979 in Lynn 2008) recorded photosynthetic rates of 1,000–2,000 mg C m^{-3} h^{-1} for a bloom of this ciliate, matching the most productive phytoplankton. More often, primary production by mixotrophic ciliates is a very minor component (Perriss et al. 1994).

Characterization and Recognition

The Phylum

General Characterization. Ciliates, with rare exceptions (i.e., *Phalacrocleptes*, a suctorian in the PHYLLOPHARYNGEA), have cilia at some stage in their life cycle. Ciliates are dikaryotic; their cells contain macronuclei and micronuclei. In this nuclear dualism, the macronucleus is physiologically dominant, actively synthesizing mRNA and rRNA while the micronucleus, the repository of the genomic DNA, is involved in genetic recombination and sexual phenomena. In most ciliates, the macronuclei contain far greater than diploid quantities of DNA and are considered to be ampliploid (i.e., containing many amplified copies of the ciliate's genome) (Lynn 2008). The micronuclei of ciliates are considered to be diploid, although polyploidy undoubtedly occurs. Nuclear division is closed: the nuclear membranes of both macro- and micronuclei remain intact while the mitotic apparatus separates the DNA. In ciliates of the HETEROTRICHEA, however, most mitotic microtubules are **external** to the macronuclear membrane, a diagnostic feature for this class. Micronuclear chromosomes are attached to microtubules by kinetochores. The macronucleus develops from a micronucleus after conjugation. Initially, the micronuclear chromosomes may be endoreplicated many times to become polytenic. Subsequently, DNA sequences are deleted using a RNA-mediated epigenetic machinery that results in subchromosomal macronuclear DNA molecules that range in length from 2 to 300 kb (Chalker 2008; Juranek and Lipps 2007; Nowacki et al. 2010; Prescott 1994). Telomeric sequences, such as the hexanucleotide CCCCAA, are added by telomerase to the chromosome ends (Blackburn 1992; Blackburn et al. 1983). The macronucleus divides amitotically by an unknown method of segregation, possibly just randomly, of these subchromosomal DNA molecules. The macronuclei of one group of ciliates, the KARYORELICTEA (see below), cannot divide: new macronuclei arise by division and differentiation of micronuclei at each cell division (Raikov 1982; Raikov 1996 in Hausmann and Bradbury 1996).

The ciliature of the body in most ciliates is specialized around the cell mouth or cytostome (Fig. 1). Because of its variability, the pattern and arrangement of this oral ciliature has been the basis for the classification of ciliates for many years (Corliss 1979; Lynn 2008; Lynn and Small 2002). Most ciliates are phagotrophic, ingesting particulate material and/or prey in food vacuoles that are formed at the cytostome. Some ciliates are astomatous and osmotrophic. On completion of the digestive cycle, the food is egested through the cell anus, typically via a well-defined cytoproct.

Other organelles that distinguish one group of ciliates from another are the position and arrangement of contractile vacuoles (Patterson 1980); the type and distribution of such extrusomes as mucocysts and toxicysts (Hausmann 1978; Rosati and Modeo 2003 in Lynn 2008); the presence of stalks, loricae, or other attachment structures; and types of encystment structures (Lynn 2008).

Reproduction, that is, the production of new individuals, occurs by transverse binary fission, also called homothetogenic fission (Lynn 2008): the fission plane

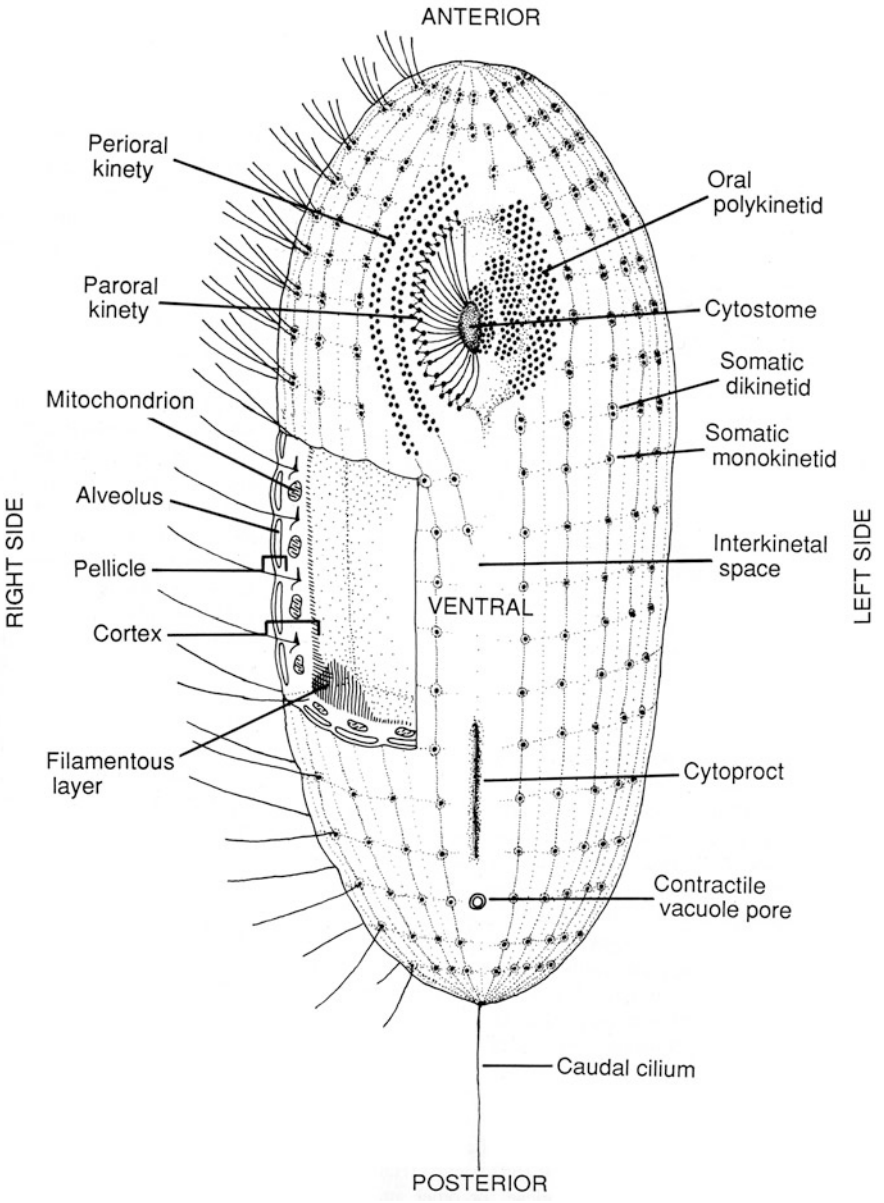

Fig. 1 Schematic figure of the ventral surface of a generalized ciliate. The cortex of a ciliate may be divided into somatic and oral regions. The locomotor units or kinetids of the somatic region are aligned in files called kineties. These kinetids can be dikinetids composed of two kinetosomes and cilia or monokinetids composed of one kinetosome and its cilium. Often a longer caudal cilium is carried posteriorly. Perioral ciliature as specializations of some somatic kineties may border the oral region. In this example, there is a paroral to the *right* of the cytostome and three oral polykinetids to the *left* of the cytostome. The cilia of these organellar complexes have not been illustrated; the

occurs across the longitudinal axis of the kineties and the body. In many taxa, binary fission may be modified so that unequal division occurs.

The sexual process, sometimes seen in field collections or lab cultures as pairing of individual ciliates of complementary mating types, is called conjugation (Miyake 1996 in Hausmann and Bradbury 1996; Nanney 1980; Orias in Collins 2012). Conjugation occurs for minutes or hours to as much as a day or so during which time the partners exchange haploid gametic micronuclei. The conjugating partners of many spirotrich, peritrich, and suctorian species can be quite different in size; in these circumstances, total conjugation or complete fusion of partners may occur. Usually, syngamy is restricted to the fusion of gametic micronuclei, which have undergone meiosis. After syngamy, the partners typically separate. During this process, new macronuclei develop from mitotic products of the zygotic nucleus through a RNA-mediated process using scan RNAs (scnRNA) (see Singh et al. 2014).

Detail of Cell Structure. In a "typical" ciliate, the cortex or the outer 1–2 μm of the cell can be divided into two main regions, the somatic and the oral region (Fig. 1). The somatic region, composed of a "skeletal" support system opposed by the hydrostatic pressure within the cell, functions in locomotion, sensing the environment, attachment to surfaces, and secretion of protective coverings. The oral region functions in sensing, acquiring, and ingesting nutrients. A complicated framework of kinetosomes, microfilaments, microtubules, and other fibers that are collectively called the infraciliature underlies these regions (Figs. 2 and 3a–d).

The infraciliature is comprised of kinetosomes arranged into longitudinal files (rows) called kineties (Fig. 1). Somatic and oral kinetal patterns are characteristic of various groups of ciliates (Lynn 2008; Lynn and Small 2002). The kinetosome is apparently the organizing center for the cortical fibrillar structures: usually two groups of microtubules and a striated kinetodesmal fibril (Figs. 2 and 3a–d) are associated with a parasomal sac. The fibrillar associates of the kinetosome anchor the cilium and provide structural support for the cortex.

Ciliates are bounded by a cell membrane, the plasmalemma (Lynn 2008). The plasmalemma in most ciliates is underlain by unit membrane-bound sacs called alveoli with which are associated a family of cortical proteins, the alveolins (Gould et al. 2008). The alveoli in their turn are subtended by a fibrous layer of varying thickness called the epiplasm, whose component proteins, the epiplasmins, form a complex skeletal network (Damaj et al. 2009) (Fig. 2). The plasma membrane, alveoli, and epiplasm comprise the pellicle, which is part of the cortex (Fig. 2).

Fig. 1 (continued) kinetosomes only have been represented as dots. The cytoproct for egestion and the contractile vacuole pore for osmoregulation are posterior to the oral region, in the interkinetal space. The cut-away portion of the somatic cortex illustrates the sac-like alveoli beneath the plasma membrane, the cortical mitochondria, and the kinetosome with its fibrillar associates. These cortical structures are sometimes separated from the endoplasm by a filamentous layer

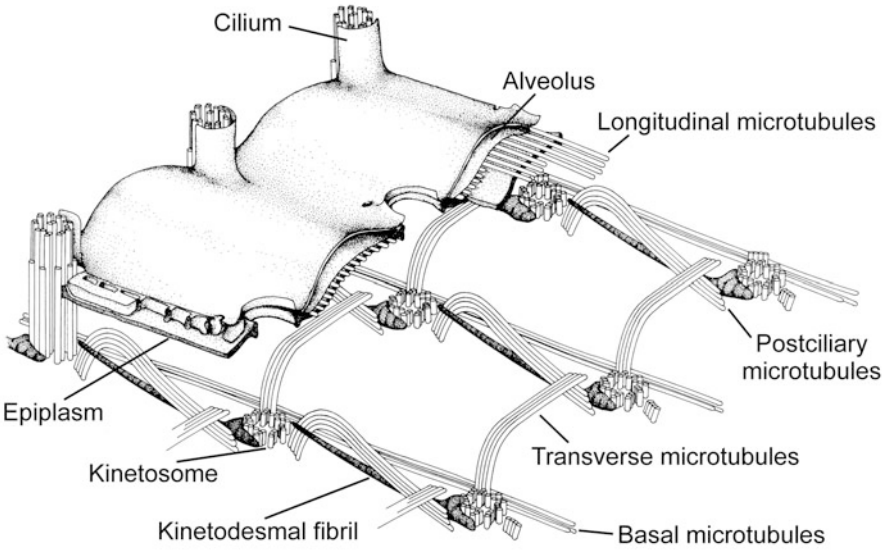

Fig. 2 This is a detailed schematic figure of the generalized somatic cortex of a ciliate. Nine locomotor units or kinetids are illustrated: six are illustrated without cilia and three are illustrated with cilia. The cell surface is covered by a unit plasma membrane (plasmalemma), which is pierced by indentations called parasomal sacs. The cortical alveoli underlie the plasma membrane between kineties and are connected to adjacent alveoli along the kinety. The alveoli, in their turn, may be underlain by microtubules that lie on top of a dense, perhaps fibrous layer called the epiplasm. The epiplasm is pierced by the parasomal sacs and by the kinetosomes. The kinetosomes are associated with three fibrillar structures: a periodically striated kinetodesmal fibril; a laterally directed transverse ribbon; and a posteriorly directed postciliary ribbon. A set of basal microtubules courses beside the kinetosomes but is not directly connected to them

A variety of other organelles is found in the cortex. The majority of the mitochondria with tubular cristae (Fig. 3b, e, g, h) are found in the cortical ridges between kineties, where they are anchored in position by connections to cortical microtubules and to the epiplasm. Mitochondria in some ciliates have transformed into hydrogenosomes (de Graaf et al. 2011), and these are typically intimately associated with symbiotic methanogenic bacteria (Boxma et al. 2005 in Lynn 2008; Fenchel and Finlay 1991a). Extrusomes (Fig. 3e, f, j) are also distributed in the cortex between and within the kineties. There are several types of these exocytotic organelles, which function to aid in the capture of prey, in building the wall in resting cysts, or for some other unknown function (Hausmann 1978; Rosati and Modeo 2003 in Lynn 2008).

The contractile vacuole pore (Figs. 1 and 3g) is a cortical structure that serves as the opening through which the products of osmoregulation or the contents of the contractile vacuole are expulsed (Allen 2000). Egestion takes place through the cytoproct (Fig. 1), usually a slit-like opening in the cortex (Allen and Wolf 1974 in Lynn 2008).

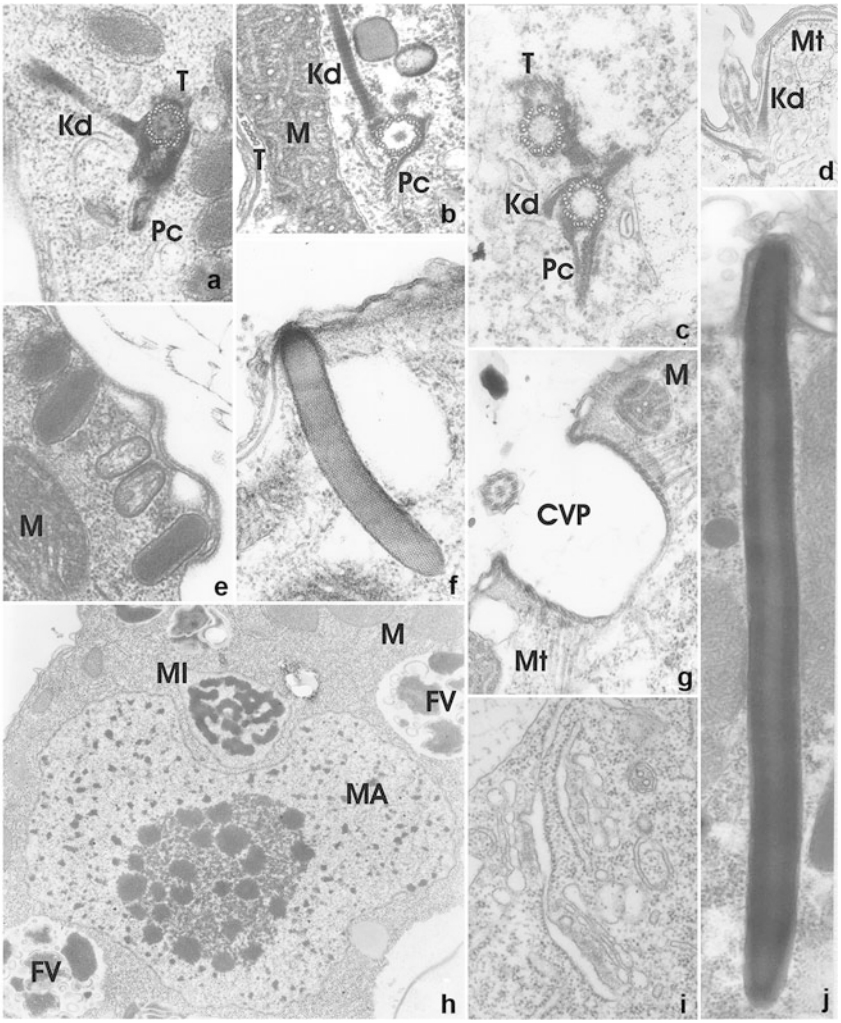

Fig. 3 (**a**–**j**) Ultrastructural features of the Phylum CILIOPHORA. (**a**–**d**) Somatic kinetids of some ciliates. (**a**) *Lepidotrachelophyllum,* a haptorian litostome. ×49,000. (**b**) *Colpidium,* a hymenostome oligohymenophorean. ×50,000. (**c**) *Colpoda,* a colpodean. ×55,000. (**d**) Oblique section through the base of the cilium and a longitudinal section of the tapering kinetodesmal fibril of *Colpoda*. Note the microtubules (*MT*) underlying the cortex with its flattened alveoli beneath the plasma membrane. *Kd* kinetodesmal fibril, *M* mitochondrion, *Pc* postciliary microtubular ribbon, *T* transverse microtubular ribbon. (**e**, **f**, **j**) Extrusomes of several ciliates. (**e**) Mucocysts of *Lepidotrachelophyllum*. ×38,000. (**f**) A mucocyst of *Colpidium*. ×35,500. (**j**) A "mucocyst" of *Ophryoglena.* ×38,000. (**g**) Contractile vacuole pore (*CVP*) of *Colpidium,* an oligohymenophorean. A set of microtubules is embedded in the epiplasm along the wall of the pore while other microtubules (*Mt*) originate in the epiplasm of the wall and extend away from the pore over the surface of the contractile vacuole. *M* mitochondrion. ×20,000. (**h**) Macronucleus (*MA*) and micronucleus (*MI*) of *Colpoda,* a colpodean. Note also the mitochondria (*M*), which have tubular cristae (see also (**e**) and (**g**) above). *FV* food vacuole ×18,000. (**i**) Golgi apparatus of *Colpoda*. ×36,000

The endoplasm of ciliates, in general, has a less obvious organization than the cortex or ectoplasm. The macronucleus and micronucleus (Fig. 3h) are among the largest endoplasmic structures. Food vacuoles are scattered throughout the endoplasm. The Golgi bodies, often called dictyosomes in ciliates and plants, are inconspicuous and scattered throughout the cytoplasm (Fig. 3i). Microtubular ribbons usually originate from cortical kinetosomes and extend into the endoplasm to direct the movement of organelles and vesicles in both directions between the endoplasm and the cortex (Allen and Fok 2000).

Some Life Cycles. The life cycle of a typical ciliate is fairly simple (Fig. 4). In the presence of nutrients, cells grow and reproduce by binary fission to increase the size of the population. As food becomes limiting, some ciliates disperse from the food

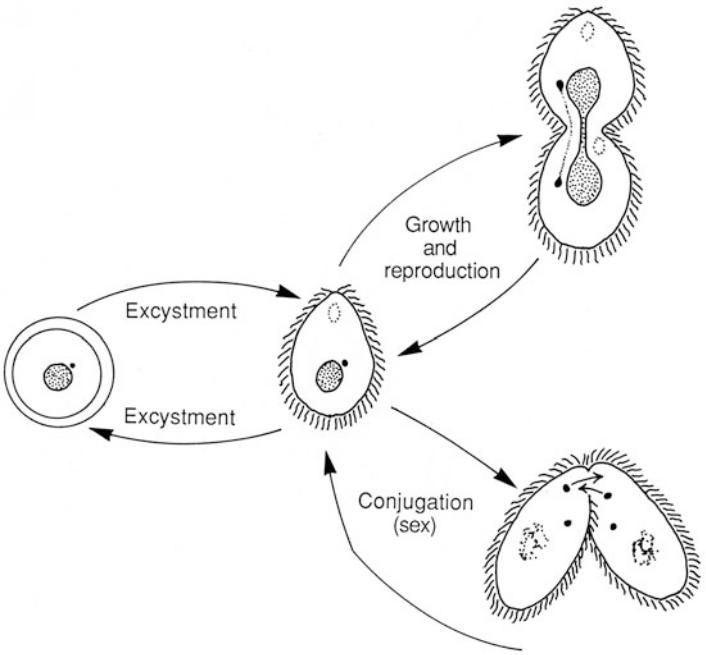

Fig. 4 This figure illustrates a generalized ciliate life cycle, divisible into three phases. The vegetative or asexual reproductive cycle involves feeding, growth, and division by binary fission. Conjugation, the sexual cycle, often stimulated by the depletion of food and the onset of starvation, involves temporary fusion of complementary mating types, meiotic reduction of chromosome number from diploid to haploid, and exchange of haploid gametic nuclei before separation of the partners as exconjugants. If food is present, growth and division ensue; if it is still absent or some other environmental stress such as pH, temperature, toxins, or desiccation stimulates it, the ciliate may enter the encystment-excystment cycle. Cysts may persist for months to years. Ciliates excyst when stimulated by the appropriate environments. According to Goodey (1915), the oldest viable ciliate cysts, two species of *Colpoda,* were more than 38 years old while other protozoan cysts from soils have remained viable for almost 50 years while Shatilovich et al. (2015) have isolated viable cells from late Pleistocene permafrost, 32–35,000 years old

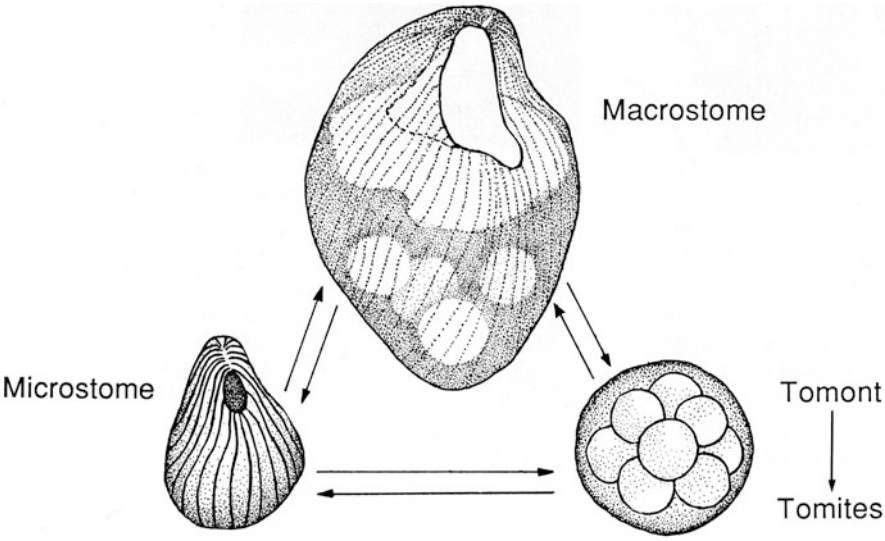

Fig. 5 Life cycle of the macrostome-microstome oligohymenophorean *Tetrahymena vorax*. The microstome form feeds on bacteria. When this food disappears or another suitable ciliate prey is present, some of the population of *T. vorax* are stimulated to undergo a morphogenetic transformation during which their bacteria-feeding oral apparatus dedifferentiates and a new, macrostome oral apparatus designed to capture ciliate prey differentiates. Cell division can occur in a cyst: the divider or tomont undergoes cell division yielding several offspring cells called tomites (After Corliss 1973 in Elliott 1973; Redrawn by S. Alexander)

source and begin to starve. Starvation initiates sexual receptivity in many species. Ciliates conjugate when they encounter complementary mating types. If no mating partner is available, autogamy (self-fertilization) may occur. If nutrients are not discovered, either prior to or subsequent to conjugation or autogamy, many species encyst by secreting a protective wall about themselves. Resting cysts may or may not withstand desiccation.

Some ciliate life cycles are more complicated. The feeding stages or trophonts can be dimorphic. In *Tetrahymena vorax*, one morph is bacterivorous while the other morph feeds on other ciliates (Fig. 5). Depletion of the bacterial population by the microstome bacterivores stimulates some individuals to differentiate as macrostome carnivores that, as cannibals, begin ingesting their siblings or, as predators, other prey ciliates; the presence of the appropriate bacteria stimulates differentiation back to the microstome morph. The life cycles of parasitic species are even more complex. The life cycle of apostome ciliates, for example, is closely linked to the molt cycle of their crustacean hosts. Some apostomes reproduce in the nutrient-rich fluid associated with the shed exoskeleton or exuvium of the host (Bradbury 1996 in Hausmann and Bradbury 1996) (Fig. 6), while other apostomes are parasitoids that kill their krill hosts (Gomez-Gutierrez et al. 2012).

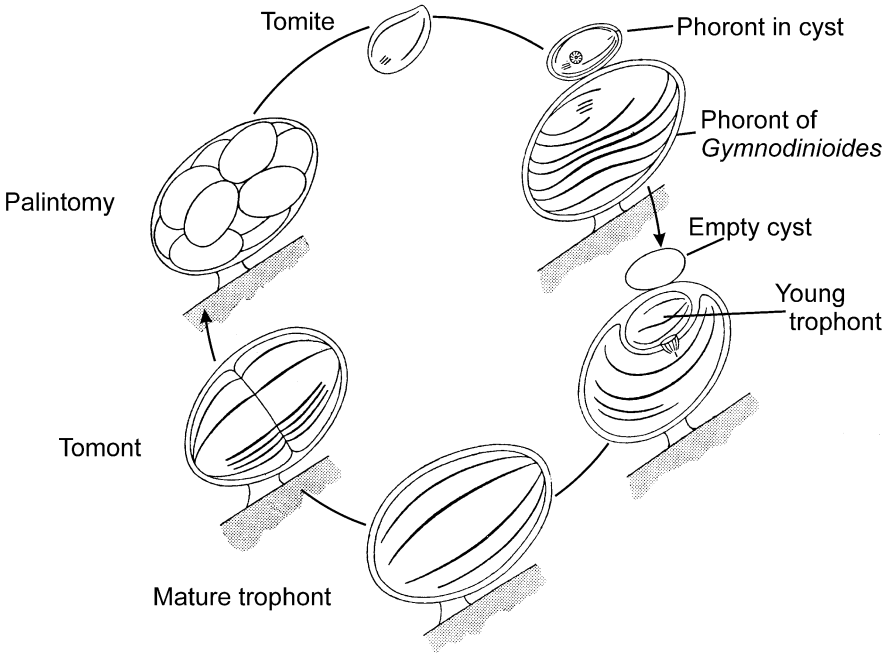

Fig. 6 Life cycle of the predatory apostome Phtorophrya, a "hyperparasite" of the exuviotrophic apostome Gymnodinioides, which itself feeds on the exuvial fluids of its crustacean host. The tomite of Phtorophrya finds a phoront of Gymnodinioides, encysted on the crustacean host's cuticle and attaches to also become a phoront. Phtorophrya then penetrates the phoront of Gymnodinioides, consumes it as a trophont, develops into a tomont that divides by palintomy to produce multiple tomites of Phtoroprhya (Modified from Chatton and Lwoff, 1935a in Lynn, 2008)

Methods and Criteria

Taxa are characterized by morphology: optical and electron microscopy are used. Increasingly, these microscopic approaches are used in conjunction with appropriate biochemical and molecular genetic techniques.

Optical Microscopy. Ciliates can be studied live or fixed and stained by several standard cytological procedures. Studying live ciliates, which requires patience, is facilitated by the combined use of differential interference contrast microscopy and a microcompressor (Skovorodkin 1990; Zinskie et al. 2015) or "slowing agents" such as methyl cellulose or nickel sulfate to retard ciliate movement.

The most informative methods for optical microscopy employ a variety of stains. Silver stains or silver impregnation techniques provide the most information about cortical structures: (1) the protargol or silver proteinate technique provides permanent preparations that reveal the most detail of cortical and subcortical structures including microtubules (Aufderheide 1982; Foissner 1991); (2) the pyridinated silver carbonate method provides either temporary or permanent preparations that

reveal the kinetodesmal fibrils and other finely filamentous cortical and subcortical structures (Fernandez-Galiano 1976 in Augustin et al. 1984; Foissner 1991); and (3) the Chatton-Lwoff silver impregnation procedure provides permanent preparations revealing the pattern of surface structures and kinetosomes (Foissner 1991; Frankel and Heckmann 1968). The only other stain that may be necessary, especially if details of nuclear morphology are needed, is the Feulgen nuclear stain (Foissner 1991) or acridine orange fluorescence stain (Coats and Heinbokel 1982).

Morphological criteria are used to determine ciliate affinities. Features used in taxonomy include, for example, the presence of complex associations of somatic cilia, of few or many oral structures, of loricae, and of stalks (see Curds 1982; Curds et al. 1983; Foissner et al. 1994, 1999; Lynn 2008; Lynn and Small 2002). Species can be determined by mating experiments: mating incompatibility is used as the criterion for a biological species (Lynn and Doerder in Collins 2012; Nanney and McCoy 1976 in Nanney 1980; Sonneborn 1975 in Nanney 1980), but because controlled conjugation is available for so few species, mating tests are not extensively used to identify species. If no mating test organisms exist, quantitative differences can be sought among clones, strains, or species, using multivariate morphometric procedures (for example, Gates 1977; Lynn and Malcolm 1983).

Electron Microscopy. Both scanning and transmission electron microscopy have been used to study ciliates. Preparation of most specimens for scanning electron microscopy is now standardized (Foissner 1991). Preparation of specimens for transmission electron microscopy, especially fixation, is quite varied: for specific methods see references in Lynn (2008).

Features revealed by transmission electron microscopy distinguish between higher taxa. The kinetid – the kinetosome and its microtubular and fibrillar associates – is the fundamental unit of the ciliate cortex. Kinetids of the somatic and oral cortex can be distinguished in the same ciliate (Lynn 2008). The structure and arrangements of the kinetids distinguish one taxon from another (Fig. 7). Clustering techniques have been used on large data sets of ultrastructural characters to determine relationships between taxa (Lynn 1979 in de Puytorac et al. 1984).

Biochemical and Molecular Genetic Techniques. Biochemical criteria restricted to easily cultured, oligohymenophorean ciliates also have been employed to determine relationships among ciliate taxa. DNA hybridization has been used with *Tetrahymena* species (Allen and Li 1974 in Nanney 1980); starch gel electrophoresis of isozymes has been used with species of *Tetrahymena* (Borden et al. 1977 in Nanney 1980) and *Paramecium* (Allen et al. 1983); polyacrylamide gel electrophoresis of cytoskeletal proteins has been used with species of *Tetrahymena* (Vaudaux et al. 1977 in Nanney 1980). However, with the invention of the polymerase chain reaction (PCR), it is now possible, even from single cells, to amplify genes that have been used in various ways to identify species: randomly amplified polymorphic DNAs (RAPDs) have been used to identify species of *Paramecium* (Stoeck et al. 1998 in Lynn 2008) and *Euplotes* (Chen et al. 2001 in Lynn 2008).

A more recent approach is to use mitochondrial genes as "barcodes." The mitochondrial cytochrome *c* oxidase subunit 1 (cox1) "barcode" can identify putative biological species of *Paramecium* (Barth et al. 2006 in Lynn 2008) and

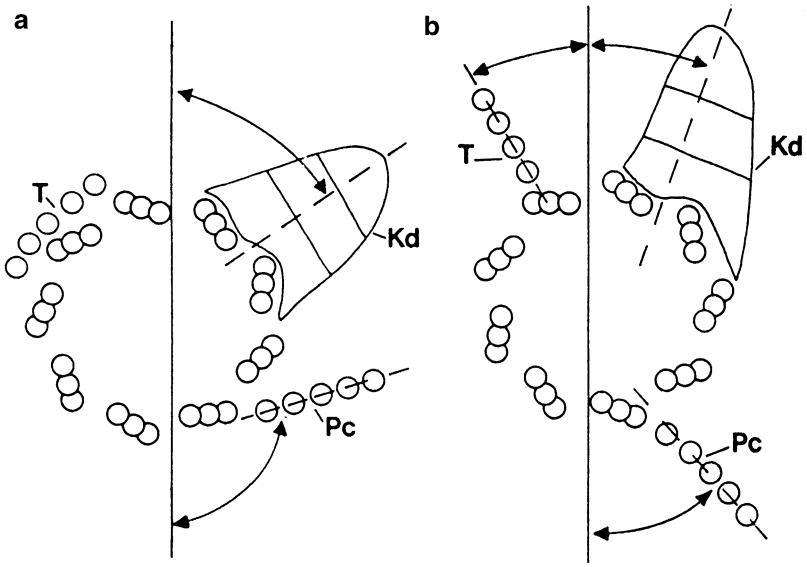

Fig. 7 Schematic figures of two ciliate kinetids illustrate the kinds of characteristics that can be recorded and quantified in comparative studies of cortical ultrastructure. The *central solid line* indicates the longitudinal axis of the kinety. The numbers of microtubules in the transverse (*T*) and postciliary ribbons (*Pc*) can be counted. The relationship of the transverse ribbon to the kinetosome perimeter can be either tangential (**a**) or radial (**b**). With all the radially oriented components, the angle with respect to the kinety axis can be measured and used either quantitatively or semiquantitatively. *Kd* kinetodesmal fibril (After Lynn 1981)

Tetrahymena (Kher et al. 2011). The cox1 barcode is broadly applicable to ciliates (Strüder-Kypke and Lynn 2010) and has been used to infer the existence of cryptic species in genera where mating crosses have not yet been used (Gentekaki and Lynn 2012; Guggiari and Peck 2008). The mitochondrial small subunit rDNA and the apocytochrome b gene also show promise as barcodes to identify cryptic species (Barth et al. 2008; Katz et al. 2011).

Phylogenomic studies are now possible with the annotation of genomes of *Tetrahymena* (Coyne et al. 2008) and *Paramecium* (Arnaiz and Sperling 2011). Gentekaki et al. (2014) published the first phylogenomic analysis of ciliates, using these published genomes along with RNA sequence libraries for representative marine species (see Marine Microbial Eukaryote Transcriptome Sequencing Project – marinemcroeukaryotes.org).

Classification

A Classification Scheme. Several revisions of the classification of the Phylum CILIOPHORA have been presented in the last 15 years: de Puytorac (1994) edited a collaborative revision to genus level with French colleagues; Jankowski (2007) has

presented a revision down to genus; and Lynn (2008) has presented a revision to family level but listing the included genera. These classifications have differences that are discussed by Lynn (2008), and a revised classification is described below, characterizing the major groups only (Table 2).

The somatic kinetid, the most highly conserved structural component of the cortex, is used as a major criterion for this taxonomic scheme, but this is now supplemented by gene sequence data (Fig. 8) (Lynn 1981, 2008). Oral kinetids and their arrangements, which are less conserved, are used to assess more recent common ancestry of the taxa already related by similarities in the somatic kinetid structure. The detailed structure of the somatic kinetid is conserved in many groups and is a more important criterion of relatedness than the number. The total number of kinetids is extremely variable. Mono- and dikinetids can occur in the same subclass or even in the same ciliate cortex, indicating that relatively small heritable changes can change the total number of kinetids, which is a less conservative feature than the number of kinetosomes per kinetid, which in turn is less conserved than the pattern and structure of the kinetid itself (Lynn 2008). Features of the somatic kinetid and the somatic cortex are used to characterize the 11 major groups, called classes by Lynn (2008) (Fig. 9). Orsi et al. (2012) proposed a 12th class, but its independence needs confirmation (cf. Fig. 8). For a more detailed description of the taxa to the family level, see Lynn (2008).

The Major Groups. Several "representative" genera from each class will be use here to illustrate diversity within each class. Because there is so much diversity among genera and because even within a species form and size may change quite dramatically, the term "representative" is an over-generalization.

The first two groups – karyorelicteans and heterotricheans, united primarily by similarities in the somatic kinetids (Fig. 9) and cortex – are placed together in the POSTCILIODESMATOPHORA (Table 2). Many postciliodesmatophorans are highly contractile, possessing similar, presumably homologous, contractile fibrous cytoplasmic structures – the filamentous myonemes, which shorten the cells. The overlapping postciliary microtubular ribbons – the postciliodesmata – extend the cells using microtubule arms that enable sliding of the ribbons on each other and so elongate the cell (Huang and Pitelka 1973 in Lynn 2008).

POSTCILIODESMATOPHORA Gerassimova and Seravin 1976. These ciliates have somatic kinetids whose postciliary microtubular ribbons overlap to form a complex of microtubules that are interconnected by arms – the postciliodesmata.

KARYORELICTEA Corliss 1974. Karyorelicteans (Fig. 10) are thought to represent the ancestral stock of the phylum (see "Evolutionary History", "Fossil Record" and "Phylogeny"). Karyorelicteans possess kinetids with conspicuous kinetodesmal fibrils and postciliary ribbons that overlap to form postciliodesmata (Fig. 9). Their cells contain two to many macronuclei with approximately the micronuclear (diploid) amount of DNA. Their macronuclei arise only by division of micronuclei at the time of cell division. These ciliates are common in estuarine or marine benthic environments.

HETEROTRICHEA Stein 1859. Heterotricheans, because of the similarities of their somatic kinetids (Fig. 9), are thought to have descended from karyorelictean-

[a]Refer to Lynn (2008) for diagnoses of these taxa and a more complete listing of included families and genera

[b]This taxon, a so-called "ribo-class/group," is based on molecular phylogenetics, primarily the SSUrRNA gene but still lacks a morphological synapomorphy

[c]This taxon is another "ribo-class/group," based on molecular phylogenetics of multiple genes (Lynn 2008) but still lacks a morphological synapomorphy. Its name derives from the major included groups (i.e., COLPODEA, OLIGOHYMENOPHOREA, NASSOPHOREA, PROSTOMATEA, PLAGIOPYLEA, PHYLLOPHARYNGEA) and should be pronounced CON-3-P

[d]The Peritrichia are traditionally divided into the Sessilida and Mobilida. Recent molecular phylogenomic analyses have confirmed the monophyly of this group (Gentekaki et al. 2017)

like ancestors (Fig. 10). Heterotrichs have kinetids with postciliary ribbons that overlap to form postciliodesmata and weakly developed kinetodesmal fibrils that often extend slightly posteriorly. The left oral ciliature usually consists of a series of oral polykinetids numerous enough to form a spiral extending out of the oral cavity onto the cell surface (Fig. 10). Their polygenomic macronuclei are capable of division using microtubular bundles that form *outside* the macronuclear envelope – *extramacronuclear* microtubules. This kind of macronuclear division is thought to have arisen independently of that exhibited by the majority of ciliates (see below INTRAMACRONUCLEATA; Lynn 2008). Heterotricheans are found in all habitats described above ("Habitats and Ecology, Habitats").

INTRAMACRONUCLEATA Lynn 1996. The other major division of ciliates is strongly supported by gene sequence data (Fig. 8) (Lynn 2008). There is at present only one significant morphological feature that appears to unite these ciliates: the division of the macronucleus by *intramacronuclear* microtubules – hence the name. Lynn (2008) speculated that a molecular genetic character may ultimately be found that supports this subdivision of the phylum. The remaining major groups are considered intramacronucleates.

SPIROTRICHEA Bütschli 1889. Spirotricheans are a morphologically and genetically diverse class (Figs. 8, 11 and 12). With the exception of *Protocruzia* and *Phacodinium*, replication bands are the specialized morphological feature that accompanies DNA replication in these ciliates (Lynn 2008). *Phacodinium* may have lost this structure as it is placed *within* the spirotrich clade (Fig. 8). On the other hand, *Protocruzia* has a quite unusual macronuclear structure, is only weakly associated with other spirotrichs based on gene sequences (Fig. 8) (Gentekaki

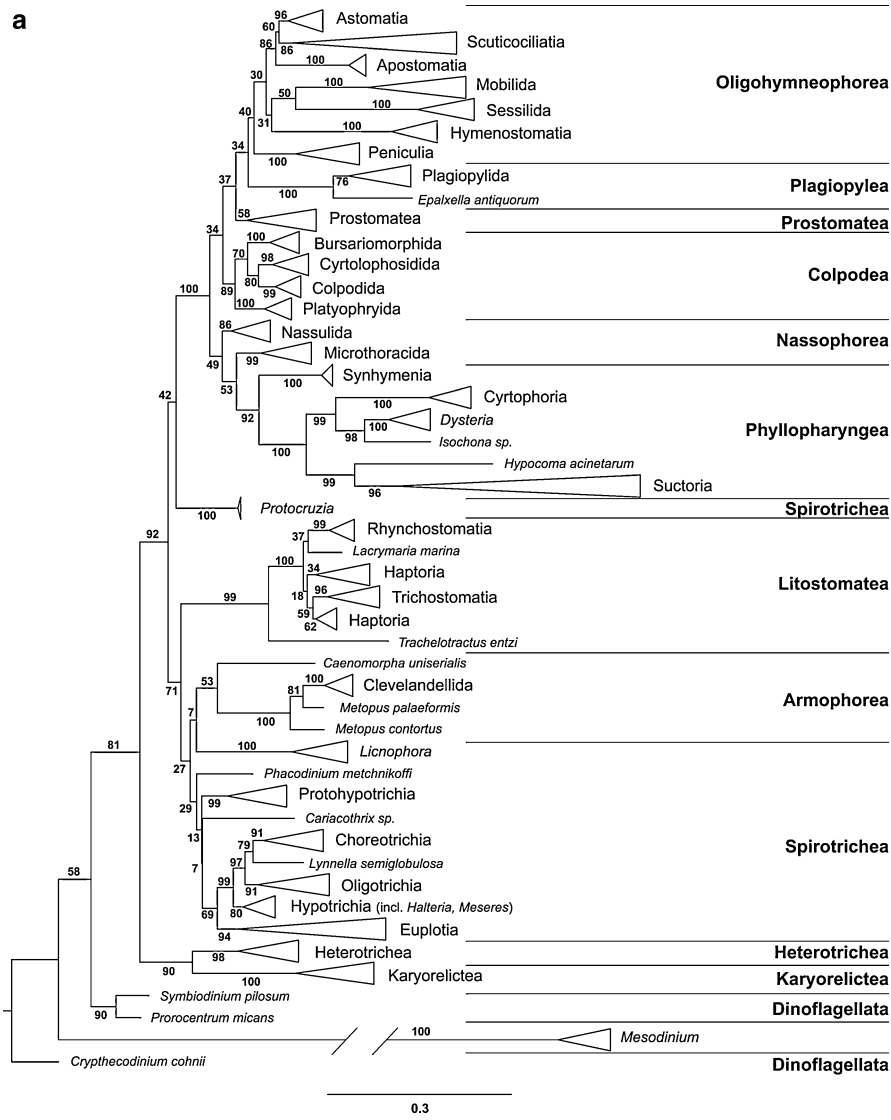

Fig. 8 (continued)

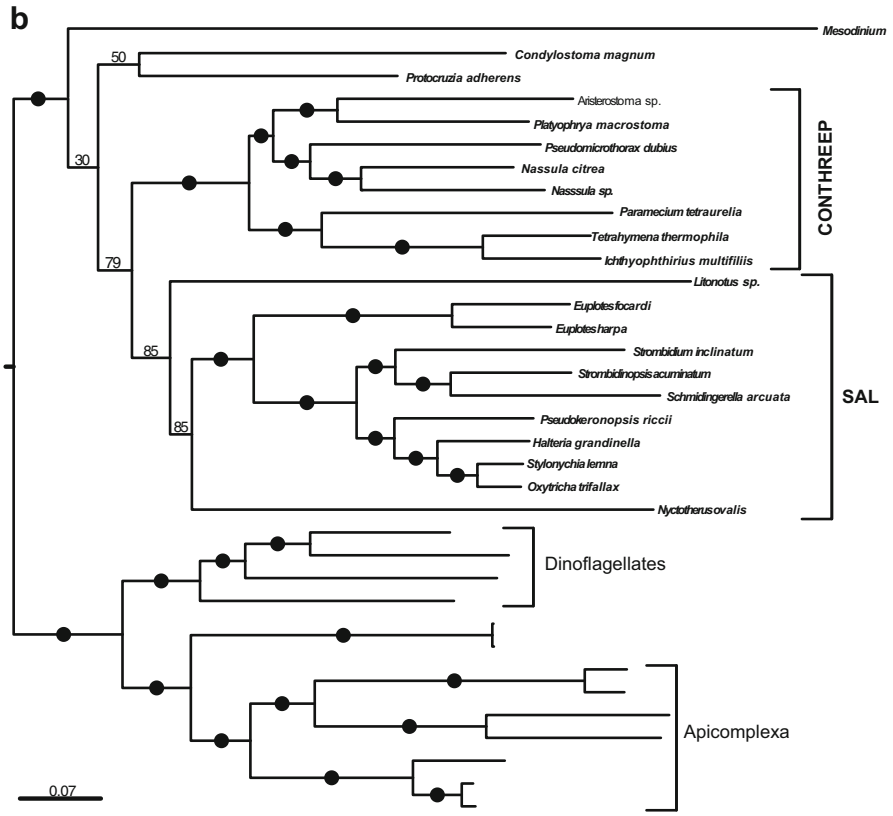

Fig. 8 Phylogenies of the ciliated protozoa based on small subunit rRNA gene sequences (**a**) and on a phylogenomic analysis (**b**). (**a**) A maximum likelihood tree inferred from small subunit rRNA gene data of ciliate species representative of the different classes. The POSTCILIODESMATOPHORA, which includes the Karyorelictea and Heterotrichea, is sister to the INTRAMACRONUCLEATA, which includes the remaining nine major groups. A new class, the Cariacotrichea including *Cariacothrix*, has been suggested by Orsi et al. (2012), but here it is embedded within the Spirotrichea. Dr. Michaela Strüder-Kypke derived this phylogeny using PhyML 3.0 with the GTR (General-Time-Reversible) model with gamma distribution and an estimate of invariable sites. The numbers at the nodes represent the support values for the maximum likelihood analysis. The scale bar represents 30 substitutions per 100 nucleotides. (**b**) A maximum likelihood tree constructed by RAxML using the LG model with empirical frequencies and gamma distribution based on a concatenated alignment of ~120 genes. The *black circles* denote 100% bootstrap support for 1,000 bootstraps (Lynn and Kolisko, unpublished)

et al. 2014), and may in fact represent the type of a new monotypic class of ciliates (Gao et al. 2016; Li et al. 2010). Spirotrichs like *Stylonychia* (Fig. 11) and *Euplotes* (Fig. 12) are typically benthic while *Halteria* (Fig. 11), *Strombidinopsis*, *Tintinnopsis*, *Cymatocylis*, and *Limnostrombidium* (Fig. 12) are typically planktonic, in both marine and freshwater habitats.

The first three groups appear to form the SAL clade, for the first letter in the name of each included group (Fig. 8) (Gentekaki et al. 2014), while the ARMOPHOREA

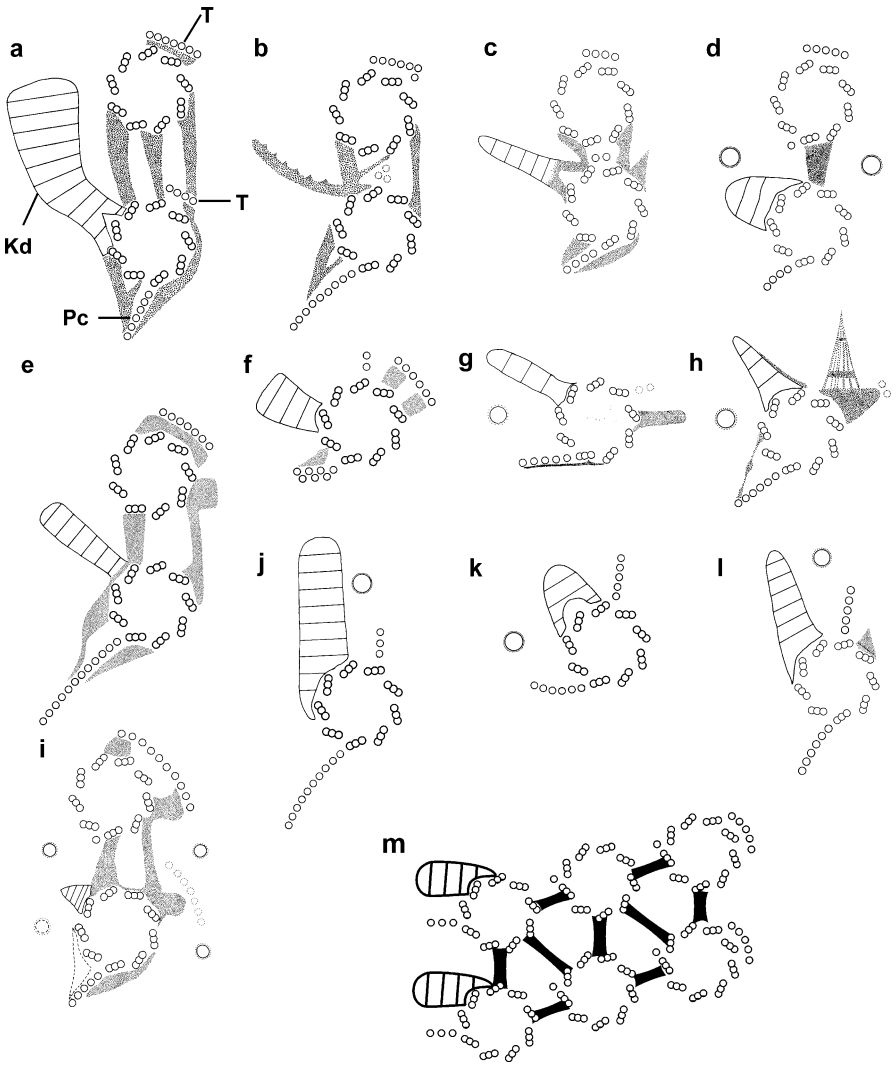

Fig. 9 Schematics of somatic kinetids of genera representative of each major group in the Phylum CILIOPHORA. and LITOSTOMATEA have been proposed to be related based on the lamella-like arrangement of postciliary ribbons that underly the somatic cortex, the so-called Lamellicorticata (Vd'ačný et al. 2010; Vd'ačný et al. 2012).

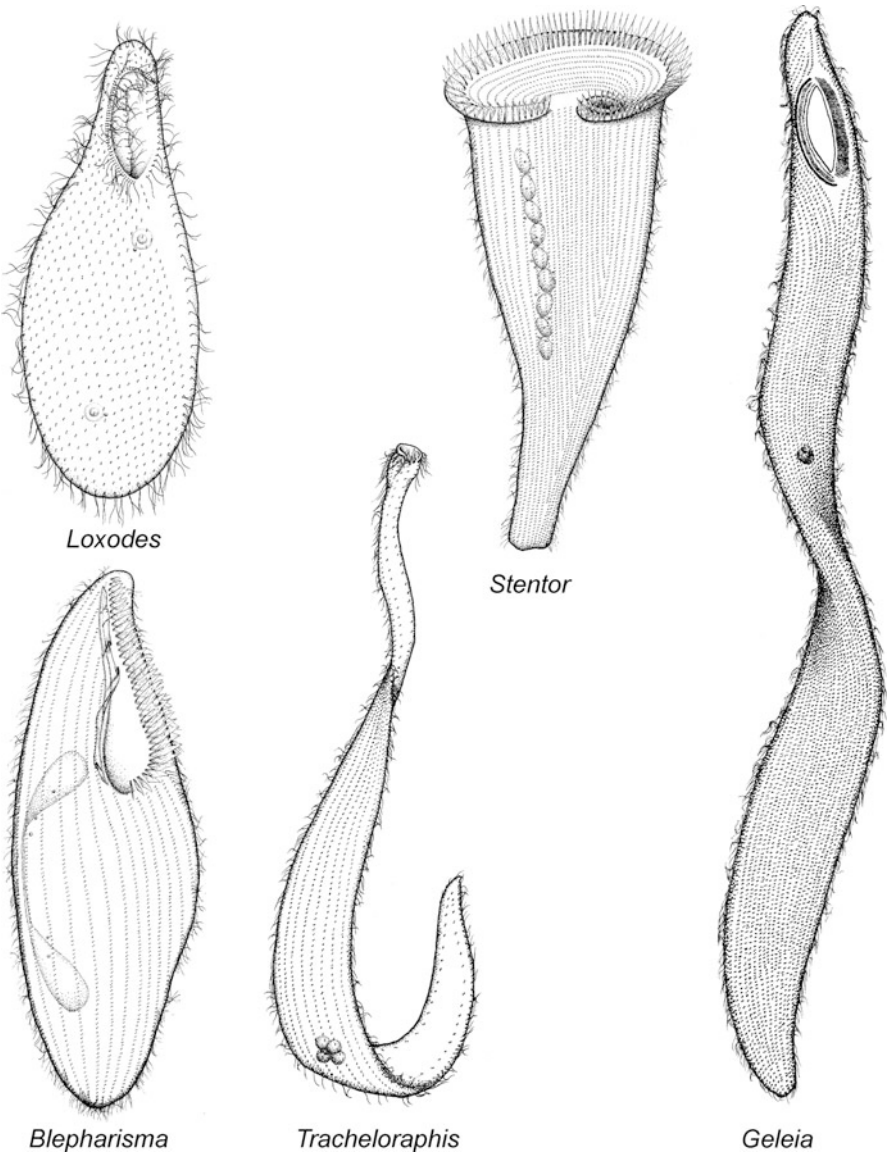

Fig. 10 Representative genera of the POSTCILIODESMATOPHORA. KARYORELICTEA. *Loxodes*, *Tracheloraphis*, and *Geleia*. HETEROTRICHEA. *Blepharisma* and *Stentor*

ARMOPHOREA Lynn 2002. Armophoreans represent one of what have been called "ribo-classes" of ciliates since they were identified as a monophyletic group only by gene sequence data (Fig. 8). In fact, like the spirotricheans, armophoreans are morphologically diverse, both at the cell level *and* at the somatic kinetid level (Figs. 9 and 13). Thus, they can be viewed as "an exception that proves the rule" that

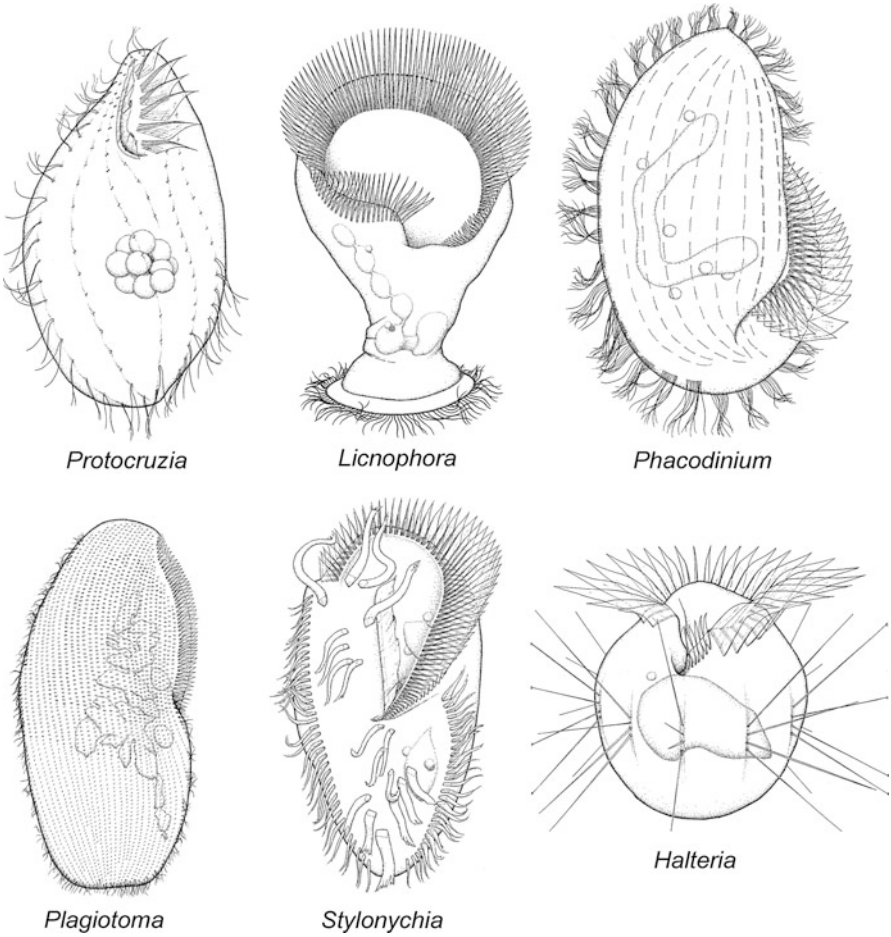

Fig. 11 Representative genera of the SPIROTRICHEA. Protocruzidiidia. *Protocruzia*. Licnophoria. *Licnophora*. Phacodiniidia. *Phacodinium*. Hypotrichia. *Plagiotoma*, *Stylonychia*, and *Halteria*

somatic kinetids generally reflect larger assemblages within the phylum. Armophoreans are typically found in anoxic freshwater and marine habitats, and the gene sequence data may ultimately be corroborated by physiological and biochemical characters since these ciliates all have hydrogenosomes rather than mitochondria. The clevelandellid armophoreans are all intestinal endosymbionts in invertebrates, such as millipedes and cockroachs, and in vertebrates, such as frogs.

LITOSTOMATEA Small and Lynn 1981. The litostomates (Fig. 14) include three rather diverse subgroups of ciliates: the Rhynchostomatia, carnivorous ciliates that use a proboscis for hunting; the Haptoria, principally free-living, carnivorous ciliates; and the Trichostomatia, principally endosymbionts of birds and mammals. These groups have somatic monokinetids with two transverse ribbons – a tangential

one and a radial one, a short, almost laterally directed kinetodesmal fibril, and convergent postciliary microtubules (Fig. 9).

The last six major groups, phyllopharygeans, nassophoreans, colpodeans, prostomateans, plagiopyleans, and oligohymenophoreans are often linked together in molecular phylogenies (Fig. 8) (Lynn 2008). Even though there is no obvious strong unifying morphological feature for this group, it has been named CONTHREEP (pronounced CON-3-P), based on the first letter of the names of the groups that are robustly clustered by genetic features.

PHYLLOPHARYNGEA de Puytorac et al. 1974. Phyllopharyngeans, like the spirotrichs, are a morphologically diverse clade (Fig. 15). However, all have somatic monokinetids with a short, laterally directed kinetodesmal fibril and a

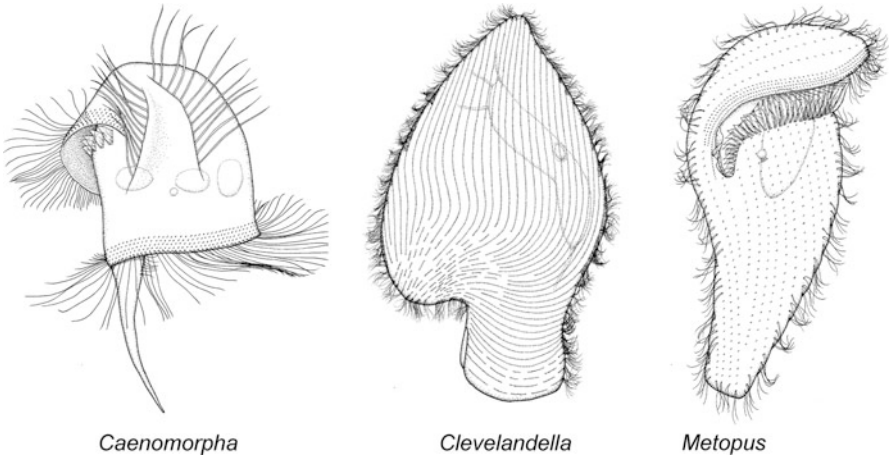

Fig. 13 Representative genera of the ARMOPHOREA. Armophorida. *Caenomorpha* and *Metopus*. Clevelandellida. *Clevelandella*

poorly developed or absent transverse microtubular ribbon accompanied by a fibrous support (Fig. 9). Their postciliary microtubules originate from the kinetosome in a convergent position; subkinetal microtubules course beneath the kinetosomes of a somatic kinety; and the cytopharynx is surrounded by radially arranged microtubular ribbons called phyllae. These ciliates are primarily benthic: chonotrichs and suctoria are sessile on nonbiological surfaces or other organisms. Some are ciliated only during dispersal: for example, the suctorians *Discophrya* and *Acineta* (Fig. 15).

NASSOPHOREA Small and Lynn 1981. The nassophoreans have singly or doubly ciliated somatic kinetids (Fig. 9). Somatic dikinetids have an anterior kinetosome with a tangential transverse ribbon and a posterior kinetosome with an anteriorly directed kinetodesmal fibril, a divergent postciliary ribbon, and often a tangential transverse ribbon. Somatic alveoli are well developed. The cytopharyngeal apparatus, which is similar to that of cyrtophorine phyllopharyngeans, is the cyrtos, a complex microtubular "basket" that functions in ingestion (Tucker 1978). Simple "oral" polykinetids are found adjacent to the cytostome or extending in bands of varying length across the body (Fig. 16). The nassophoreans are commonly free-living, benthic ciliates typically found in fresh, brackish, and salt water, typically feeding on filamentous cyanobacteria.

COLPODEA de Puytorac et al. 1974. The somatic kinetid of colpodeans is strikingly unique (Fig. 9). Colpodeans have dikinetids with a short, laterally directed kinetodesmal fibril and a set of prominent overlapping transverse microtubular ribbons that arise from the posterior kinetosome. Colpodeans clearly demonstrate the range in variability of oral structures while the somatic structures remain invariable (Lynn 2008) (Fig. 17). These ciliates are commonly found in temporary freshwater or soil habitats where they encyst when the environment dries.

PROSTOMATEA Schewiakoff 1896. The distinguishing features of the prostomateans include somatic monokinetids with probably a radial transverse ribbon and well-developed, right-anteriorly directed kinetodesmal fibrils (Fig. 9), and the perimeter of the oral area supported by oral dikinetid postciliary ribbons that,

at least in *Urotricha*, extend from each dikinetid to overlap each other in a circular microtubular band. The prostomateans (Fig. 18) apparently evolved toxicysts independently from the litostomateans, since members of both classes have these organelles. Prostomateans are found in a wide variety of habitats; commonly, they are benthic and most species are marine.

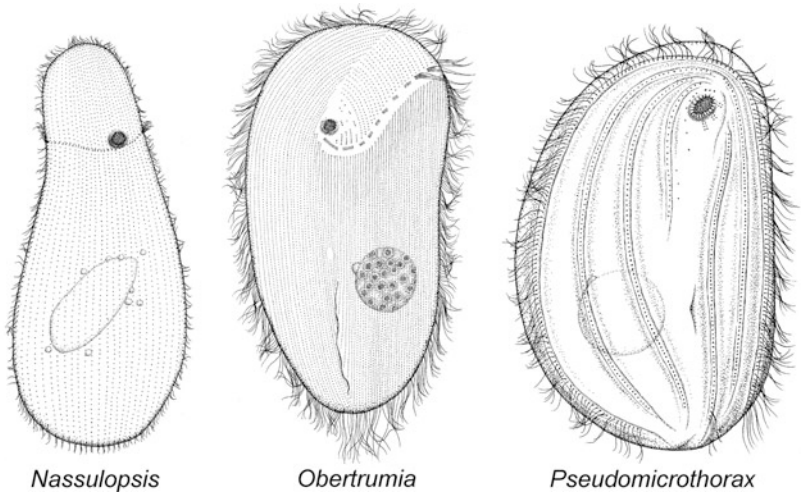

Fig. 16 Representative genera of the NASSOPHOREA. Nassulida. *Nassulopsis* and *Obertrumia*. Microthoracida. *Pseudomicrothorax*

PLAGIOPYLEA Small and Lynn 1985. Like the ARMOPHOREA, the plagiopyleans represent a "ribo-class" as they were recognized as a monophyletic unit based *only* on the sequences of the small subunit rRNA gene (Stoeck et al. 2007 in Lynn 2008). Two groups are now placed in this class – the plagiopylids and odontostomatids, but they are morphologically extremely dissimilar (Fig. 19). Like armophoreans, plagiopyleans are typically inhabitants of anoxic freshwater and marine habitats and have hydrogenosomes, which can be associated with intracellular methanogenic bacteria or with extracellular ectosymbiotic methanogens that increase the ciliate's metabolic efficiency in these habitats. Thus, a unifying biochemical or physiological feature may eventually be discovered to explain this assemblage.

OLIGOHYMENOPHOREA de Puytorac et al. 1974. Oligohymenophoreans are a diverse group morphologically characterized as having a paroral on the right side of the cytostome and typically three oral polykinetids on the left, although their cellular form is quite varied (Figs. 20 and 21). Their somatic kinetids have a *radially* oriented transverse ribbon associated with the posterior kinetosome of a dikinetid or with the monokinetid kinetosome, but the peniculines, such as *Paramecium*, are an exception to this rule (Fig. 9). Postciliary microtubules are divergent and are directed posteriorly, whereas the kinetodesmal fibril associated with the posterior kinetosome of a dikinetid is anteriorly directed and strongly overlapping. The Peritrichia, such as *Vorticella* (Fig. 20), are adapted to sessility and lack somatic kinetids but are related to the other oligohymenophoreans by the pattern of division morphogenesis (i.e., the structure and formation of the oral region). Oligohymenophorean ciliates are common in all habitats described (see above "Habitats and Ecology, Habitats").

Maintenance and Cultivation

Collection and Isolation from Nature

Collection. Procedures for collecting ciliates vary depending upon the habitat in which the organisms are found (see "Habitats and Ecology, Habitats"). Collection methods for benthic habitats and soils have been outlined by Uhlig (1972), Alabouvette et al. (1981), and Acosta-Mercado and Lynn (2003). Planktonic ciliates

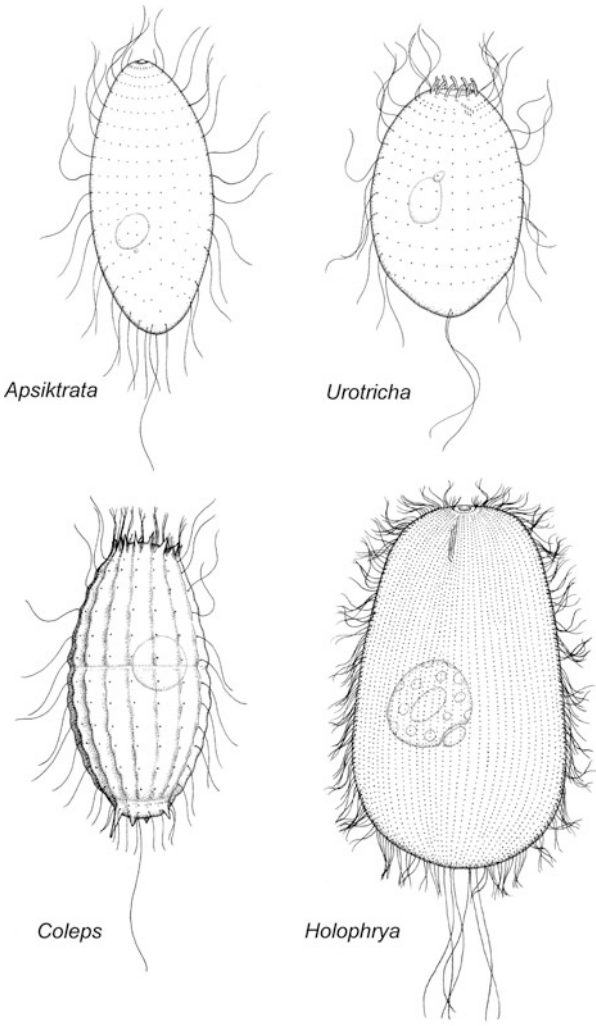

Fig. 18 Representative genera of the PROSTOMATEA. Prostomatida. *Apsiktrata*. Prorodontida. *Urotricha*, *Coleps*, and *Holophrya*

are best collected by using bottles or whole water sampling apparatuses (Montagnes and Lynn 1993).

Enumeration. For enumeration of ciliates, several methods have been published for benthic collections (Dye 1979; Finlay et al. 1979 in Finlay and Ochsenbein-Gattlen 1982; Wickham et al. 2000) and soils (Acosta-Mercado and Lynn 2003). For planktonic collections, counting chambers may be used: the ciliates can be counted alive (Dale and Burkhill 1982) or can be fixed using a concentrated Bouin's fixative and stained using the quantitative protargol stain (Montagnes and Lynn 1993).

Isolation. Field collections can be examined immediately and the species of interest isolated using flame-drawn Pasteur pipettes. Alternatively, the collection can be enriched by the addition of *small* quantities of boiled leaves, seeds, grains,

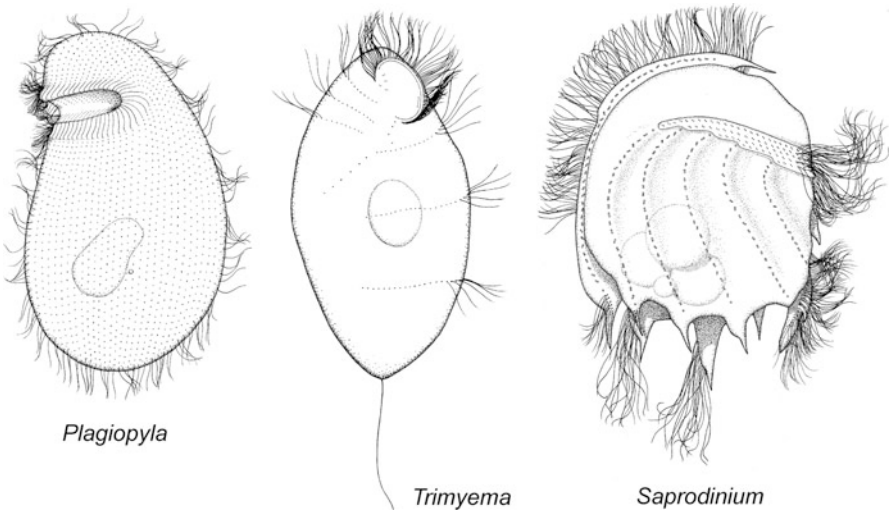

Fig. 19 Representative genera of the PLAGIOPYLEA. Plagiopylida. *Plagiopyla* and *Trimyema*. Odontostomatida. *Saprodinium*

animal tissues, or nutrient media, such as proteose peptone. After a few days, the cultures can be examined and species of interest isolated, usually by hand pipetting single ciliates under a low power microscope (Foissner 1991).

Nyberg (1981) isolated *Tetrahymena* species by enriching field collections with proteose peptone and adding antibiotics to inhibit bacterial growth. Kosinski (1979) described a method of producing axenic cultures by several passages of a bacterized batch culture through sterilized tubes, each transfer being made using sterile hypodermic needles.

Cultivation

Monoxenic Cultures. Many species of ciliates have been grown on a variety of food sources. Observations of what the ciliate of interest feeds upon in nature must be made prior to establishing the organism in culture. The nutritional value of a variety of bacterial species for selected ciliates has been discussed by Dive (1973 in Lynn 2008). There are many variables to consider in order to successfully establish a species in culture (see, for example, Hamilton and Preslan 1969 in Lynn 2008); these become especially complex when culturing planktonic species, such as tintinnids (Gold 1973) or "carnivorous" (ciliativorous) species, that is, ciliates that eat other ciliates.

Axenic Culture. Very few ciliates have been grown in axenic cultures. *Tetrahymena* species were the first, and almost all other axenically grown ciliate species are members of the Class OLIGOHYMENOPHOREA. *Tetrahymena* species are cultured on proteose peptone (Cassidy-Hanley in Collins 2012; Nyberg 1981; Keenan

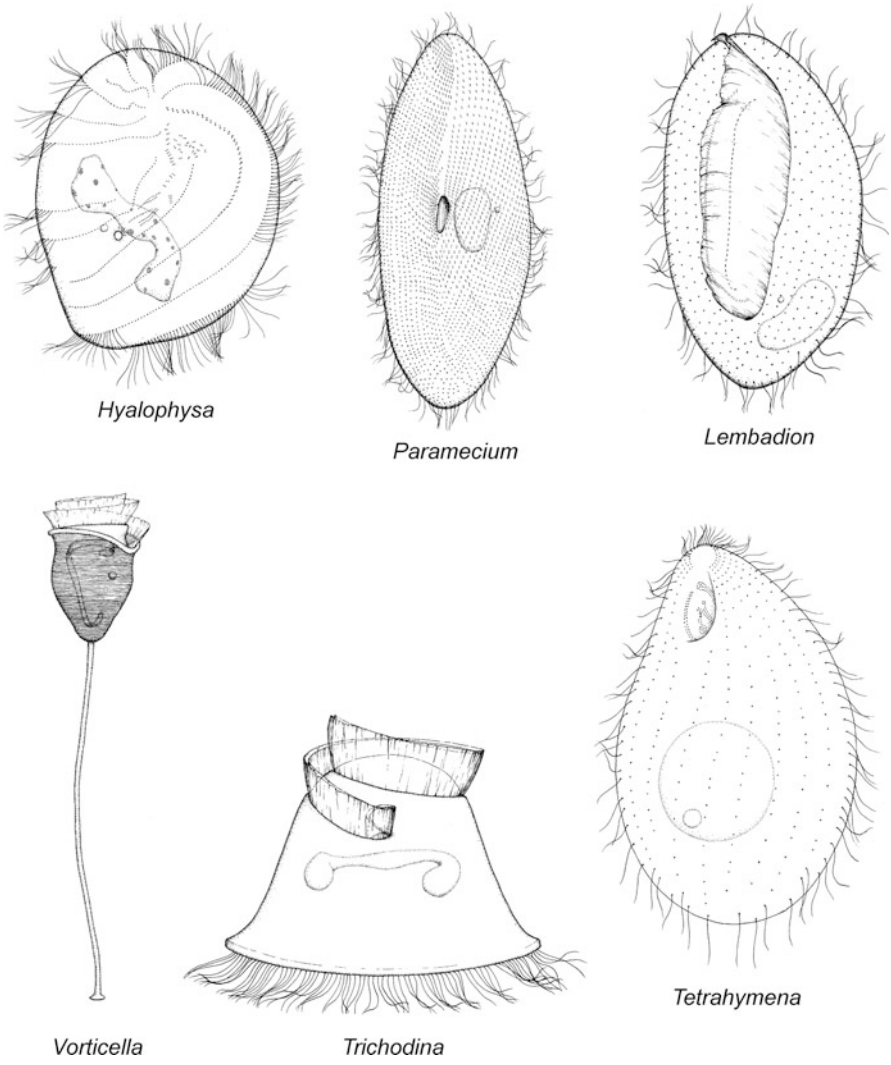

Fig. 20 Representative genera of the OLIGOHYMENOPHOREA. Apostomatia. *Hyalophysa*. Peniculia. *Paramecium* and *Lembadion*. Peritrichia. *Vorticella* and *Trichodina*. Hymenostomatia. *Tetrahymena*

et al. 1978). *Paramecium* species can also be grown on proteose peptone-trypticase media (Fok and Allen 1979; Soldo et al. 1966 in Fok and Allen 1979). *Uronema* and some related scuticociliates are marine forms that have been successfully cultivated axenically on proteose peptone-trypticase media (Iglesias et al. 2003 in Lynn 2008; Soldo and Merlin 1972 in Soldo et al. 1974).

Large-Scale Cultivation. Large-scale cultivation of *Tetrahymena* and *Paramecium* is accomplished by increasing the volume of axenic medium (Thiele et al.

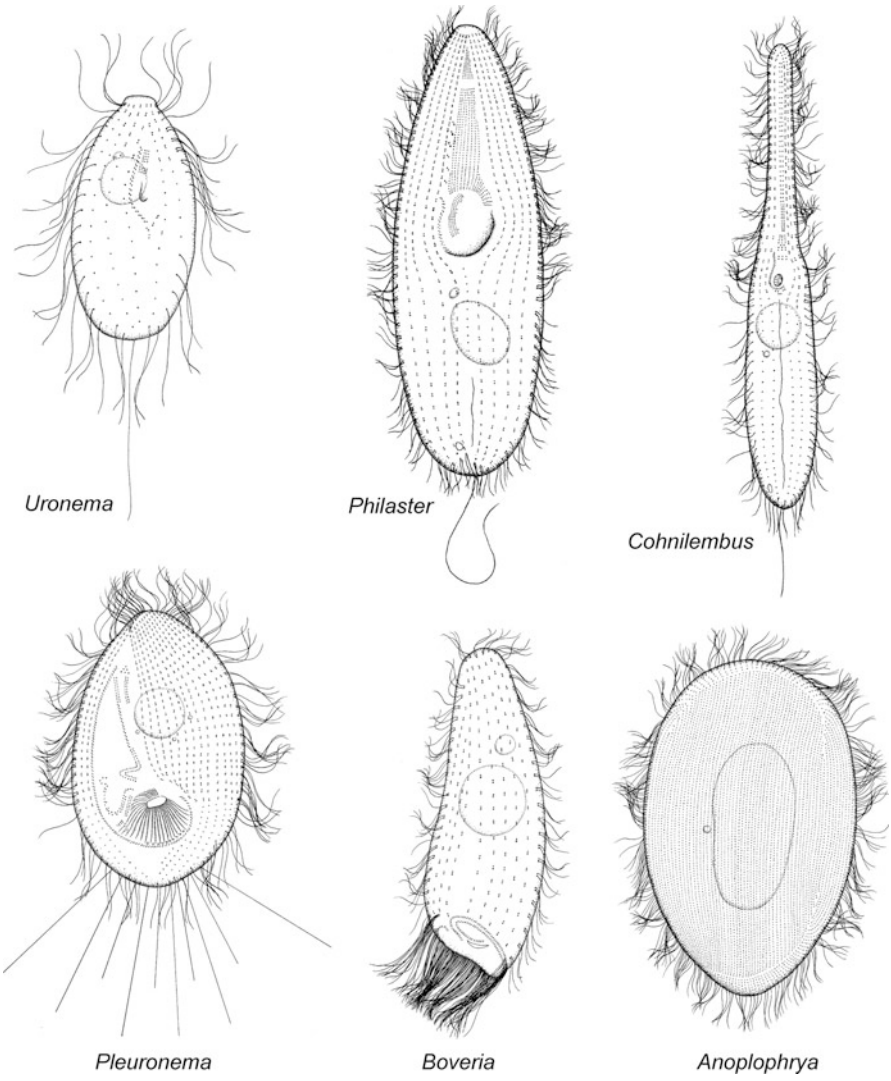

Fig. 21 Representative genera of the OLIGOHYMENOPHOREA cont'd. Scuticociliatia. *Uronema*, *Philaster*, *Cohnilembus*, *Pleuronema*, and *Boveria*. Astomatia. *Anoplophrya*

1980 in Schmidt 1982). Care must be taken that adequate oxygen is provided either by aeration or through having a high surface area to volume ratio in the culture flask.

Large-scale monoxenic cultures must be carefully regulated to ensure maximum growth of the predatory ciliates relative to the food. Several methods have been described for cultivating euplotian and hypotrich ciliates (Laughlin et al. 1983; Schmidt 1982).

Long Term Preservation. Little information exists on methods of long-term preservation of ciliates. A combination of low temperature and cryoprotectant seems to be most successful (Anderson et al. 2009; Cassidy-Hanley in Collins 2012; Krenek and Berendonk 2009). Encystment by some ciliates, such as colpodids, allows for simple, long-term dry storage on vegetation or filter paper.

Culture Media. Media have been devised for the cultivation of a number of species of ciliates. Recipes are listed for two very common media: a medium for bacterized cultures based on an infusion derived from dried cereal grass leaves and a proteose peptone-based medium for axenic culture of some tetrahymenid ciliates (Tables 3 and 4). Two good sources for recipes of a large number of media are an old publication prepared by the Committee on Cultures, Society of Protozoologists (1958), which gives the appropriate media for a variety of species, and the American Type Culture Collection Catalogue of Strains I (1982), in which the species are cross-referenced to the appropriate medium.

Cultivation of anaerobic ciliates began first with those resident in the rumen (Coleman 1969 in Michalowski et al. 1985). Free-living anaerobes, such as the armophorean *Metopus* (Narayan et al. 2007), the plagiopyleans *Trimyema* (Wagener and Pfennig 1987) and *Plagiopyla* (Fenchel and Finlay 1991b), and scuticociliates (Dyer 1989 in Lynn 2008), have now been isolated from various habitats and cultivated using similar techniques.

Table 3 Recipe for proteose peptone-yeast extract culture medium

5–10 g	Proteose peptone (Difco)
5–10 g	Yeast extract (water soluble portion of autolyzed yeast)
2 g	Glucose
1 l	Distilled water
Add the dry ingredients to the distilled water and heat until they are dissolved. Dispense into culture vessels and autoclave to sterilize	
Note: This medium is useful only for axenic cultivation of some tetrahymenid ciliates	

Table 4 Recipe for culture medium based on extract of cereal grass leaves

Preparation of stock infusion of cereal grass leaves	*Preparation of the culture medium*
50 g powdered, dehydrated cereal grass leaves (Sigma) Calcium carbonate (pinch) 1 l distilled water (or, for marine ciliates, ½ strength sea water) Add the cereal grass leaves to the distilled water and boil for 10 min taking care that the suspension does not boil over. Filter the suspension using a Buchner funnel and bring the filtrate back to the 1l volume. Dispense as 10-ml aliquots in screw cap tubes. Autoclave to sterilize and store in the refrigerator	Dilute the stock infusion into 250–1000 ml of distilled water, sterile pond water, or a dilute salt solution; the more dilute the medium, the less populous the bacteria will be. Ciliates may be transferred from nature to this medium. Alternatively, introduce prey bacteria by inoculating the medium with *Aerobacter aerogenes* or other suitable Gram-negative aerobic bacterial prey. Incubate at room temperature for 6–24 h, and then transfer the ciliates to this medium

Evolutionary History

Fossil Record

Ciliates, being soft-bodied organisms, are poorly represented in the fossil record. A number of species have "hard" parts that have the potential to be preserved: *Coleps* species of the PROSTOMATEA secrete internal calcium carbonate structures; *Loxodes* species of the KARYORELICTEA accumulate barium sulfate as conspicuous intracellular granules (Finlay et al. 1983); a variety of tintinnid species of the choreotrich SPIROTRICHEA secrete loricae to which are agglomerated or attached mineral particles from the water column; or the calcium carbonate tests of coccolithophorids (Tappan and Loeblich 1973). The mineral components of *Coleps* and *Loxodes* may be too small and inconspicuous to be recorded as body fossils. Remarkably, whole cells of *Coleps*, *Paramecium*, and *Colpoda* species have been discovered embedded in fossilized amber over 200 million years old (Martín-González et al. 2008; Schmidt et al. 2006).

The loricas of tintinnids, possibly by partial recrystallization of attached coccolith tests, deposited by the tintinnid when alive, and by secondary growth of calcite crystals, have provided a record of the history of this group of ciliates. The tintinnids apparently reached peak diversity during the Jurassic and Cretaceous (Fig. 22; Tappan and Loeblich 1973). Some have argued that fossil tintinnids might be of Proterozoic origins, but this is highly unlikely (Lipps, Stoeck, and Dunthorn in Dolan et al. 2013). Since fossil genera have been placed in present-day families of tintinnids, very little can be said about the rate and degree of divergence of taxa (Lipps et al. in Dolan et al. 2013; Lynn 2008). Lipps et al. (in Dolan et al. 2013) make a strong case that the calpionellids are likely not tintinnids.

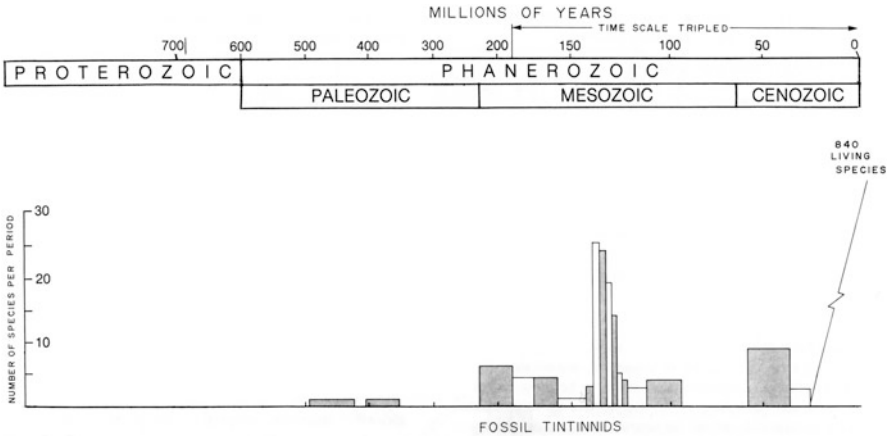

Fig. 22 Total number of species of tintinnids per geological period from their earliest appearance in the Ordovician up to the present. Taxa in the *shaded columns* are likely not tintinnids (After Tappan and Loeblich 1973; Redrawn by K. Wellencamp)

Phylogeny

Phylogeny Within the Phylum CILIOPHORA. The presumed phylogenetic relationships of the major clades of ciliates have been briefly mentioned above (Characterization and Recognition, *Classification*). The most informative data on the adaptive diversification of ciliates is provided by gene sequences, particularly that of the small subunit rRNA gene (Fig. 8a) and now phylogenomic analyses (Fig. 8b) (Gentekaki et al. 2014; Lynn 2008). This is because it is almost impossible to understand how one kind of cortical ultrastructure is related to or transformed into another kind of cortical ultrastructure.

From the molecular genetic perspective, the phylum is unambiguously divided into two major clades (Fig. 8, Table 2). Within the POSTCILIODESMATOPHORA, it has been argued that macronuclear division evolved from a division-less ancestral karyorelictean-like state by the use of *extramacronuclear* microtubules while macronuclear division evolved independently in the other clade – the INTRAMACRONUCLEATA – by use of *intramacronuclear* microtubules (Orias 1991a in Lynn 2008).

How the various groups of intramacronucleates diverged varies somewhat depending upon what gene one uses as the data source (Lynn 2008). The spirotrichs, armophoreans, and litostomes (SAL) appear to be related robustly in phylogenomic analyses, while the remaining six classes form a clade that is often well supported and has been labeled CONTHREEP, an acronym standing for the first letters of the included groups (Fig. 8).

Origin of the Phylum CILIOPHORA. The origin of the Phylum CILIOPHORA is as conjectural as the origin of the groups within it. The putative ancestor could have been a "corticoflagellate": a flagellate with a locomotory dikinetid, cytostome, and with a cortex and infraciliature similar to that of the ciliates (Lynn and Small 1981 in Lynn 2008). There are at least two contemporary taxa that exhibit these features: the dinoflagellates and *Colponema* spp. have dikinetids with ribbons of microtubules associated with each kinetosome, a striated rootlet fibril associated with at least one kinetosome and extending toward the cell surface, and cortical alveoli similar to those of ciliates. Gene sequences confirm the associations of these three contemporary taxa with other alveolates (see ► Dinoflagellata, and ► Apicomplexa).

From this flagellate ancestor, polymerization or an increase in numbers of kinetid units must have occurred to form the ciliary files or kineties. The most plausible model to date has been presented by Eisler (1992). It is imagined that this ancestor had a file of dikinetids, the homologue to the paroral, associated with its cytostome. These paroral dikinetids replicated laterally to produce a file or row of dikinetids to their right, and this would produce the first somatic kinety. Repeated replication of this process would generate multiple kineties that would eventually "cover" the cortical surface (Eisler 1992). It is further proposed that the adoral ciliary structures (i.e., those on the left side of the cytostome) differentiated from somatic kineties adjacent to the left side of the cytostome, a process that often happens in contemporary ciliates but in very diverse ways.

Acknowledgments

I thank David Montagnes for his artistic rendering of Figs. 1 and 2, Dr. Michaela Strüder-Kypke for assistance with molecular phylogenetics, Owen Lonsdale for the schematic drawings of genera representative of the different major groups included in Figs. 9, 10, 11, 12, 13, 14, 15, 16, 17, 18, 19, 20, and 21, Sandra Ackerley for her dedicated technical assistance with electron microscopy, and Ian Smith for assistance with the graphics. A Natural Science and Engineering Research Council of Canada Discovery Grant awarded to DHL provided support.

Radiolaria and Phaeodaria

19

Demetrio Boltovskoy, O. Roger Anderson, and Nancy M. Correa

Abstract

Polycystina (~400–800 living species and several thousand extinct forms) and Phaeodaria (~400–500 living species) are exclusively marine, open-ocean planktonic protists, most of which possess elaborate siliceous skeletons. The cytoplasm is divided into an internal part (endoplasm) separated from the external, more vacuolated one (ectoplasm) by a perforated membrane – the central capsule. The Polycystina protrude long and slender cytoplasmic projections (axopodia) supported internally by a rigid central rod (axoneme); while the Phaeodria have a network of peripheral finely interconnected pseudopodia. A few Polycystina are colonial, but most, as well as all Phaeodaria, are solitary, around 40 μm to almost 2 mm in size. Most polycystine species peak in abundance between 0 and 100 m, whereas phaeodarians tend to live deeper, often below 300 m. Polycystines have a rich fossil record dating from the Cambrian and are important for stratigraphic, paleoecologic, and evolutionary studies. The world-wide biogeography and diversity of radiolarians is chiefly governed by water temperature. Radiolarian prey includes bacteria, algae, protozoa, and microinvertebrates. Many surface-dwelling species of Polycystina possess symbiotic algae and photosynthetic

cyanobacteria that provide nourishment to the host. Some colonial radiolaria reproduce by binary fission of the central capsules. Sexual reproduction of polycystines or Phaeodaria has not been confirmed, but the release of motile swarmers, likely gametes, has been widely documented. In species with a radial symmetry (Spumellaria) shell-growth is centrifugal, whereas in the Nassellaria the internal cephalic elements and the cephalis appear first. Individual longevity is estimated to range between 2 and 3 weeks and 1–2 months.

Introduction

General Characteristics

Polycystines and phaeodarians (Fig. 1) are marine protists, previously assigned to the phylum Actinopoda because they both possess elaborate siliceous skeletons surrounding an organic central capsule with pores, from which axopodia emerge in most members of the phylum. However, the phylum Actinopoda is no longer accepted as a valid taxonomic category, and Polycystinea are assigned to the higher-level group Retaria, and Phaeodaria are now assigned to the higher-level group Thecofilosea (Adl et al. 2012). Axopodia are long and slender cytoplasmic projections that protrude radially from the cell and are supported internally by a rigid central rod composed of a shaft of microtubules. Axopodia support a web-like network of sticky cytoplasmic strands of pseudopodia that aid in the capture of prey. Presently, we know that only polycystines possess typical axopodia, whereas Phaeodaria characteristically produce a network of peripheral finely interconnected pseudopodia that arise from two, specialized protoplasmic strands (parapylae) emerging from two pores in the central capsule. In addition there is a more massive cytoplasmic mass that emanates from an aperature (astropyle) resembling the oral aperture of some testate amoebae. Neither the astropyle nor the accessory openings *parapylae* exhibit structures resembling axopodia or fusules (Anderson 1983). All Phaeodaria are solitary, but Polycystinea include some colonial forms. Single cells vary in size from below 40 μm to almost 2 mm (Phaeodaria are usually larger than Polycystinea), but colonies may exceptionally be as long as 3 m (Swanberg 1979).

Occurrence

Radiolarians are present in all major oceans but absent from some marginal seas, such as the White Sea (Bjørklund and Kruglikova 2003). Different species have different depth preferences; polycystines usually peak in abundance between 0 and 100 m and have secondary peaks at various other depths, whereas phaeodarians tend to live deeper, often below 300 m. Both groups are almost entirely restricted to waters with normal open-ocean salinity levels.

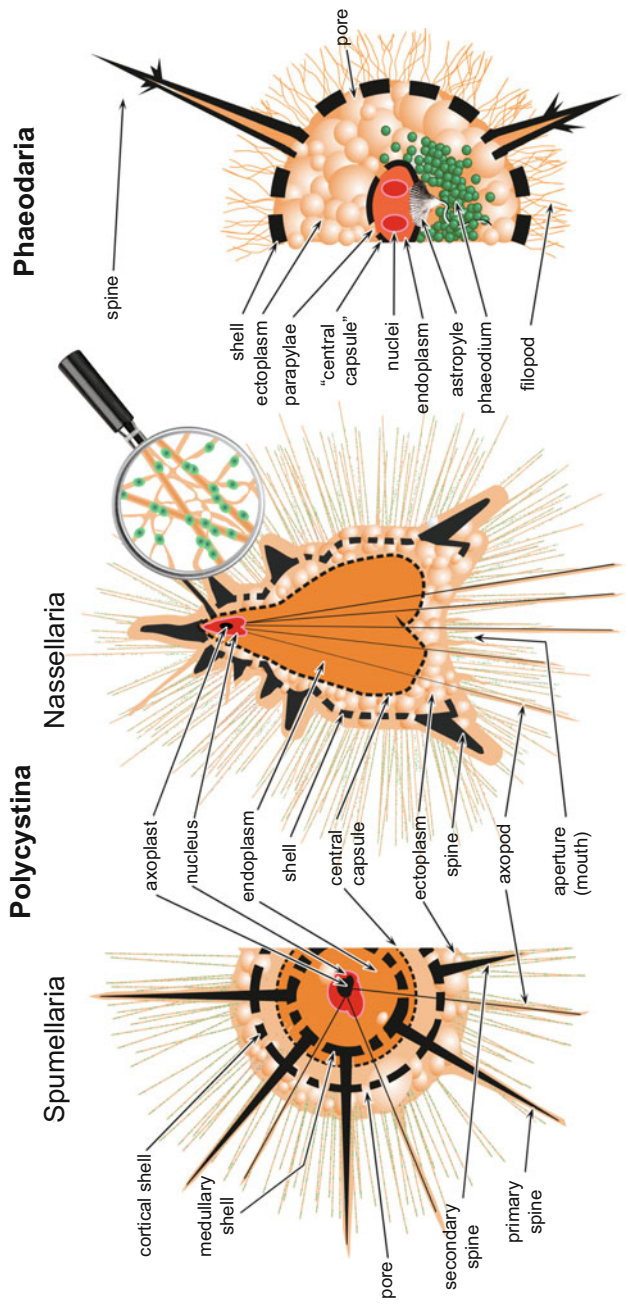

Fig. 1 Schematic diagram of the cellular organization in polycystine radiolarians (Spumellaria and Nassellaria) and phaeodarians. Detail (magnifying glass) shows web-like network of cytoplasmic strands supported by the axopodia and associated symbionts

Literature

The cornerstone of radiolarian studies, including Phaeodaria, is Haeckel's 1887 monograph based on planktonic and sedimentary materials collected by the Challenger Expedition (Haeckel 1887). Kling (1978), Anderson (1983), Petrushevskaya (1986), Anderson et al. (2000), Takahashi and Anderson (2000), De Wever et al. (2001), Afanasieva et al. (2005), Boltovskoy and Pujana (2008), and Nakamura and Suzuki (2015) produced general accounts on radiolarian knowledge. The catalogue assembled by Nigrini and Moore (1979) is still one of the most widely used references for the identification and distribution of the ca. 100 most common recent polycystine species. Other salient references are the works of Petrushevskaya (1967, 1971b) (profusely illustrated descriptions of practically all extant nassellarians and all Antarctic spumellarians); Sanfilippo et al. (1985) (a detailed guide for Cenozoic stratigraphy based on polycystines); Riedel and Foreman (1995) (a catalogue of all the polycystine species described up to 1930); and Boltovskoy et al. (2010) (a compilation of all the distributional data available on Recent polycystines up to 2008).

History of Knowledge

The first description of a living radiolarian is ascribed to Meyen (1834), whereas the first fossil one was recorded by Ehrenberg (1838), who also coined the term "Polycystina". The name "Radiolaria" was first proposed by Müller (1858) to designate planktonic protists with radiating skeletal elements and subsequently used by Haeckel as an informal term encompassing acantharians, polycystines, and phaeodarians (De Wever et al. 2001). The foundation of modern radiolarian studies is Haeckel's (1887) exquisitely illustrated monograph; around the same years several important publications were produced, but interest in the group was limited until the 1950s, when William Riedel and coworkers showed that polycystines could be used for stratigraphic purposes. First stratigraphy, and later paleoecology, fostered radiolarian research, which was particularly active in the 1970s and 1980s (Lazarus 2005; Suzuki and Aita 2011). At present there are about 150–200 specialists that are partially or entirely dedicated to radiolarian studies, over 90% of them with geological-paleontological backgrounds and centered on fossil materials. However, with the advent of modern biological techniques such as electron microscopy and molecular phylogenetic analyses, an increasing number of biologists have begun to elucidate the natural affinities among major groups of radiolaria toward clarifying their taxonomic relations (e.g., Amaral Zettler et al. 1998, 1999; Anderson et al. 1999; Biard et al. 2015; López-García et al. 2002; Polet et al. 2004; Suzuki and Aita 2011).

Practical Importance

During the second half of the twentieth century, studies of polycystines from continuous, well-preserved, mostly Cenozoic sections retrieved by the Deep Sea Drilling

Project (later Ocean Drilling Program, now the Intergrated Ocean Drilling Program) proved the usefulness of these organisms for stratigraphic purposes. By the mid-1970s, a relatively stable tropical zonation had been developed for the Cenozoic (Sanfilippo et al. 1985), and somewhat later several schemes for the polar oceans were proposed (Lazarus 2005). Polycystines are particularly important in Neogene Polar sediments and in red clay bottoms, where carbonate microfossils are largely absent. Polycystine faunas have also been instrumental to the development of paleoenvironmental studies (paleotemperature, paleoceanography, and paleoproductivity), chiefly of open-ocean areas (CLIMAP 1976). Polycystines offer major advantages as material for evolution research: the preservation of almost all species in fossil form, high-resolution chronology, the possibility to sample the entire geographic and chronologic span of the populations, etc. Evolutionary studies of these organisms, in particular speciation and phyletic evolution, have made significant contributions to understanding evolutionary processes in pelagic animals in general. A major limitation in the use of polycystines in all these fields is the problematic species-level taxonomy of the group (Lazarus et al. 2015).

Habitats and Ecology

Geographic Distribution and Biogeography

Horizontal distribution and biogeography. Radiolarians are present in all oceans from the surface to bathypelagic depths, but, with the only known exception of *Lophophaena rioplatensis*, which thrives in the brackish waters of the Río de la Plata estuary at salinities as low as 15.4 PSU (Boltovskoy et al. 2003), they do not tolerate salinities below ca. 30 PSU and are therefore absent from most shelf areas and many inner and marginal seas (e.g., Black Sea, Azov Sea, Caspian Sea, White Sea, Baltic Sea). However, in areas with a narrow shelf where oceanic waters impinge on the shore (e.g. off California, in Norwegian fjords), radiolarians can be collected from the coast. Polycystine densities are usually around 1 cell per liter of water, whereas phaeodarians are normally 15–100 times less abundant (Boltovskoy et al. 1993). Productive, upwelling waters can host 5–10 and up to 70–80 cells/L (Caron and Swanberg 1990). Interestingly, the highest concentrations so far reported (394 cells/L) are those of the monospecific, brackish population of *Lophophaena rioplatensis* in the South American Río de la Plata estuary (Boltovskoy et al. 2003). Polycystine endemicity is generally low, as specific composition changes little with oceanic basin. Even the Arctic and the Antarctic share most of their species (Stepanjants et al. 2004). According to data from 4774 plankton, sediment trap and surface sediment samples compiled by (Boltovskoy et al. 2010), only *Artobotrys borealis* consistently occurs in Arctic and Subarctic waters and has not been recorded in the Antarctic or Subantarctic, but several species are here much more common and abundant than in cold waters of the Southern Hemisphere (*Amphimelissa setosa*, *Artostrobus annulatus*, *Artostrobus jorgenseni*, *Lithomelissa setosa*, *Phormacantha hystrix*, *Plectacantha oikiskos*, *Pseudocubus obeliscus*, *Rhizoplegma boreale*, *Saccospyris conithorax*, and

Siphocampe lineata) (Boltovskoy and Correa 2016a). Species probably restricted to – or at least much more abundant in – the Southern Ocean, include *Actinomma antarcticum*, *Antarctissa denticulata-strelkovi*, *Saccospyris antarctica*, and *Ceraspyris antarctica* (Boltovskoy and Correa 2016a). The other major oceanic climatic belts, defined chiefly by their different water temperature regimes, host dissimilar radiolarian assemblages (Fig. 2), but most of the species occur, albeit sparsely, in more than one area. Within the ranges of normal oceanic conditions (basically salinity), temperature is by far the most important factor in defining polycystine distribution patterns (Boltovskoy and Correa 2016a), followed by nutrients and primary productivity. At ocean basin scales, temperature is also most probably responsible for the fact that polycystine assemblages off the Pacific coasts of Central America differ from the tropical-subtropical ones elsewhere (Fig. 2). In contrast to many open-ocean organisms, whose diversity has been reported to peak at intermediate latitudes (~15–30°N) and drop at the equator (e.g., Foraminifera, Tintinnina, Euphausiacea, and Copepoda), polycystine species numbers are tightly coupled with temperature throughout the entire thermal range of marine waters peaking at the equator (Fig. 3; Boltovskoy and Correa 2016b). In high-latitude assemblages, numerical dominance of a few species is very high, with 1–2 radiolarians often accounting for up to 90% of all the individuals (e.g., *Amphimelissa setosa* in the Atlantic sector of the Arctic and *Antarctissa denticulata-strelkovi* in the Southern Ocean). In warm waters, dominance is much less marked, the most abundant species normally accounting for <5% of the overall inventories in each sample. Throughout the World Ocean, occurrence and abundance of the species are highly correlated: radiolarians recorded in more samples also account for larger proportions of the taxocoenoses analyzed.

Phaeodarian biogeography is still very insufficiently known, but the scarce available evidences suggest that their world-wide patterns are less clearly associated with latitudinal climatic belts. This may be due to the fact that many phaeodarian species are deep-living forms, especially in warm water areas (Nakamura and Suzuki 2015; see below) that inhabit large areas where water temperature is more uniform (Fig. 4).

Vertical distribution. In tropical and subtropical waters polycystines are usually concentrated in the upper 50–100 m (Boltovskoy et al. 2010). Sometimes several discrete maxima are recorded, one at or near the surface and a second one between 50 and 100 m (Kling and Boltovskoy 1995) (Fig. 5). In polar waters, however, peak abundances seem to be associated with deeper and warmer layers, at around 200–400 m and overall polycystine abundances are much lower than in the tropics (Boltovskoy and Alder 1992; Nimmergut and Abelmann 2002; Petrushevskaya 1967) (Fig. 5).

The vertical ranges of most polycystines can be described by the following four patterns: (1) surface (with at least one peak above 100 m), (2) subsurface (around 100 m), (3) intermediate (between 100 and 300 m), and (4) deep (below 300 m) (Fig. 6) (Boltovskoy et al. 2010; Kling 1979; Kling and Boltovskoy 1995). However, worldwide depth zonations cannot be defined in terms of fixed depths because the distribution of radiolarian species is related to water masses which move vertically as well as horizontally. As a result, the same radiolarian species can occupy quite different depth intervals at different locations (Kling 1976). Many cold water radiolarians that

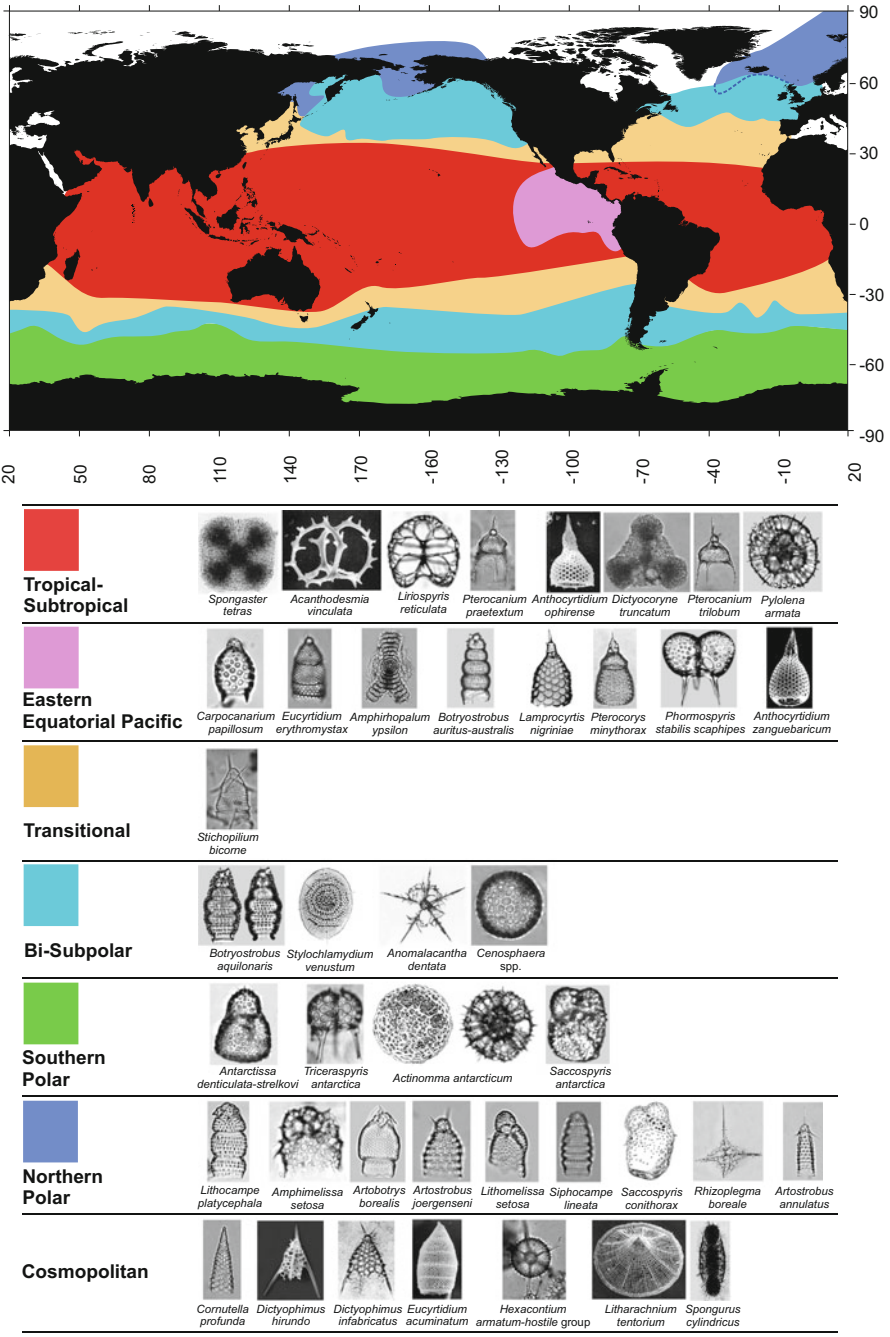

Fig. 2 Biogeographic regions of the World Ocean based on the distribution of polycystines in surface sediments and their most representative species (very few of these are restricted to the provinces indicated) (Simplified from Boltovskoy and Correa (2016a))

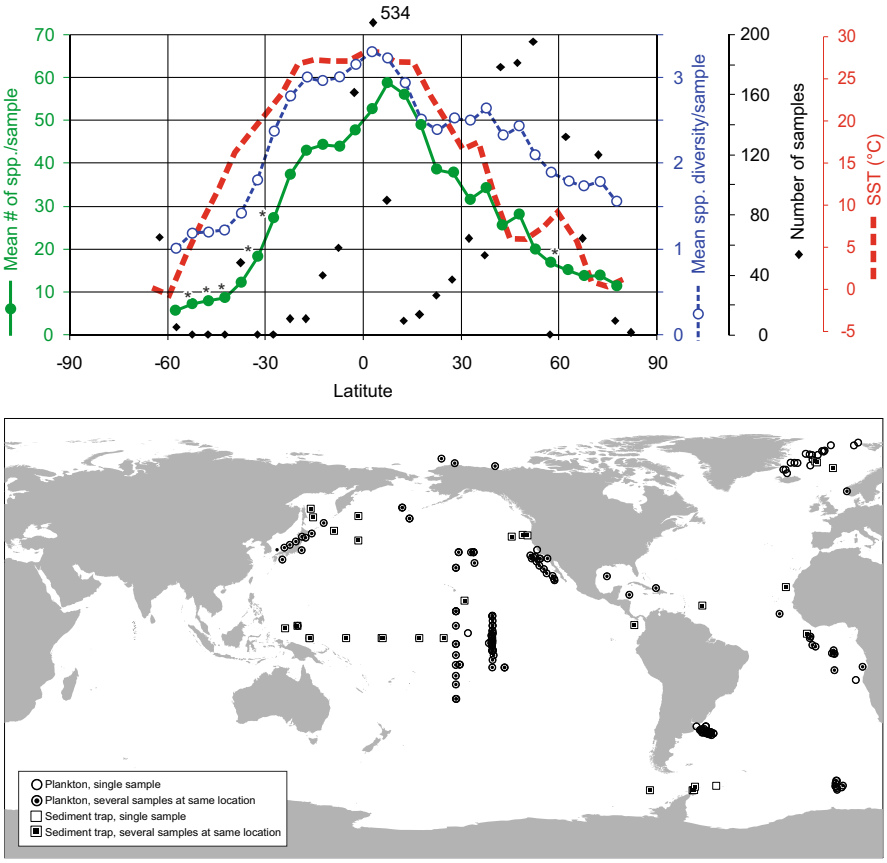

Fig. 3 Numbers of polycystine species, specific diversity (Shannon-Wiener log base 2), and sea surface temperature (SST) in the World Ocean as a function of latitude (pooled data for 5° intervals, 3-point running means, interpolated values are asterisked). Lower panel shows positions of the 2081 water column (plankton and sediment trap) samples used (*diamond symbols* in upper panel). Radiolarian data are based on compilation by Boltovskoy et al. (2010). Temperature curve is representative of mean SST values at the sampling sites involved only (rather than world-wide) (SST data are from Boyer et al. (2013))

inhabit the upper layers at high latitudes submerge with their corresponding water masses and can be found at depth in mid- and low-latitude areas (Boltovskoy 1988; Boltovskoy and Correa 2016b; Casey et al. 1982; Kling 1976).

Vertical changes in radiolarian diversity are more difficult to assess because the living (in situ populations) and dead individuals (i.e., settling shells exported from the upper strata) are seldom adequately differentiated in plankton collections. It is highly probable that protoplasm staining techniques, which are usually applied for these estimates, strongly overestimate the living depth ranges of the species because of the time it takes for the protists' protoplasm to decompose and disappear

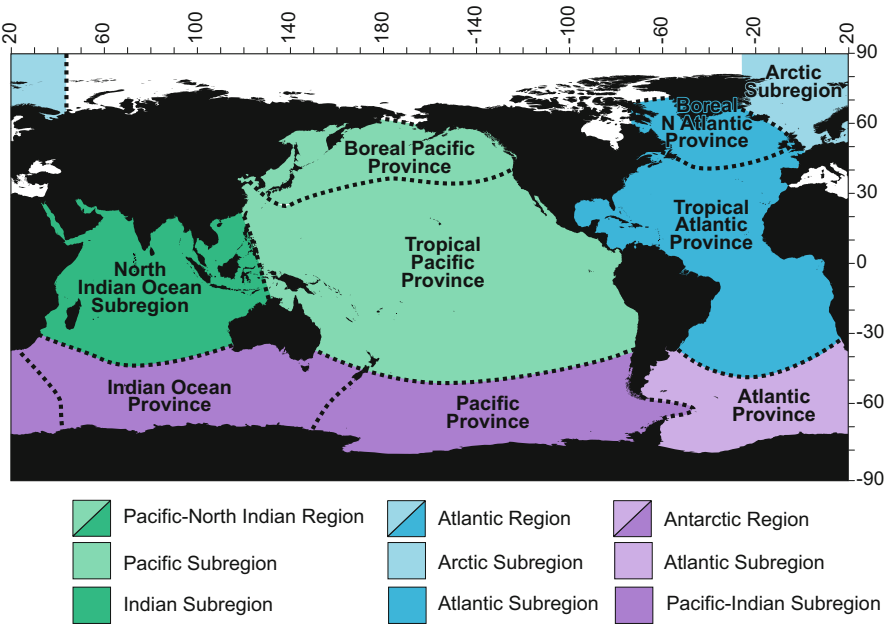

Fig. 4 Biogeographic zonation of the World Ocean based on deep-water Phaeodaria (Redrawn from Reshetnjak (1966))

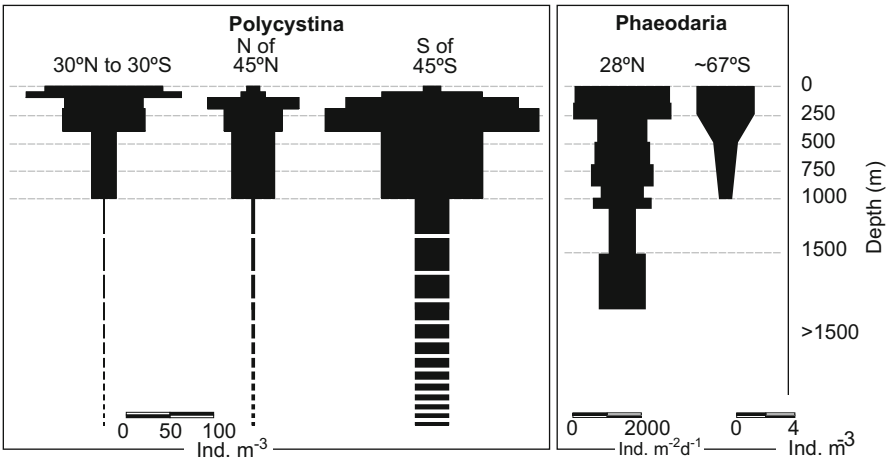

Fig. 5 Vertical profiles of radiolarian abundance in warm water and in cold water areas. Values for Polycystina are based on pooled data from 20 published surveys and our unpublished information from 1145 plankton samples. Values for Phaeodaria are from Gowing (1986) (28°N, North Pacific Central Gyre, sediment trap samples, living specimens only), and from Nothig and Gowing (1991) (Weddell Sea, plankton samples, phaeodarians >0.4 mm only). Notice differences in scales and units

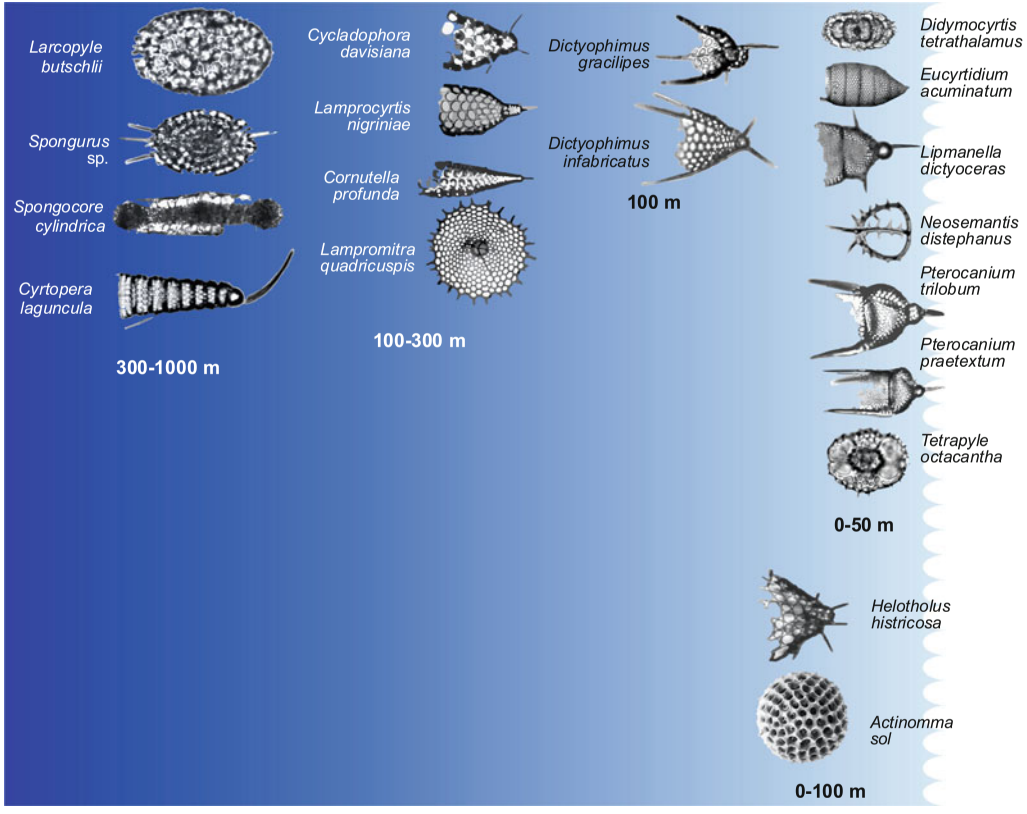

Fig. 6 Vertical distribution of polycystine species, as exemplified by some forms abundant in the northern subtropical Pacific (Based on data from Kling and Boltovskoy (1995))

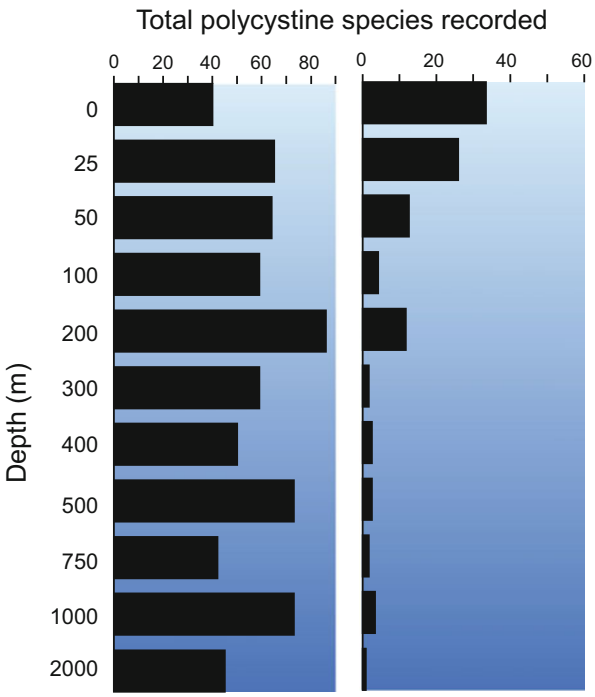

Fig. 7 Total number of polycystine species recorded per sample (*left*) and number of new species added to the inventory of the overlying waters (*right*) in a set of vertical plankton tows performed in the eastern subtropical Pacific. The absence of significant vertical diversity changes (*left panel*) is attributed to the presence at depth of dead, sedimenting skeletons of species whose living ranges are restricted to the upper layers (Adapted from Kling and Boltovskoy (1995))

(Bernhard 1988). The widespread occurrence of large numbers of healthy diatoms, dinoflagellates, and Cyanobacteria at depth >4000 m (Agusti et al. 2015) confirms the assumption that radiolarian sedimentation velocities are fast enough to yield large proportions of stained individuals well below their living depth range. Thus, raw data often show little species richness variation with depth (Fig. 7, left panel). On the other hand, when raw numbers are reinterpreted taking this artifact into account, highest diversities are clearly associated with the uppermost levels (Fig. 7, right panel).

Unlike most other sarcodines, phaeodarians are typically deep-water organisms usually peaking in both abundance and diversity below 200 m (Nakamura and Suzuki 2015), although high concentrations near the surface are not uncommon (Fig. 5). A detailed depth zonation for the area of the Kurile-Kamchatka trench was produced by Reshetnjak (1955, 1966). She concluded that only two (of the 103 species recorded) inhabit the upper 50 m; approximately 30 more have restricted vertical ranges at various depths, while over 50% of the taxa were retrieved from the broad depth interval of 50 to 2000–8000 m. These vertical patterns at a given locale, however, may change significantly because of the dynamics of deep ocean circulation, with species exhibiting quite variable depth ranges over oceanic distances. Vertical profiles in the North Pacific (Kling 1966, 1976) illustrate that species dwelling in near surface water (25 m depth) at high latitudes, are distributed gradually toward lower depths in decreasing latitudes, and dwell at depths

>300 m closer to the equator. Thus, as with the polycystines, depth distributions of phaeodarians on regional scales are not describable in terms of fixed ranges.

Equatorward submergence may account for so-called bipolar distributional patterns characteristic of many radiolarians. High-latitude species could pass under equatorial waters via the Intermediate Water or the Deep Water, to reappear near the surface in the opposite polar or subpolar seas where the adequately colder water temperatures support their growth (Aita et al. 2009; Stepanjants et al. 2006). In the Pacific Ocean, the Intermediate Water circulates in anti-cyclonic gyres that mimic the surface circulation (Reid 1965), thus providing continuity for the water masses and their biological contents. Such bipolar patterns have been described for a number of zooplanktonic species in both the Atlantic (Darling et al. 2000; Pierrot-Bults 1974) and the Pacific Ocean (Alvariño 1965), whereby the north and south polar or subpolar near-surface populations are joined at depths of 800–1000 m across the equator. The fact that these apparently disjoint populations interbreed through their deep-water, tropical and subtropical representatives has been suggested for some protists (Darling et al. 2000).

Radiolarian studies based on sedimentary materials. Because their skeletons preserve in the geological record, studies of extant polycystines have been chiefly based on sedimentary – rather than on planktonic – samples (phaeodarian skeletons very seldom preserve in the sediments). Sediment samples present some advantages but also several important shortcomings (Fig. 8) (Boltovskoy 1994). Whereas polycystine abundances seldom exceed 5 cells per liter in the plankton (Caron and Swanberg 1990), one gram of surface sediments can contain thousands to hundreds of thousands of radiolarian skeletons. Plankton samples yield a snapshot-type image of the composition of the assemblages, which does not necessarily adequately reflect long-term trends. The daily, seasonal, and interannual variability involved is

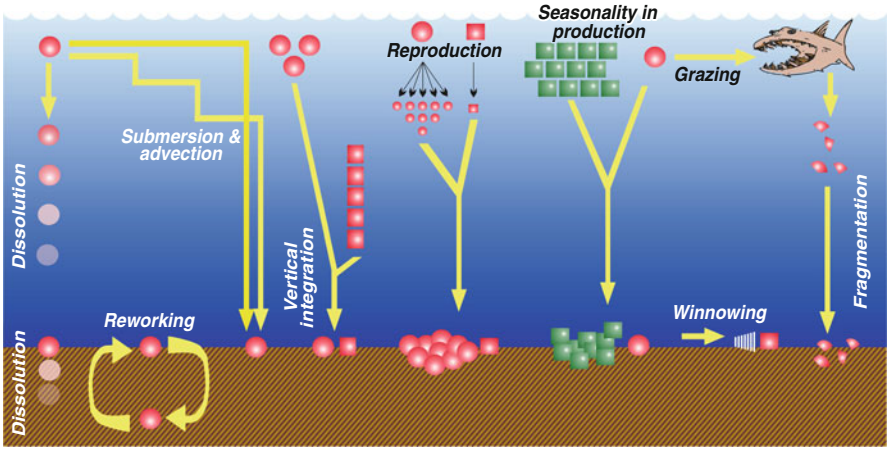

Fig. 8 Schematic diagram of the mechanisms that can distort the sedimentary imprint of the planktonic pattern of fossilizable microplankton in general, and of polycystine radiolarians in particular

smoothed out in the sedimentary record, which may be a welcome trait when general patterns are sought. Further, sedimentary materials are more readily available from the various repositories around the globe than plankton samples. On the other hand, interpretation of the geographic distribution of extant radiolarians on the basis of sediment samples presents several important drawbacks. On their way to the sea-floor and after settling, radiolarian remains dissolve and are grazed upon by various consumers thus breaking their skeletons into unidentifiable fragments. Because more delicate shells are destroyed more readily than the more robust ones, specific skeletal compositions on the bottom and at mid-depths can differ significantly from the living assemblage in the upper water-column. Bottom materials can be reworked after deposition (as a result of which non-Recent deposits, sometimes characteristic of quite dissimilar oceanographic settings, are brought up to the surface layer, or winnowed by bottom currents dislodging settled skeletons and carrying them thousands of kilometers away). Sediments integrate the imprint of near-surface faunas (which are generally associated with surficial environmental traits, as well as with currents and water masses), with the meso- and bathypelagic species whose geographic distribution is uncoupled with upper-water oceanography. The sedimentary distributions of cold-water species tend to show conspicuous equatorward extensions as compared with their planktonic patterns. This distortion is most probably due to the fact that extended survival of the cold water taxa that are expatriated towards lower latitudes is facilitated by submersion (Boltovskoy 1988, 1994; Boltovskoy and Correa 2016a); as a consequence, sediment-derived species-specific ranges may wrongly suggest an enhanced tolerance to gradients in the ecological factors.

Characterization and Recognition

Cell Ultrastructure

Cellular Organization. In broad view, three categories of pseudopod-producing protoctista (including amoebae, Foraminifera and Radiolaria) have been described based on cellular ultrastructure (Anderson 1983): (1) Diffuse, e.g., the naked amoebae without enclosing shells or thecae and a flowing, changeable cell shape, (2) Transitional, including the testate amoebae and foraminifera with a surrounding theca or shell that demarcates a more condensed cytoplasm internally from the web-like, pseudopodial array externally, and (3) Zonal, exemplified by the polycystine Radiolaria with a distinctive porous capsule wall that separates the central, sometimes lobate, intracapsular cytoplasm from the outer, extracapsular, layer of cytoplasm where prey is captured and digested. Interestingly, the Phaeodaria are categorized as transitional since they have a "capsule" with at least one large opening through which the endoplasm protrudes into the ectoplasm, similar to that of testate amoebae. Molecular genetic evidence indicates that Phaeodaria are closely related to testate amoebae within the group Cercozoa (Yuasa et al. 2006) (see below). The

chemical composition of the siliceous skeleton and the test-like capsular wall of Phaeodaria also are similar to that of testate amoebae.

Polycystine Radiolaria. The polycystine Radiolaria include the Spumellaria and Nassellaria (See Systematics). The Spumellaria have a spherical body plan with a centrally located nucleus surrounded by radially arranged lobes of cytoplasm, enclosed by a porous capsular wall (Figs. 1 and 9a, b), (Anderson 1980, 1983; Hollande et al. 1971). Axopodia emanate through pores (fusules) in the capsular wall and protrude radially (Cachon and Cachon 1976a, b). The axopodia support a web-like network of cytoplasmic strands that are sticky and aid in the capture of prey. The external cytoplasm encloses or coats the siliceous skeleton, when present. The Nassellaria have a monoaxial body plan (Anderson 1977), typically an elongated, ovoid, central capsule with a porous plate at the base where the axopodia emerge through closely spaced fusules (Fig. 9c, d). Shafts of microtubules in the axopodia emerge from a conical array of microtubules (podoconus) within the intracapsular cytoplasm (arrow, Fig. 10). Skeletons vary from simple tripods to elaborate, helmet-shaped structures, often with spines or other ornamentation (e.g., Figs. 9c, d and 11). The extracapsular cytoplasm coats the siliceous skeleton, when present, and extends outward as a halo of axopodia and their associated network of rhizopodia, including fine, tapered extensions known as filopodia that are present in Nassellaria and Spumellaria (Fig. 1). In polycystines, digested prey products are transported in small vesicles through the fusules into the intracapsular cytoplasm (Anderson 1977).

Phaeodaria. The ultrastructure of Phaeodaria is distinctly different from the polycystines. The "capsular wall" surrounding the denser endoplasm lacks fusules. There is one large opening (astropyle) containing an emergent massive strand of cytoplasm and two smaller openings (parapylae) with finer strands of cytoplasm (Fig. 9e, f). A large, often darkly colored, mass of partially digested food (phaeodium) is typically located external to the capsule near the astropyle (Figs. 1 and 9e). The continuous, massive strand of cytoplasm in the astropyle provides a pathway for digested prey matter to be carried into the endoplasm as occurs with some testate amoebae and foraminifera (Anderson 1983; Swanberg et al. 1986).

The Skeleton

The skeleton of polycystine Radiolaria, when present, is composed of amorphous silica and is deposited outside of the cytoplasm, but within an enclosing cytoplasmic sheath called the cytokalymma (Anderson 1983). The cytokalymma is a dynamic, living sheath that molds the shape of the silica deposited within it as silicification takes place during skeletal growth. Thus, the species-specific shape of the skeleton is determined by cellular dynamics and undoubtedly is under genetic control. Skeletal morphology is remarkably diverse (Anderson et al. 2000), but species specific.

The two major divisions of the Polycystinea, Spumellaria and Nassellaria, differ in the symmetry of their skeletons. Most spumellarians have a radial or spherical

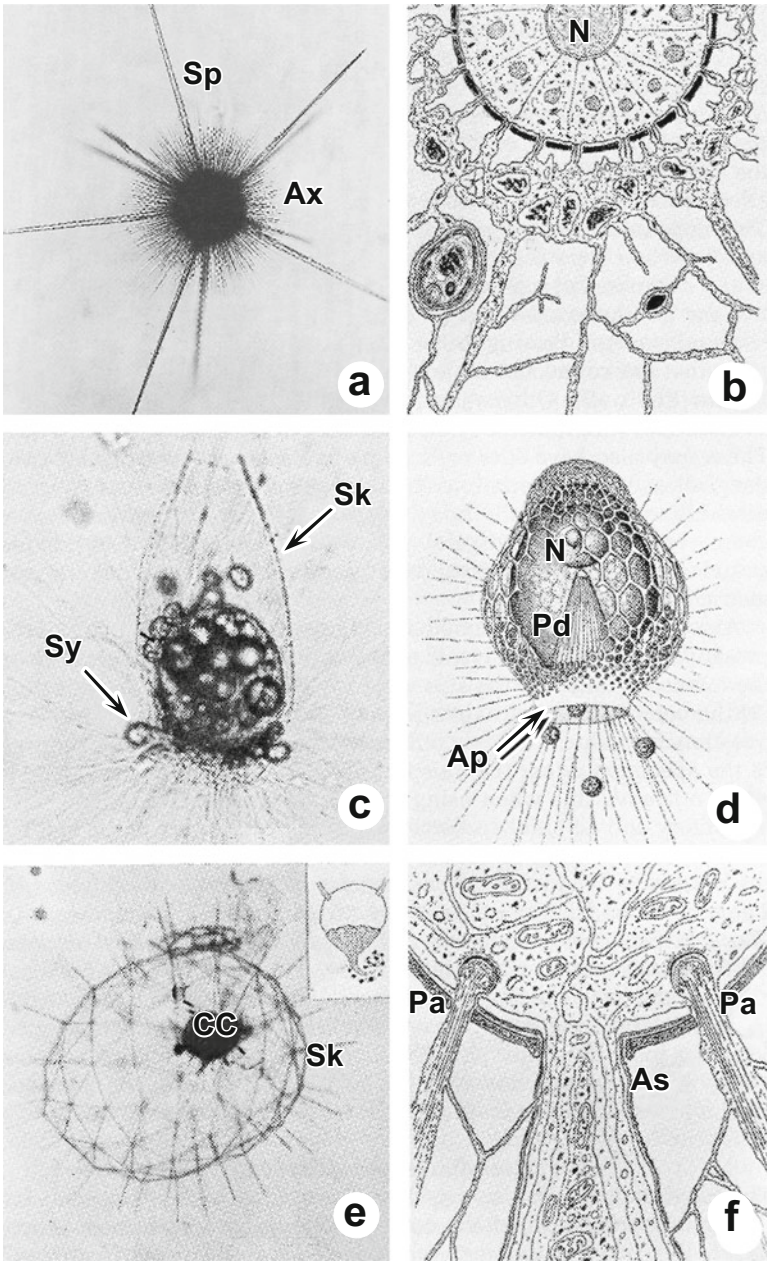

Fig. 9 Comparative morphology and cellular organization of Spumellaria (**a**, **b**), Nassellaria (**c**, **d**), and Phaeodaria (**e**, **f**). (**a**) A living spumellarian with radiating siliceous spines (Sp) and a halo of axopodia (Ax) surrounding the cell. (**b**) A diagram of the cellular organization of a spumellarian showing the centrally located nucleus (N) surrounded by radial lobes of cytoplasm that extend as cytoplasmic strands through pores (fusules) in the dense capsular wall and produce an extracapsular

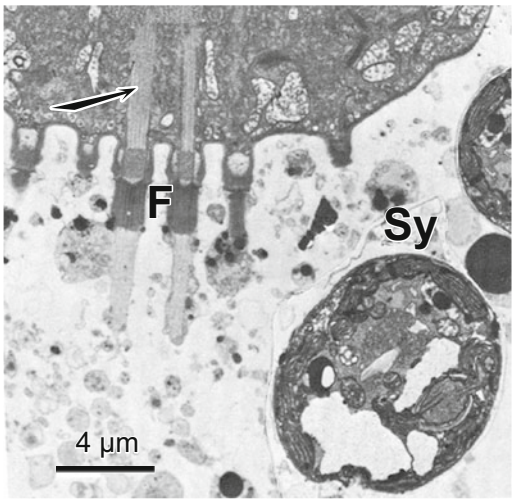

Fig. 10 A transmission electron micrograph of the lower portion of a Nassellarian central capsule showing the shafts of microtubules in the conical podoconus (*Arrow*) that extend from the intracapsular cytoplasm through the pore-like fusules (F) in the capsular wall and protrude outward as axopodia surrounding the cell. Algal symbionts (Sy) are scattered in the peripheral axopodial array (Adapted from Anderson (1983))

symmetry, whereas in nassellarians the body plan usually includes an anteroposterior axis. Figure 11 shows a characteristic, spherical spumellarian whose skeleton comprises several concentric shells. Growth in spumellarians starts with the first, innermost shell and proceeds centrifugally. Nassellarian shells often comprise several sections aligned along an axis. Shell growth starts with the inner, often tripodal, skeleton located inside the first section, or cephalis, and proceeds along the axis to form the thorax, the abdomen, and the postabdominal segments (when present). The wealth of skeletal shapes and morphologies is, however, very ample, including simple spines arranged as a tripod, porous, helmet-shaped skeletons, porous spherical shells, single or multiple concentric geodesic shells composed of rod-like elements joined at nodes in a framework (with or without radially arranged spines), spongiose shells of varied shapes ranging from flattened discs to spheres, and a myriad of other forms, some with ideal geometric shapes (e.g., regular icosahedrons,

Fig. 9 (continued) layer of cytoplasm within a network of rhizopodia. (**c**) A living small nassellarian showing the siliceous skeleton (Sk) forming a conical porous shell (cephalis) surrounding the ovate central capsule. Algal symbionts (Sy) are distributed within the extracapsular rhizopodial network. (**d**) A diagram of the nassellarian cephalis, and a cut-away view of the central capsule showing the nucleus (N) and conical array of microtubules, forming the podoconus (Pd), that extend out of the central capsule as axopodia through the aperture (Ap) at the base of the cephalis. See also Fig. 9. (**e**) A living phaeodarian showing the geodesic siliceous skeletal framework (Sk) surrounding a network of rhizopodia that emerge from a dense central capsule (CC) and the morphology of the central capsule (inset) with a major cytoplasmic strand (astropyle) emerging at the base and two smaller cytoplasmic strands (parapylae) emerging at the opposite pole. (**f**) A diagram of a section of the base of a phaeodarian central capsule showing the emergence of the massive astropyle (As) and smaller parapylae (Pa) projecting outward through openings in the capsular wall (Adapted from Anderson (1983) and J. Cachon et al. (1990))

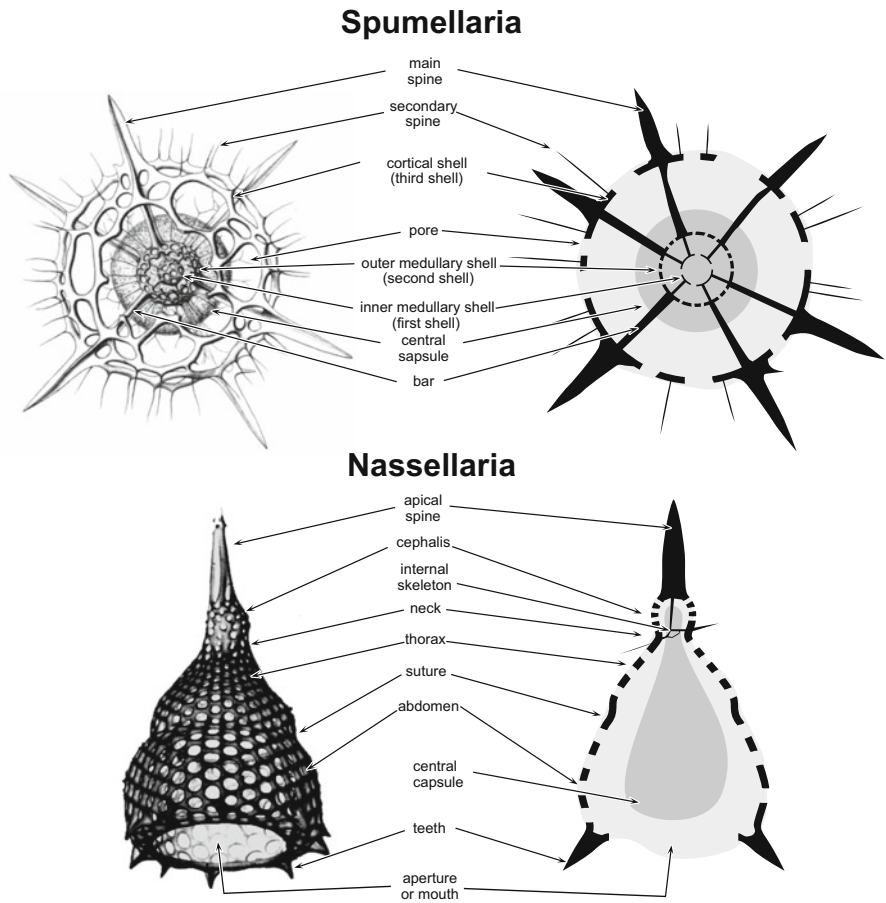

Fig. 11 Scheme of the skeletal elements of the shell of a typical Spumellaria and Nassellaria (Adapted from Boltovskoy and Correa (2014))

dodecahedrons, and octahedrons; Fig. 12) not found in any other living organism (Afanasieva 2006, 2007; Anderson 1983).

The skeleton of Phaeodaria is also composed of amorphous silica but may contain more organic matter than polycystines. The skeletal framework in some species is composed of hollow tubes (e.g., Fig. 9e), not solid rods as in the polycystines. Other species of Phaeodaria have ornate spicules scattered in the external cytoplasm or shells that are either bivalved, resembling small clams or vase-like to pouch-shaped with ornate protuberances around the opening (Fig. 13). Other species have only much branched antler-like spines protruding from a central shell (Fig. 13) (Takahashi and Anderson 2000). However, overall, porous microstructures and basic tubular ultrastructures appear to be common in most of the taxa examined in plankton and sedimentary trap samples from several open ocean locations (Takahashi and Hurd 2007).

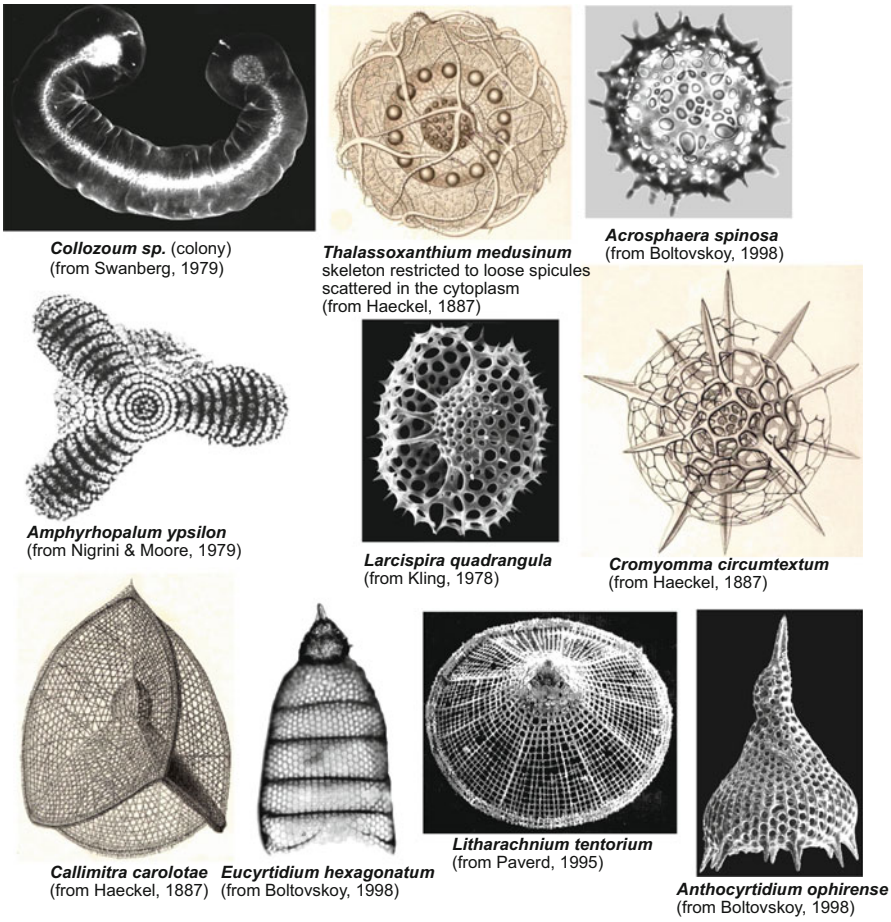

Fig. 12 Representative examples of polycystine species (figures are not to scale)

Feeding, Symbionts, Necrotrophs, and Predators

Feeding. Considerably more is known about the feeding behavior of polycystine Radiolaria compared to Phaeodaria, although our knowledge is still rather limited. Polycystines consume a wide variety of prey including bacteria, algae, protozoa, and microinvertebrates such as copepods and small larvae of marine arthropods. In a rather extensive study of prey observed in SCUBA-collected radiolaria from epipelagic plankton, Swanberg and Caron (1991) noted that a relatively small proportion of captured radiolaria possessed prey (46%), but there was a wide variety of prey consumed including diatoms, tintinnids, and more frequently copepods and their nauplii, or mollusc larvae. Smaller radiolarian species prey largely on bacteria and algae, whereas larger radiolaria also consume small invertebrates (Anderson 1983, 1996; Caron and Swanberg 1990).

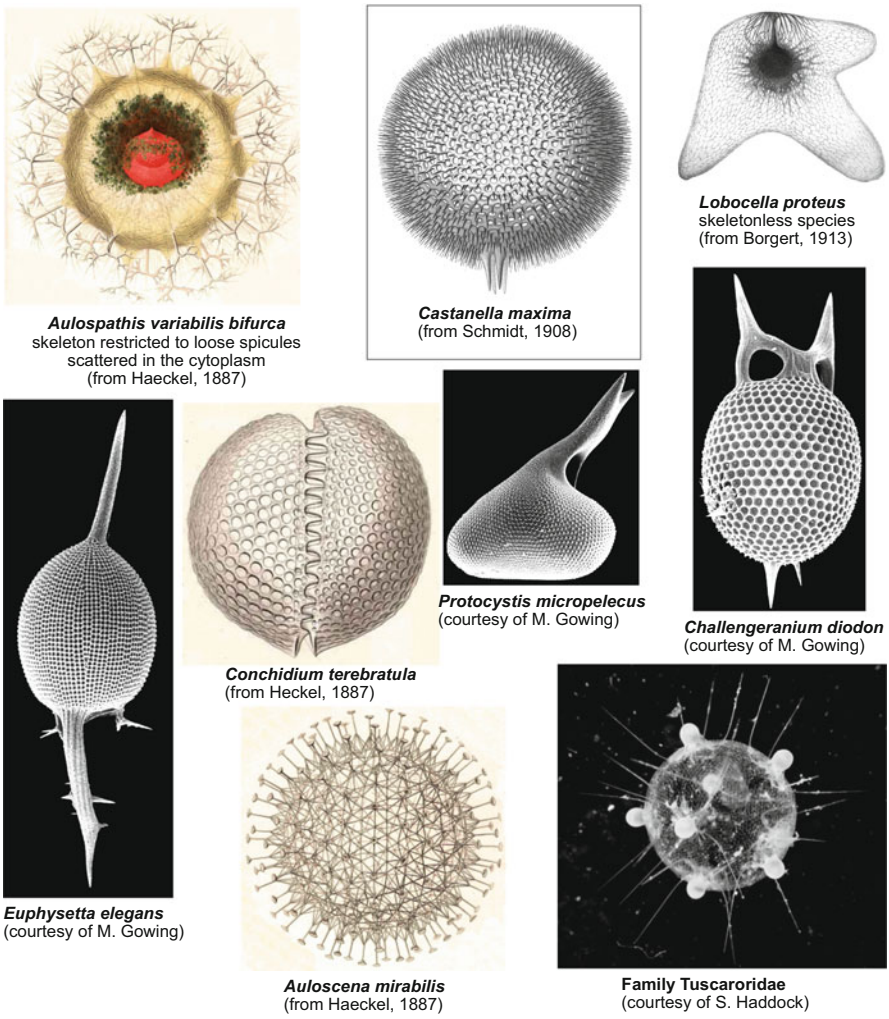

Fig. 13 Representative examples of phaeodarian species (figures are not to scale)

The algal and protozoan prey become snared on the sticky surface of the axopodial array and is engulfed by invagination of the surface membrane to form an intracytoplasmic food vacuole. The food vacuole is converted to a digestive vacuole by secretion of digestive enzymes (Anderson 1996). A much more elaborate mechanism of predation occurs when small arthropods, such as copepods, are consumed (Anderson 1978). The prey becomes entangled within the axopodia and associated rhizopodial network. Eventually, it is surrounded by the rhizopodia that penetrate through weak zones of the prey exoskeleton. Once inside of the host body, the rhizopodia engulf large segments of prey tissue, enclosing them within digestive vacuoles that are carried by cytoplasmic streaming out of the host into the radiolarian

cytoplasm near the central capsule. Small vesicles containing the digestive products are transported through the fusules into the intracapsular cytoplasm where food reserves are stored and major metabolic activities take place. Vacuoles containing undigested, waste material are eventually ejected from the axopodial array by cytoplasmic streaming (Anderson 1983). Among the limited evidence of phaeodarian predation, Swanberg et al. (1986) reported that a mesopelagic, coelographic phaeodarian contained microflagellate and metazoan prey. Copepods and salps also were snared when introduced in the laboratory cultures.

Symbionts. A wide variety of symbionts are sequestered within vacuoles (symbiosomes) including algae and photosynthetic cyanobacteria (Bråte et al. 2012; Probert et al. 2014; Yuasa et al. 2012). Algal symbionts include dinoflagellates (golden yellow), prasinophytes (yellow green), and prymnesiophytes (tawny brown) (Anderson 1978; M. Cachon and Caram 1979; Hollande and Carré 1974). Algal symbionts are highly productive photosynthetically, fixing more carbon than primary producers in an equivalent volume of the surrounding seawater of the Sargasso Sea (Caron et al. 1995). A similar assessment was reported in earlier studies by Khmeleva (1967) in the Red Sea and Gulf of Aden. The symbionts associated with radiolaria, however, account for only a small fraction of the total primary production of the entire water column in the Sargasso Sea studies. The symbionts may provide substantial nourishment to the host. Cytochemical and ^{14}C isotopic tracer studies have shown that the symbionts release organic nutrients that are assimilated by the host and that the host occasionally digests some of them by secretion of enzymes within the normally benign symbiosome vacuoles (Anderson 1983).

Necrotrophs. Dinoflagellate necrotrophs (e.g., *Meriodinium brandti*) infect some species of spumellaria, including colonial radiolaria. *M. brandti* invades the nucleus where it forms a plasmodium (Anderson 1983; Hollande 1974 ; Hollande and Enjumet 1953). Eventually, the *Meriodinium* nuclei divide profusely leading to necrosis of the radiolarian nucleus. The parasite nuclei become segregated from the plasmodial mass to form swarmers with undulipodia and typical dinoflagellate morphology including an epicone and hypocone. They escape from the host to initiate another infective cycle. In other species of *Meriodinium*, the initial proliferation in the nucleus is followed by release of plasmodial fragments that invade the intracapsular cytoplasm and eventually release motile infective swarmers with characteristic dinoflagellate features. The large, skeletonless radiolarian, *Thalassicolla* sp., is parasitized by *Solenodinium fallax*. This dinoflagellate invades the nucleus, forms a plasmodium, and produces tubular inclusions that subsequently emerge from the disintegrating nucleus and protrude into the surrounding intracapsular cytoplasm. The tubules eventually give rise to numerous infective swarmers with typical dinoflagellate morphology. Necrotrophs also have been reported in Phaeodaria, including *Syndinium nucleophaga* (Cachon-Enjumet 1961; Hovasse 1923).

Predators. Our knowledge of radiolarian predators is very limited, but based on digestive tract samples from diverse geographic locations, radiolaria have been detected in tunicates (e.g., salps), crustacea such as copepods, euphausids, and in certain penaeidae, among others. There is some evidence that planktonic

foraminifera prey occasionally on radiolaria. Amphipods have been reported invading and ingesting cells of colonial radiolaria (Swanberg 1979). However, much more detailed analyses of the digestive tract contents of freshly collected predators is needed to verify predatory pressures on radiolaria.

Reproduction, Growth and Longevity

Reproduction. Reproduction in Polycystinea and Phaeodaria has been observed in laboratory cultures. Collodarian Radiolaria (e.g., some colonial Radiolaria) reproduce by binary fission of the central capsules. Sexual reproduction of Polycystinea or Phaeodaria has not been confirmed, but numerous instances of the release of motile swarmers, likely gametes, bearing two undulipodia have been documented (Anderson 1983; Kimoto et al. 2011). Among polycystines, impending reproduction is signaled by contraction of the extracapsular cytoplasm and jettisoning of symbionts and waste matter. The nucleus undergoes repeated division, eventually filling the intracapsular cytoplasm. Each nucleus becomes segregated from the cytoplasmic mass as swarmers that escape through ruptures in the capsule wall. The fate of the swarmers is unknown. Syngamy (swarmer fusion) has not been observed (Anderson 1983; Cachon et al. 1973). Each swarmer contains a vacuolar-bound strontium sulfate (celestite) crystal (Anderson 1983; Hollande and Martoja 1974) enclosed by an organic envelope that appears to control the ultimate shape of the crystal (Anderson et al. 1990). In the phaeodarian *Coelodendrum ramosissimum*, reproduction begins with the disappearance of the phaeodium, followed by degeneration of the capsule and the appearance of small plasmodial spheres in the ectoplasm. Each of the spheres produces hundreds of polynucleated amoeboids that eventually form swarmers with two undulipodia (Borgert 1900, 1909; Cachon-Enjumet 1964).

Growth and Longevity. During the course of maturation, some skeletal-bearing species exhibit a "stair-step" pattern of growth, undergoing one to several days of silica deposition and increase in size followed by plateaus for several days before the next growth phase (Anderson et al. 1989). However, no predictable periodicity of silica deposition has been observed within a given species, and the stair-step curves are highly variable. Further research is needed to document patterns of growth among a wide variety of polycystines. Among the Polycystinea, two processes of skeletal growth and maturation appear to account for all examples of skeletal morphology: (1) Rim growth, commonly found in porous shells, with round to nearly round pores. The pores are formed by deposition of silica on the rims of larger pores that become increasingly smaller in diameter during maturation. (2) Bridge growth, producing geodesic frameworks and latticed shells that are formed by repeated production of rod like elements that grow from one node to another across an opening in the framework, thus producing a skeleton with increasingly more complex design, and in some cases increasingly smaller openings (Anderson 1983). Species with concentric spherical shells construct the innermost, small, primary shell first, typically by bridge growth. Spines elongate from the primary shell and provide scaffolding for the construction of successive larger

surrounding shells, also by bridge growth. Some spongiose skeletal species deposit a small spherical, porous shell initially, followed by very fine bridge growth producing a surrounding meshwork of silica with the characteristic morphology of the species. The skeleton provides protection for the delicate cytoplasmic structures and also supports the axopodia and network of pseudopodial strands radiating from the central cell body, thus permitting efficient capture of prey, including invertebrates such as copepods that may be larger than the radiolarian (Anderson 1978).

Our knowledge of the longevity of radiolaria is limited. Evidence from laboratory maintenance cultures of radiolaria, and inferential data based on environmental observations of the periodic appearance of juvenile and adult stages of radiolarian species, indicates that they live for several weeks to several months before reproducing. Additional research is needed on comparative analyses of life spans of different species and also on the effects of environmental variables on longevity, such as abundance of prey, temperature, and other seasonal and biogeographic factors (Anderson 1983; Casey et al. 1970).

Systematics

Polycystinea. Haeckel (1887) produced one of the earliest comprehensive systems of radiolarian classification describing over 3000 polycystine species, ~2400 of which were new to science. Haeckel's work is still a necessary reference guide, but it does not satisfactorily represent natural relationships because groupings are only based on morphologic similarities, and because the rigidity of these geometry-based diagnoses often ignores the ample intraspecific variability of the radiolarians (Lazarus et al. 2015). Efforts to improve upon the classification schemes inherited from earlier workers have mainly followed two different approaches: cytological data and evolutionary studies. Several authors (Cachon and Cachon 1972a, b; Hollande and Enjumet 1960; Petrushevskaya 1981; Petrushevskaya et al. 1976) proposed revisions which rely heavily on cytoplasmic features, in particular the "nucleoaxopodial complex" (Petrushevskaya 1981). Although these schemes are probably sounder in biological terms, their application to fossil and subfossil materials lacking the protoplasm is problematic, which is one of the reasons for their very limited acceptance among radiolarian workers. Analyses of evolutionary lineages in geological sequences were used as a basis to assess the taxonomic value of key skeletal traits; it was concluded that many of them (e.g., number of segments, number of supplementary concentric spheres, number of feet, number of rays and of equatorial spines in discoidal Spumellaria, and presence and nature of thoracic wings) have little or no suprageneric value. In contrast, several others (especially cephalic structure, but also pore arrangement, shell terminations in Nassellaria, etc.), traditionally considered as of minor value, are conservative through time, reveal evolutionary lineages and, therefore, are relevant for higher-rank divisions (Riedel and Sanfilippo 1986). These results are at least partly in disagreement with the conclusions of the major review by De Wever et al. (2001), who based their classification scheme on the notion that "the farther the skeletal elements are from the first shell, or

initial skeleton, the less important they are for higher level systematics." Riedel (1967, 1971); Petrushevskaya (1971a); (Petrushevskaya 1986); Goll (1968); (Goll 1969); Sanfilippo and Riedel (1970); Dumitrica (1989); De Wever et al. (2001) based on skeletal features alone worked out alternative classifications, either for the entire group or for selected parts of it. Of these, Riedel's (1967, 1971) suprageneric system has become the most widely accepted for extant and Cenozoic radiolarians and is the one adopted herewith with slight modifications. Classification of pre-Cenozoic polycystines follows De Wever et al. (2001).

Phaeodaria. The classification of this group proposed by Haeckel (1862, 1887) has been used by subsequent students with but minor additions. Generic assignments have been followed with few modifications, with the exception of some occasional revisions (Korsun 2011; Nakamura et al. 2015; Nakamura and Suzuki 2015; Reshetnjak 1966), but inconsistent usage (particularly among the family Challengeridae) persists into modern times (Kling and Boltovskoy 1999). The morphology of each family is so distinctive that there has been essentially no controversy as to their taxonomic identity, although lack of discrepancy is probably more a reflection of reduced interest and absence of new research, than of the quality of the information available.

Outline Classification

The classification outlined below incorporates the major higher-order categories defined on the basis of molecular phylogenetic studies, particularly the results of Adl et al. (2012). The classification outline proposed by these authors deliberately omits formal taxonomic categories; for the sake of clarity, we have included them (in parentheses, after the taxon name), as used in traditional classification systems. Adl's divisions within Polycystinea and Phaeodaria are practically identical to those of traditional taxonomy, which seems to be justified by the very scarce information available so far (Ishitani et al. 2012a, b). On the other hand, molecular results obtained with other planktonic protists (e.g., Foraminifera) (Darling and Wade 2008; De Vargas et al. 2004; Seears et al. 2012) suggest that many existing morphospecies include several genetically different organisms with more or less distinct distributional patterns. The few data on Polycystinea published in the last years support this assumption, suggesting that taxonomic assignments based on morphologic features often conflict with genetic molecular studies (Biard et al. 2015; Sierra et al. 2013) and that genetically defined units can differ both morphologically and distributionally (Ishitani et al. 2012b, 2014). It should be stressed that these results do not necessarily imply that traditional, morphological classifications are wrong and those based on molecular data are correct. While molecular studies are undoubtedly a very powerful tool for evolutionary and taxonomic investigations, as any other technique they have important limitations (Decelle et al. 2014). Among other limitations, the use of a single gene to decipher phylogenetic relationships may bias the results, and use of more than one gene often improves the analyses. However, the usefulness of molecular analyses as an additional tool is beyond doubt, not only for addressing taxonomic and phylogenetic issues, including conflicting identifications based on skeletal features (Yuasa et al. 2009), but also for addressing distributional, evolutionary and ecologic problems.

Rhizaria
Cercozoa
Thecofilosea
Phaeodaria (=Tripylea) (Superorder) Siliceous skeleton, when present, may consist of scattered spicules or a well-developed meshwork, but skeletal rods are usually hollow and skeletal material is provided with an organic matrix. Skeletons rarely preserve in sediments. The central capsule normally with one large and two smaller pores. Around 400–500 extant species.
Phaeoconchia (Order) Skeleton formed by two symmetrical valves that can be large and conspicuous (family Concharidae) or small, internal, surrounded by an elaborate meshwork of tubes and spines (family Coelodendridae) (living representatives only, two families).
Phaeocystina (Order) Skeleton absent or formed by loose elements around the central capsule (living representatives only, four families).
Phaeogromia (Order) Skeleton, when present, represented by a globular or ovoidal solid structure with one large opening, often with one or more large radial spines. Very heterogeneous group (a few shelled forms known since the Eocene, 8 families).
Phaeosphaeria (Order) Skeleton usually represented by a large sphere with triangular meshes (living representatives only, 3 families).
Retaria
Acantharia (Subclass)
Polycystinea (Subclass/Superorder) Usually endowed with a siliceous skeleton with solid bars. Cytoplasm divided into two regions: an inner endoplasm and an outer ectoplasm or calymma, separated by a perforated organic membrane, the central capsule. Probably around 400–800 extant species and several thousands of fossil forms.
Collodaria (Order) Solitary or colonial polycystines without a siliceous skeleton or provided with simple or branched spicules scattered in the calymma. (Eocene?-Holocene, four families, all with extant representatives).
Spumellaria (Order) Solitary or colonial (one family only: Collosphaeridae). Shell well developed, with radial symmetry or one derived from it (spiral, discoidal or lenticular biconvex, triaxonic, quadrangular, etc.) or asymmetric. Central capsule with many small pores (Paleozoic-Holocene, 37 families, eight with extant representatives).
Nassellaria (Order) Solitary. Shell represented by several fused spicules only, by a D-shaped ring and associated spines, or by more elaborate mono- or multilocular latticed skeletons. The symmetry of the shell is characterized by the fact that the two extremes of its major axis define two morphologically different poles (Devonian- Holocene, 54 families, seven with extant representatives).
Archaeospicularia, **Albaillellaria**, **Latenfistularia**, **Entactiniaria** (Orders) Fossil polycystines (Cambrian-Triassic, 37 families).

Evolutionary History

Polycystines possess some exceptional traits for their use in evolutionary studies: they appear very early – in the Lower Cambrian (Nazarov 1973; Obut and Iwata 2000), they preserve well in the geological record, they are highly diversified, and they are often very abundant. However, their potential is seriously hindered by the generally poor state of their taxonomy, which affects not only the species concept but also the definition of supraspecific categories and the taxonomic and evolutionary value of most morphologic traits. Thus, with the exception of a few well-researched Cenozoic lineages, our understanding of the evolution of the polycystines is still in an embryonic stage. Modern molecular phylogenetic research, in addition to clarifying the taxonomy of polycystines, has provided additional sources of evidence to trace their origins and divergences during the evolution of this group in relation to other taxa in the tree of life (Ishitani et al. 2012a; Sierra et al. 2013).

Although some authors have presented debatable evidence of links with benthic ancestors (Petrushevskaya 1986), the origin of radiolarians is uncertain. Until the Permian, their diversification was moderate, but in the Triassic, many new families appeared and from there on the number of extinctions was roughly balanced with that of new forms. For the Paleozoic, over 600 polycystine species (80 genera) have been described, suggesting a speciation rate of about 1–2 species per million years (Vishnevskaya and Kostyuchenko 2000). For the Mesozoic, this rate soars to over 10 species per million years; the total number of Mesozoic species described is around 2500 (Vishnevskaya and Kostyuchenko 2000), including the first multisegmented nassellarians, the appearance of twisted spines in spumellarians, etc. In agreement with most other organisms, polycystines show a strong diversity drop around the Cretaceous-Tertiary boundary, recovering in the Eocene (Sanfilippo et al. 1985; Vishnevskaya and Agarkov 1998). In the Cenozoic, the number of polycystine species varies around 400–800. The skeletons of these species are conspicuously lighter than those of most pre-Cenozoic forms, presumably due to the competition for dissolved silica with the diatoms (Lazarus et al. 2009). The longevity of most Cenozoic species ranges around 1–5 Ma (before going extinct or changing sufficiently to be identified as a different species) (Sanfilippo et al. 1985). Thus, despite the fact that polycystines represent potentially useful evolutionary and stratigraphic tools, taxonomic inconsistencies and the scarcity of specialists hinder their extensive use in these fields.

Maintenance and Cultivation

Continuous, reproducing cultures of radiolaria have not been established in the laboratory, probably due to the particular environmental requirements of the earliest growth stages. However, juvenile radiolaria that are collected by gentle drift tows using nets, or captured in hand-held small jars by SCUBA divers, can be maintained in laboratory culture (Anderson 1992). Individual radiolaria are retrieved from the sample using pipettes fitted with a rubber bulb and a tip with a large opening. The

radiolarian is gently deposited in glass culture dishes or small vials containing seawater, freshly collected from the sampling site. Symbiont-bearing species are illuminated by fluorescent lights and temperature is maintained by surrounding the dishes with recirculating water from a constant temperature bath set at a temperature equivalent to the sampling site. Algal cultures established in the laboratory, including planktonic diatoms, dinoflagellates, and other small protists, provide a source of protistan prey. Small droplets are introduced into the culture vessels, but only sparingly and at intervals of several days to avoid fouling the culture dishes with overgrowth. Small crustacea or young nauplii of brine shrimp (*Artemia*) reared in the laboratory are suitable additional prey for larger species. In some cases, the freshly collected, unfiltered, seawater from the sample site contains sufficient prey to sustain growth of illuminated radiolarian cultures if the seawater is replaced with freshly collected seawater every several days. No additional prey are required, especially if the cultures are illuminated. The larger radiolaria can be observed using a high-power dissecting microscope. Inverted microscopes with long-distance objective lenses can be used for more detailed visualization of smaller floating radiolaria, preferentially maintained in small culture vials with optically clear flat bottoms.

Chlorarachniophytes

20

Patrick J. Keeling

Abstract

The chlorarachniophytes are a group of single-celled phototrophic, mixotrophic eukaryotes in marine environments. They are most common in tropical and temperate seas. The group is primarily studied due to their evolutionary history. Chlorarachniophytes acquired photosynthesis by secondary endosymbiosis, where an amoeboflagellate host took up a green algal symbiont and retained it. The symbiont is distinguished by having retained a relict nucleus, or nucleomorph, which has been intensively studied to help elucidate the process of organelle origins by endosymbiosis. Historically, work on the nucleomorph was an important clue suggesting that secondary endosymbiosis played a role in the distribution of photosynthesis and plastids in eukaryotes. More recently, a number of genomic and cell biological studies, in particular focusing on gene flow within the cell and protein targeting, have further contributed to our understanding of organelle integration during endosymbiosis. The host component is now known to be a member of the Cercozoa and can include amoeboid, flagellate, and cyst stages, various species having any combination of one or more stages in the life cycle.

Introduction

The chlorarachniophytes are a small group of tropical to temperate marine amoeboflagellates with chlorophyll *a*- and *b*-containing chloroplasts. They have attracted the attention of biologists primarily due to their complex cell biology and evolutionary history, stemming from the fact that they acquired their green chloroplasts by secondary endosymbiosis and have retained a vestigial nucleus of the engulfed alga, now called a nucleomorph (McFadden et al. 1994; Archibald 2007). All known chlorarachniophytes are phototrophic and can possess from one to several chloroplasts, each associated with a nucleomorph. The host cells may be found as amoebae, some plasmodial with individual cells linked by a network of reticulopodia, as thick-walled coccoid cells, or as highly motile uniflagellated zoospore. In some genera, all three cell types are found, although one type is the dominant trophic stage, whereas in other genera, only two or one of the cell types have been observed (Ishida et al. 2007). The endosymbiont is known to be derived from a green alga, and the host is a member of the Cercozoa (Cavalier-Smith 1999; Rogers et al. 2007).

The type species for the group is *Chlorarachnion reptans*, originally described by Geitler (Geitler 1930) and also the first species to be investigated in detail by light microscopy (LM), electron microscopy (EM), and pigment composition analysis

(Hibberd and Norris 1984). *Bigelowiella natans* has since emerged as the best-studied species, and now most of our information comes from this organism.

History of Study and Literature

For many years after the discovery of *C. reptans*, there remained little literature on chlorarachniophytes (Hibberd 1990). The suggestion that they originated by secondary endosymbiosis led to new interest in the group, and early work proving this and preliminary characterization of the nucleomorph both led to a surge in reports on the group, in particular on *B. natans*. Recent work has focused on genomics (McFadden et al. 1997a; Williams et al. 2005; Gilson et al. 2006; Rogers et al. 2007; Curtis et al. 2012), molecular evolution (Archibald et al. 2002, 2003; Takishita et al. 2005; Burki et al. 2007), protein trafficking (Rogers et al. 2004; Gile and Keeling 2008; Hirakawa and Ishida 2010; Hirakawa et al. 2009, 2010, 2011a, 2012a, b), and on the description of new species. Many genomes are now available, especially from *B. natans*, but the emerging model for cell biology is *Amorphochlora amoebiformis*, due to the creation of a transient transfection system that has been used with green fluorescent protein (GFP) markers (Hirakawa et al. 2009). Most information on the cell structure, life history, and habitat is found in the formal descriptions of the 14 species described to date (Hibberd and Norris 1984; Calderon-Saenz and Schnetter 1987; Ishida and Hara 1994; Ishida et al. 1996, 2000, 2011b; Moestrup and Sengco 2001; Dietz et al. 2003; Ota et al. 2005, 2007a, b, 2009a, b, 2011, 2012). There is a large number of review articles on chlorarachniophytes, almost all focusing on molecular biology and endosymbiosis, due to the presence of the nucleomorph and its importance to understanding genome reduction and the endosymbiotic history of plastids (McFadden and Gilson 1995; Gilson et al. 1997; Gilson and McFadden 1997, 2002; McFadden et al. 1997a; Gilson 2001; Archibald and Keeling 2002; Cavalier-Smith 2002; Archibald 2007; Ishida et al. 2007).

Characterization and Recognition

General Characteristics

Although there is much variation between members of the group, there are three common life history stages in chlorarachniophytes: amoeboid, coccoid, and zoospore. In some species all three stages have been observed, whereas in others only one or two stages have been observed, and where more than one is known, the dominant trophic stage can vary. Characteristics common to different stages are discussed here, and stage-specific characteristics will be discussed in turn.

Cells contain a single nucleus (with the exception of a giant amoeboid/coccoid stage of *Gymnochlora dimorpha*/*Lotharella reticulosa* (Ota et al. 2011, 2012)), which divides by open or semi-open mitosis. Mitochondria display typical tubular cristae and are dispersed throughout the cell. Extrusomes have been observed in

several species. Cells contain numerous Golgi bodies, some associated with the pyrenoid and the pyrenoid-capping vesicle. The pyrenoid-capping vesicle is bounded by a single membrane and contains a homogeneous material that has been shown to react with antibodies specific to β-1,3-glucans, which are the primary carbohydrate storage product (McFadden et al. 1997b). The chloroplast lacks starch (Hibberd and Norris 1984), so all carbohydrate storage seems to be carried out in this form by the host. The lipid composition of chlorarachniophytes has also been examined and found to be unlike that of other algae (Leblond et al. 2005).

The chloroplast is the best-studied structure of chlorarachniophytes. All cells contain one or more bilobed, peripheral, chlorophyll *a*- and *b*-containing chloroplasts, typically with a central, inwardly projecting pyrenoid that is closely surrounded by a capping vesicle. Chloroplast lamellae are usually composed of one to three thylakoids, and a girdle lamella is absent. Each chloroplast is bounded by four membranes that may appear closely appressed or as two pairs separated by a space. The outermost membrane is derived from the endomembrane system of the Cercozoan host but is smooth and is not directly connected to the rough endoplasmic reticulum (ER), as is the case in several other algal groups with secondary plastids. The second membrane is derived from the plasma membrane of the green algal endosymbiont. The space between the outer pair and inner pair (which corresponds to the cytoplasm of the green alga) is sometimes referred to as the periplastid space or periplastidial compartment. The inner pair of membranes is derived from the chloroplast envelope. Protein targeting to the plastid has been examined in some detail and is mediated by a bipartite leader consisting of a signal peptide followed by a transit peptide-like (TPL) sequence. The signal peptide directs the protein to the endomembrane system, and the TPL directs it across the remaining three membranes (Hirakawa et al. 2009, 2010, 2012a). Proteins cross the last two membranes using a fairly conventional plastid translocon complex (TOC and TIC systems: Hirakawa et al. 2012a), but how proteins cross the membrane derived from the endosymbiont plasma membrane remains mysterious. The characteristics of the leader that mediate this process are understood, but the mechanism is unknown: currently it seems unlikely that chlorarachniophytes use symbiont ERAD-like machinery (SELMA) including Der1 proteins (Hirakawa et al. 2012a), which is used by red algal secondary plastids (Hempel et al. 2009).

The periplastid space contains a dense homogeneous matrix including many visible ribosomes equivalent in size to eukaryotic cytosolic ribosomes (Hibberd and Norris 1984; McFadden et al. 1994). The periplastid space is generally only a thin layer around most of the chloroplast, but around the base of the pyrenoid or within a wedge-shaped invagination in the pyrenoid, the space is enlarged and contains the nucleomorph, the relict nucleus of the green algal endosymbiont (Fig. 1i). The nucleomorph is small, bounded by a double membrane with pores (Hibberd and Norris 1984; Ludwig and Gibbs 1989; McFadden et al. 1994), and has been shown in all examined species to contain three small, linear chromosomes amounting to 330–1133 kbp of DNA (Gilson and McFadden 1999; Silver et al. 2007; Ishida et al. 2011a). Like the plastid, the periplastidal space also lacks sufficient nucleomorph-encoded genes for function (Gilson et al. 2006), and now a

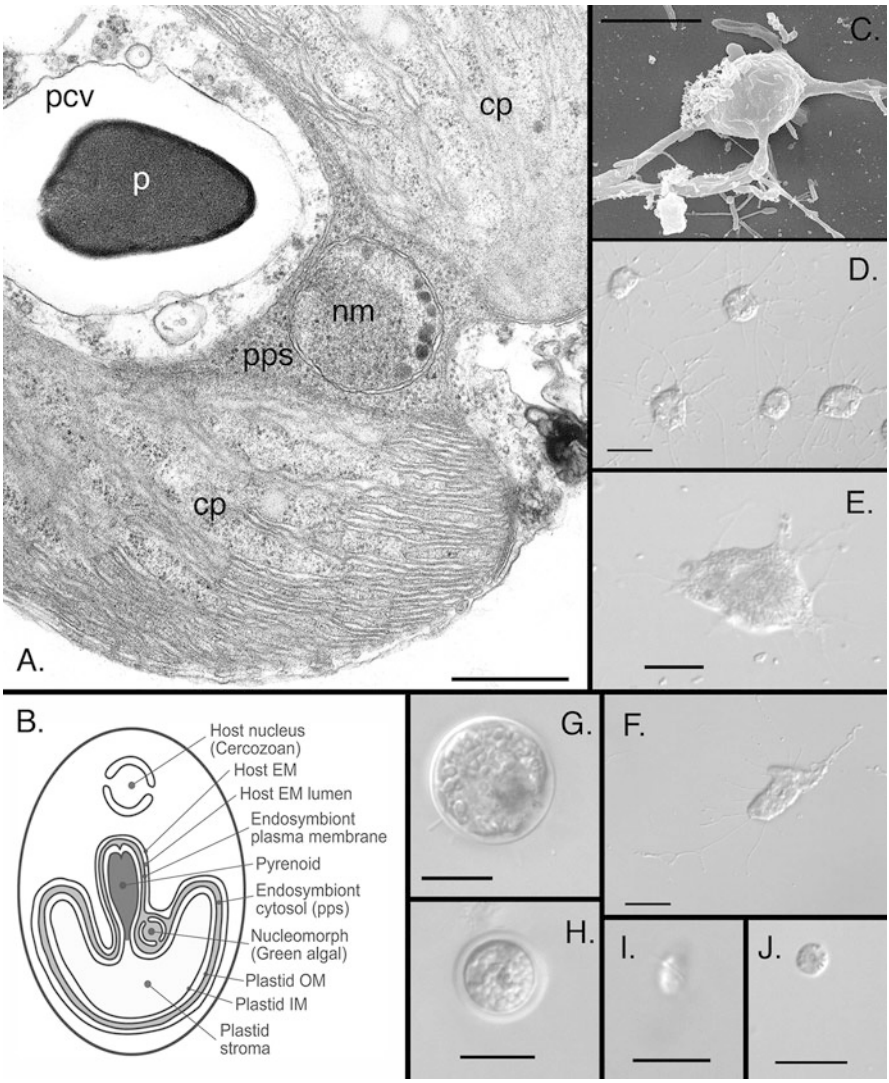

Fig. 1 Morphology and diversity of chlorarachniophytes. (**a**) Transmission electron micrograph of *B. natans* showing the nucleomorph (*nm*), periplastid space with eukaryotic size ribosomes (*pps*), two lobes of the chloroplast (*cp*), and bulbous pyrenoid (*p*) with pyrenoid-capping vesicle (*pcv*). (**b**) Schematic diagram of chlorarachniophyte plastid. Labeled to the right are the three genome-containing compartments (host and endosymbiont nucleus and plastid – the mitochondrion is not shown), the pyrenoid (the pyrenoid-capping vesicle is not shown), and the various membranes and compartments of the complex plastid, including their evolutionary origin (abbreviations are: *EM* endomembrane, *pps* periplastid space, *OM* outer membrane, *IM* inner membrane). (**c**–**f**) Examples of the amoeboid stage: a scanning electron micrograph of *G. stellata* showing cell body and emerging filopodia is shown in (**c**), and light micrographs of amoeboid stages are shown for *G. stellata* (**d**), *Lotharella amoeboformis* (**e**), and *Chlorarachnion reptans* (**f**). (**g**–**h**) Examples of the coccoid stage from *Lotharella vacuolata* (**g**) and *Chlorarachnion reptans*

number of nucleus-encoded periplastid-targeted proteins have been identified. Direct evidence for targeting is only available for three such proteins, histones H2A and H2B (which are targeted to the nucleomorph: Hirakawa et al. 2011a) and EFL (Gile and Keeling 2008). Targeting of these proteins is mediated by a bipartite leader resembling the plastid-targeting leader, except that the TPL portion is distinguished by a net neutral/negative charge, and some proteins have a hydrophilic tail enriched with lysine and aspartic acid residues (Hirakawa et al. 2009, 2010). A large group of potentially periplastidal compartment (PPC)-targeted proteins were identified in the nuclear genome with similar characteristics (Curtis et al. 2012).

Amoeboid Stage

Amoeboid cells (Fig. 1c, e–h) are roughly isodiametric, angular cells found in benthic environments, ranging from 8 to 20 μm (not including the filopodia). From each cell radiate several filose pseudopodia, in *C. reptans*, *L. polymorpha*, *L. vaculolata*, and *L. reticulosa* apparently fusing to form a network of reticulopodia (Hibberd and Norris 1984; Dietz et al. 2003; Ota et al. 2005, 2012) but in others remaining distinct and unconnected (Calderon-Saenz and Schnetter 1989; Ishida et al. 1996, 2000; Ota et al. 2007b). Movement on surfaces is very slow and in some species nonexistent (Ota et al. 2007a), although cytoplasmic streaming can readily be seen in the pseudopodia. Contents of filopodia are mostly restricted to microtubules and vesicular and granular material; mitochondria are the only organelles occurring in the reticulopodia. The amoeboid cells are phagotrophic, engulfing a variety of motile and nonmotile eukaryotes and prokaryotes in the pseudopodia, which may develop large ingestion vesicles. Uptake of prey species has been described for *C. reptans* as differentiated, and some species are taken up preferentially and digested quickly whereas others are resistant to digestion (Hibberd and Norris 1984). Most digestion takes place in pseudopodia (Hibberd and Norris 1984) but has infrequently been observed in the cell body (Ishida et al. 1996). Amoeboid cells may divide or give rise directly to zoospores or coccoid cells, depending on the species.

Walled Coccoid Stage

Coccoid cells (Fig. 1d–e) are also found in benthic environments and are spherical cells 5–15 μm in diameter with a firm wall of variable thickness composed of

Fig. 1 (continued) (**h**) where the thickened wall is apparent. (**i**–**j**) Examples of the zoospore stage from unnamed strain (CCMP622) of the *Lotharella* clade (**i**), in which the helically coiled flagellum can be seen, and *Bigelowiella natans* (**j**). Scale bars on all LM and SEM parts are 10 μm. Scale bar on TEM scale bar is 500 nm (TEM is courtesy of Ø. Moestrup, SEM is courtesy of S. Bowser, and all differential interference contrast light micrographs are by P. Keeling)

multiple layers (Ishida and Hara 1994; Ota et al. 2005). They are often found in older cultures where they probably act as a resting stage or cyst (Hibberd and Norris 1984; Ota et al. 2007b), but in some species, the main vegetative cell type is walled or walled amoebae with short pseudopodia can extending from the wall (Ishida and Hara 1994; Dietz et al. 2003; Ota et al. 2005, 2007a). These have more irregularly shaped chloroplasts than in the amoeboid stage, a laterally positioned nucleus, and contain a large number of vesicles with contents similar in appearance to those of the pyrenoid-capping vesicles. Coccoid cells may divide or give rise directly to the amoeboid stage and also to zoospores via a tetrad division, depending on the species.

Zoospore Stage

Zoospores (Fig. 1a–b, i) are small, planktonic, pyriform, ellipsoid, or ovoid cells ranging from 4 to 24 μm long × 3–7 μm wide. The cytoplasm often has a distinct granular appearance at the anterior end. Zoospores are uniflagellate, although ultrastructural investigation of *B. natans* has revealed a vestigial second basal body (Moestrup and Sengco 2001). The flagellum typically has a hair point and fine lateral hairs and is anchored by a root system consisting of a microtubular component and a second root (Hibberd and Norris 1984; Moestrup and Sengco 2001). During swimming, the flagellum is wrapped helically around the cell body within a concavity. Swimming is rapid – about 100 μm per second for *C. reptans* and faster for smaller cells. In some species the zoospore may become temporarily amoeboid, with the anterior end forming one or more blunt pseudopodia (Hibberd and Norris 1984; Moestrup and Sengco 2001). Zoospores may divide or give rise directly to the amoeboid or coccoid stages, depending on the species.

Reproduction and Life Cycle

The division of the nucleus, nucleomorph, and plastid has all been examined, as has the order of events in *B. natans* where the order of division is pyrenoid, nucleomorph, chloroplast, and finally the nucleus (Moestrup and Sengco 2001). In nuclear division, the envelope breaks down but fragments of it remain, and mitosis is otherwise not unusual (Moestrup and Sengco 2001). Separation of the daughter cells, on the other hand, can be by very unusual means, including a variation on cytoplasmic streaming in *B. longifolia* and *L. vacuolata* (Ota et al. 2005, 2007b). The nucleomorph divides amitotically: no chromosomal condensation or microtubules have been observed. Rather, the inner membrane invaginates and joins to form a barrier, after which the outer membrane invaginates and the two daughter nucleomorphs are separated (Ludwig and Gibbs 1989). Sexual reproduction is poorly understood in chlorarachniophytes, but gametes and sexual reproduction have been reported in zoospores of *C. reptans* (Grell 1990) and amoebae of *Cryptochlora perforans* (Calderon-Saenz and Schnetter 1989).

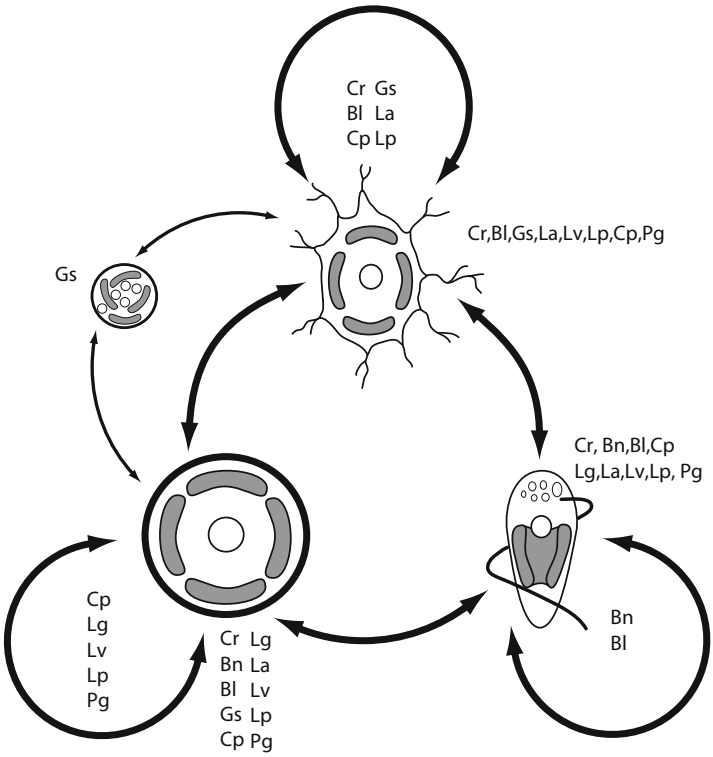

Fig. 2 Life history stages common to chlorarachniophytes. Amoeboid, coccoid, and zoospore states are illustrated, with *arrows* representing transitions (between stages) or vegetative division of a stage. Initials adjacent to stages or within vegetative division loops represent the genus and species where that stage or that vegetative division has been observed (see Classification section for all full genus and species names). *G. stellata* is also known to form a plasmodial form that divides through synchronous cytokinesis, shown parallel to the transition between amoeboid and coccoid stages. All transitions have not been observed in all species, but each transition is known in at least one species

As described above, there are three main life history stages, and in some species all three are known whereas in others one or two are absent. Life history stages have been documented from members of all eight genera, although direct observation of transformations between the various stages is lacking for some species. Available data on which life history stages are present in which genera are summarized in Fig. 2 and Table 1, and see Ishida et al. (2007) for review.

Classification

Chlorarachniophytes are currently classified as members of the Cercozoa, as described below. Currently only 14 species and one variety have been formally described, distributed in 8 genera (Table 1). Classification schemes have relied

Table 1 Summary of characteristics used to classify the six genera of chlorarachniophytes

Genus	Main vegetative stage	Amoeboid	Coccoid	Zoospore	Pyrenoid structure	Nucleomorph location
Chlorarachnion	Amoeboid	+	+	+	Nucleomorph-embedded	Embedded in pyrenoid
Bigelowiella	Zoospore	+/−	+/−	+	Shallow slit	Near pyrenoid base
Lotharella	Amoeboid/ Coccoid	+/−	+	+	Deep slit	Near pyrenoid base
Gymnochlora	Amoeboid	+	−	−	Tubular invaginations	Near pyrenoid base
Amorphochlora	Amoeboid	+	+	+	Deep slit	Near pyrenoid base
Norrisiella	Coccoid	−	+	+	Shallow slit	Near pyrenoid base
Partenskyella	Coccoid	+	+	+	No pyrenoid	Inside chloroplast cup
Cryptochlora	Coccoid	+	+	+	?	?

on pyrenoid shape, location of the nucleomorph, presence or absence of different life history stages, and molecular phylogeny (see Ishida et al. 2007 for review).

Chlorarachnion reptans (Hibberd and Norris 1984) is the type species and only described species of *Chlorarachnion*. It includes all three cell types in its life history and is also distinguished by the location of its nucleomorph within the pyrenoid slit. The genus *Bigelowiella* includes *B. natans* (Moestrup and Sengco 2001), the model species for most chlorarachniophyte cell and molecular biology, and *B. longifolia* (Ota et al. 2007b). *B. natans* has only been observed as zoospores (although they can form pseudopodia (Moestrup and Sengco 2001)), whereas a true amoeboid stage is known in *B. longifolia* (Ota et al. 2007b). There are currently six known species of *Lotharella*: *L. vacuolata* (Ota et al. 2005), *L. globosa* (Ishida and Hara 1994), *L. globosa var. fortis* (Hirakawa et al. 2011b), *L. polymorpha* (Dietz et al. 2003), *L. oceanica* (Ota et al. 2009b), and *L. reticulosa* (Ota and Vaulot 2012), some of which are primarily coccoid and some primarily amoeboid, but all share a pyrenoid with a deep slit and a nucleomorph positioned at the base of the pyrenoid. *Amorphochlora amoebiformis* was originally described as *L. amoeboformis* (Ishida et al. 2000) but was transferred to a new genus based on molecular phylogenetic evidence (Ishida et al. 2011b). *Gymnochlora stellata* and *G. dimorpha* are the described species of *Gymnochlora* (Ishida et al. 1996; Ota et al. 2011), and *Norrisiella sphaerica* is the only described species of *Norrisiella* (Ota et al. 2007a). Both are distinguished from other genera by pyrenoid and nucleomorph characters. *Partenskyella glossopodia* is the only species of *Partenskyella* and is distinguished by a complete absence of a pyrenoid (Ota et al. 2009a). A last genus comprises the enigmatic and poorly described species *Cryptochlora perforans*, which is a mixotrophic species that is attracted to damaged algal *thalli* that it can physically penetrate and feed upon. It has been classified as a chlorarachniophyte based on similarities in life history complexity and plastid characteristics (Calderon-Saenz and Schnetter 1987, 1989). Unfortunately, it has not been described at the ultrastructural or molecular levels, so its exact relationship to chlorarachniophytes is not completely clear.

The relationships between chlorarachniophyte genera are not at all clear from morphological characters, but molecular phylogenies based on genes from the nucleus, nucleomorph, and mitochondria all support the currently analyzable species as being distinct, as well as genera-level distinctions. Phylogenies generally support an overall picture shown in Fig. 3. There is a consistent and well-supported close relationship between the genera *Bigelowiella* and *Norrisiella*, both of which are in turn related to *Chlorarachnion*, with *Partenskyella*, *Lotharella*, and *Gymnochlora* forming an unresolved radiation at the base of the group (Gilson and McFadden 1999; Ishida and Cavalier-Smith 1999; Silver et al. 2007; Ota et al. 2009a; Ota and Vaulot 2012).

Molecular bar codes have been established and tested for all chlorarachniophyte species available in culture (Gile et al. 2010). Nucleomorph ribosomal RNA intergenic spacer (ITS) sequence was found to provide good resolution at the species

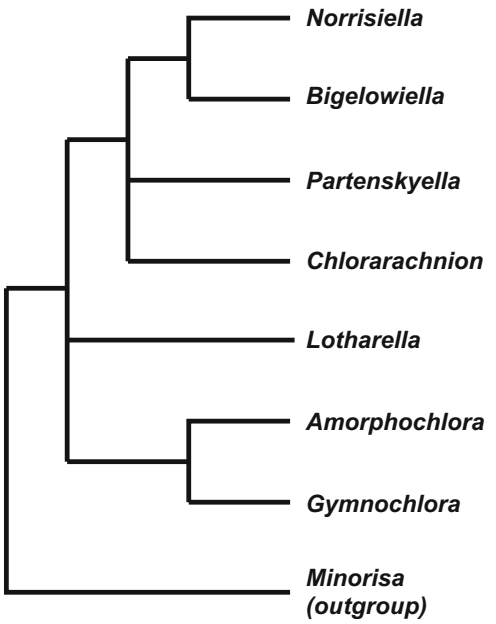

Fig. 3 Phylogeny of described chlorarachniophytes. A schematic molecular phylogeny predominantly based on analyses of SSU rRNA, and the DNA bar code marker ITS is shown

level, at least for the few genera with multiple species, and was subsequently used to characterize new isolates (Hirakawa et al. 2011b; Ota and Vaulot 2012).

Maintenance and Cultivation

Many species grow easily but slowly in a variety of marine media (see Hibberd and Norris 1984; Ishida et al. 2000; Moestrup and Sengco 2001; Ota et al. 2007a, b). Primarily amoeboid and coccoid species mostly accumulate in masses on surfaces, while primarily flagellated forms can be grown to high densities by shaking or aeration. Currently over 30 strains are available from several culture collections, the largest collection of strains being at the Provasoli-Guillard National Center for Culture of Marine Phytoplankton.

Genomics

The unique evolutionary history and current complexity of chlorarachniophytes has led to several genomic and comparative genomic projects. Currently complete genomes for all four compartments, plastid, mitochondrion, nucleomorph, and nucleus, have been sequenced for the model species *B. natans* (Gilson et al. 2006; Rogers et al. 2007; Curtis et al. 2012). Organelle genomes, proteomics, and surveys of gene expression have also been carried out for a number of species (Williams et al. 2005; Slamovits and Keeling 2009; Hopkins et al. 2012; Tanifuji et al. 2014;

Suzuki et al. 2015), all revealing a model for the effects of endosymbiotic integration and nuclear genome compaction. The nucleomorph genome is severely reduced with only about 300 tightly packed genes but still retains over 800 introns that are all compacted, nearly all to 18–21 bp in length (Gilson et al. 2006; Slamovits and Keeling 2009). Nuclear genome organization is conventional but revealed a large number of genes derived by horizontal gene transfer, as well as genes originating by endosymbiotic gene transfer from the endosymbiont (Archibald et al. 2003; Gile et al. 2008; Hirakawa et al. 2011a; Curtis et al. 2012). The nucleus is haploid and nucleomorph diploid (Hirakawa and Ishida 2014).

Evolutionary History

The unique combination of characters found in chlorarachniophytes led to much speculation and confusion about their possible evolutionary origin in early studies (Geitler 1930; Hibberd and Norris 1984; Grell 1990; Hibberd 1990), particularly before it was understood that they are a symbiotic fusion of a colorless amoeboflagellate and a green alga (Whatley and Whatley 1981; Cavalier-Smith 1982). Now this endosymbiotic origin of chlorarachniophytes has been demonstrated beyond any doubt by ultrastructural studies and characterization of the nucleomorph genome (Ludwig and Gibbs 1989; McFadden et al. 1994; Gilson et al. 2006). While the nucleomorph and its genome have been retained, many endosymbiont genes were moved to the host nucleus (Deane et al. 2000; Archibald et al. 2003; Gile and Keeling 2008; Hirakawa et al. 2011a; Curtis et al. 2012) and many other features simply lost, for example, Golgi bodies, mitochondria, locomotary organelles, and carbohydrate storage, during the integration of chlorarachniophyte plastids.

Even after the endosymbiotic origin of chlorarachniophytes was well established, however, the origin of both the host and the endosymbiont continued to be controversial. The presence of chlorophyll *b* immediately suggested a link to green algae (Hibberd and Norris 1984), but numerous theories about which kind of green algae were put forward (Sasa et al. 1882; Cavalier-Smith et al. 1994; Van de Peer et al. 1996; Ishida et al. 1997; Ishida and Cavalier-Smith 1999). Current data only suggest it is a member of the ulvophyte-trebouxiophyte-chlorophyte complex (Rogers et al. 2007; Turmel et al. 2009). The evolutionary history of the host was considerably more obscure since chlorarachniophytes do not share any obvious defining morphological feature with any other group. Molecular data have shed considerable light on this, however, and consistently show the chlorarachniophyte host to be part of a large and diverse group of flagellates, amoebae, and amoeboflagellates, called Cercozoa (Cavalier-Smith 1999). There are currently no structural characteristics that uniquely unite all Cercozoa, but phylogenies based on all genes that have been examined individually or as large concatenates (Bhattacharya et al. 1995; Cavalier-Smith and Chao 1997; Keeling et al. 1998; Keeling 2001; Longet et al. 2003; Nikolaev et al. 2004; Takishita et al. 2005; Burki et al. 2007, 2012), as well as the presence of unique insertion/deletions in polyubiquitins and

rRNA (Cavalier-Smith and Chao 1997; Archibald et al. 2002), all consistently show Cercozoa to be monophyletic group that includes chlorarachniophytes, likely as an early-branching subgroup. Cercozoa, in turn has been shown to be part of an even larger group called Rhizaria, which also includes a number of mostly amoeboid lineages such as foraminiferans, acantharians, and polycystines (Sierra et al. 2012). Altogether, Rhizaria consistently branch as sisters to the alveolates and stramenopiles in large multigene phylogenetic analyses (Burki et al. 2007, 2012). The closest cercozoan sister group to the chlorarachniophytes in current phylogenies appears to be the pico-heterotroph, *Minorisa*, one of the smallest known eukaryotes (del Campo et al. 2013).

Phytomyxea

21

Simon Bulman and Sigrid Neuhauser

Abstract

Phytomyxea are endoparasites of Plantae or heterokont hosts. They are distributed between two orders, the Plasmodiophorida and Phagomyxida. Several phytomyxids cause the formation of large galls on their hosts, but many are only visible via light microscopy of roots, hyphae, or phytoplankton. PCR and sequencing from environmental DNA samples is beginning to reveal many new phytomyxid lineages. Phytomyxids persist in the environment as thick-walled, uninucleate resting spores. These germinate to produce zoospores which locate hosts via the propulsion of heterokont flagellae. Cell penetration by encysting zoospores is via a distinctive projectile-like extrusome. Intracellular growth forms are multinucleate, unwalled protoplasts termed plasmodia. A synapomorphy for the class is cruciform mitotic division at metaphase. Plasmodiophorids occupy a phylogenetically distinct position from most other plant parasites. They cause several economically important diseases such as clubroot of Brassicaceae and powdery scab of potatoes. Plasmodiophorids also act as vectors of damaging plant viruses.

●●**Plasmodiophorida** (*Plasmodiophora*, *Spongospora*, *Woronina*, etc.)
●●**Phagomyxida** (*Phagomyxa*, *Maullinia*, etc.)

Introduction

General Characteristics

Organisms in the class Phytomyxea are endoparasites of plants or heterokonts. They are distributed between two orders, the Plasmodiophorida, to date found in soil/freshwater, and Phagomyxida, found in marine ecosystems. Phytomyxids persist in the environment as thick-walled, uninucleate resting spores. Upon resting spore germination, the released zoospores locate hosts propelled by smooth heterokont flagellae. Cell penetration is via a distinctive projectile-like extrusome. Intracellular growth forms are multinucleate, unwalled protoplasts termed plasmodia. A synapomorphy for the class is cruciform mitotic division at metaphase. Plasmodiophorids cause several economically important plant diseases – either directly or as vectors of viruses.

Literature and History of Knowledge

The first phytomyxid genus was erected by Woronin in 1877 to accommodate *Plasmodiophora brassicae*, the organism causing clubroot of cabbage. Literature

published in the early 1900s was based largely on light microscopy (Cook 1933). Much of the phytomyxid species discovery occurred during this period, with knowledge summarized in important monographs by Karling (1942, 1968). Ultrastructural and karyological studies predominated into the 1990s, leading to a greatly increased understanding of phytomyxid lifecycles (Dylewski 1990; Braselton 1995; Bulman and Braselton 2014). Considerable research during this period was carried out on the oomycete parasite *Woronina* and on the *Veronica* parasite, *Sorosphaerula veronicae*, whereas little has been published on these organisms in subsequent decades. Continuing research is centered upon phytomyxid species that cause diseases of economically important crops, while reports on other phytomyxids are infrequent. Physical identification of new phytomyxid species, such as the recently described parasite of grapes *Sorosphaerula viticola* (Kirchmair et al. 2005), is rare. With greater focus on marine ecosystems, a small number of new phagomyxid parasites have been discovered (Maier et al. 2000; Schnepf et al. 2000; Goecke et al. 2012). An accessible and important source of information on the plasmodiophorids remains the Plasmodiophorid Home Page (http://oak.cats.ohiou.edu/~braselto/plasmos/).

Beginning with first the DNA-based studies (Mutasa et al. 1993), techniques of molecular biology are now driving large changes to our understanding of phytomyxid biology and diversity. Molecular tools were initially developed for pathogen detection (Buhariwalla et al. 1995), delineation of populations and species within *Polymyxa*, and assessing the presence of plant viruses associated with phytomyxids (Legreve et al. 2002; Kanyuka et al. 2003; Smith et al. 2013). Molecular phylogenetic analyses succeeded in finding a taxonomic home for the phytomyxids in Rhizaria (CavalierSmith and Chao 1997; Archibald and Keeling 2004; Nikolaev et al. 2004; Burki et al. 2010) and confirmed the close relationship of Phagomyxida with Plasmodiophorida (Bulman et al. 2001; Neuhauser et al. 2014). While identification of new phytomyxid lineages in broadly targeted culture-independent studies is not common, such works do suggest a diversity of phytomyxids not yet seen with the naked eye or by microscopy (Takishita et al. 2005, 2007). Importantly, anonymous DNA sequencing coupled with targeted PCR amplification is revealing many new lineages of plasmodiophorids (Neuhauser et al. 2014). Studies of phytomyxid genomes, which were initially slowed by the obligate biotrophic nature of these protists, began with small collections of DNA sequences (Bulman et al. 2006, 2007; Siemens et al. 2009). Early utilization of next-generation sequencing techniques provided a better understanding of the phylogenomics of plasmodiophorids (Burki et al. 2010). A complete mitochondrial DNA sequence from *Spongospora subterranea* (Gutierrez et al. 2014) and the first complete phytomyxid genome sequence, from *P. brassicae* (Schwelm et al. 2015a), have been published. The greatest amount of research continues to be focused on *P. brassicae* infection of the model plant *Arabidopsis thaliana* (Devos et al. 2006; Siemens et al. 2006; Malinowski et al. 2012). Biochemical and cellular characterization of this interaction is accelerating based on new genomic data (Feng et al. 2010; Ludwig-Muller et al. 2015). The first technique for the genetic transformation of *P. brassicae* has recently been published, potentially opening up greater opportunities for characterization of gene function in this parasite (Feng et al. 2013).

A node of clubroot research has developed as a response to the large losses caused by the disease in the Canadian canola industry (Hwang et al. 2012).

Practical Importance

The best studied phytomyxids infect important agricultural food plants worldwide. *Plasmodiophora brassicae* causes clubroot in Brassicaceae (Dixon 2009). *Spongospora subterranea* causes powdery scab of potato (Merz and Falloon 2009). *Spongospora nasturtii* causes crook root disease in watercress (Claxton et al. 1996). *Polymyxa graminis* infects the roots of grasses such as wheat, oats, and rice, and *Polymyxa betae* grows in the roots of sugar beets. Phytomyxids are known to transmit about 20 plant viruses, all but one of which are non-enveloped, positive polarity, single-stranded RNA viruses (Rochon et al. 2004). *Polymyxa* species do not directly cause disease but instead transmit a range of damaging viruses (Kanyuka et al. 2003; Rochon et al. 2004). Viruses transmitted by *P. graminis* include *wheat spindle streak mosaic virus*, *oat golden stripe virus*, *rice necrosis mosaic virus*, and *peanut clump virus*. *Polymyxa betae* transmits viruses including beet *necrotic yellow vein virus*, the cause of sugar beet rhizomania. *Spongospora subterranea* and *S. nasturtii*, respectively, transmit *potato mop-top virus* and *watercress yellow spot virus*. The resting spores of plasmodiophorids remain viable in soil for many years, and there are few pesticides available for control of diseases caused by plasmodiophorids. Once soils become infested with resting spores, it is difficult to continue cropping of the susceptible host.

The ecological roles of phagomyxids in marine environments are a matter of increasing interest but as yet have been little studied (Neuhauser et al. 2011).

Habitats and Ecology

As obligate biotrophs, phytomyxid distribution follows that of their hosts (Table 1). Phytomyxids are mostly not available from culture collections. To date, Plasmodiophorida are found in terrestrial and freshwater environments where they parasitize plants and heterokonts such as *Phytophthora* and *Pythium* spp. Both *P. brassicae* and *S. subterranea* are found worldwide in soils where Brassicaceae and potatoes are grown. *Polymyxa*, *Sorosphaerula*, and *Ligniera* species are common soilborne plant parasites, found widely in arable and natural environments. Several phytomyxids including *Spongospora nasturtii*, *Tetramyxa* spp., *Sorodiscus callitrichis*, and *Membranosorus* spp. parasitize aquatic vascular plants. *Sorodiscus karlingii* infects charophyte algae. Phagomyxida so far discovered are marine parasites of heterokonts, including diatoms and brown algae.

Since the retirement of prominent researchers in this field, knowledge of sites to collect many phytomyxid species is restricted. Records of non-crop-infecting phytomyxids are increasingly sporadic and often in the realm of citizen science. Species of *Tetramyxa*, *Sorodiscus*, *Membranosorus*, and, especially, *Octomyxa* are

[a]Numbers in superscript indicate phylogenetic clades from Neuhauser et al. (2014). A subset of phytomyxid clades that have only been detected via environmental sequencing (Env) is also shown. A citation specifically focused on the organism in question, or a review article giving such information, is also provided

currently little studied. Although the distribution of many phytomyxids is reportedly limited, some studies of herbarium samples suggest a broader geographical distribution than previously recognized (Forest et al. 1986; den Hartog 1989).

Anonymous DNA sequencing techniques have revealed new phagomyxid lineages in anoxic marine/saline environments (Takishita et al. 2005, 2007) and plasmodiophorid lineages from geographically widespread soil and rhizosphere sites (Lesaulnier et al. 2008; Bass et al. 2009; Neuhauser et al. 2014). Although anonymous phytomyxid sequences have not so far been associated with specific hosts, the low diversity of sequences in any one sample, and greater abundance in rhizosphere versus bulk soil, implies a close relationship with plant hosts (Neuhauser et al. 2014). Cloning of anonymous sequences also suggests that oomycete-infecting phytomyxids are diverse and widely distributed in soils (Neuhauser et al. 2014).

Characterization and Recognition

By far the majority of phytomyxid life-cycle research has been carried out on plasmodiophorids such as *P. brassicae* (Kageyama and Asano 2009), *S. veronicae* (Miller 1958), and *W. pythii* (Dylewski 1990), rather than phagomyxids. The most recognized phytomyxid life cycle has a bipartite format; a composite life-cycle scheme, most strongly drawn from plant-infecting Plasmodiophorida, is presented here (Fig. 1).

Penetration of Host

Phytomyxids persist over time through environmentally resistant resting spores. These germinate to produce heterokont *primary* zoospores that exhibit a cyclotic

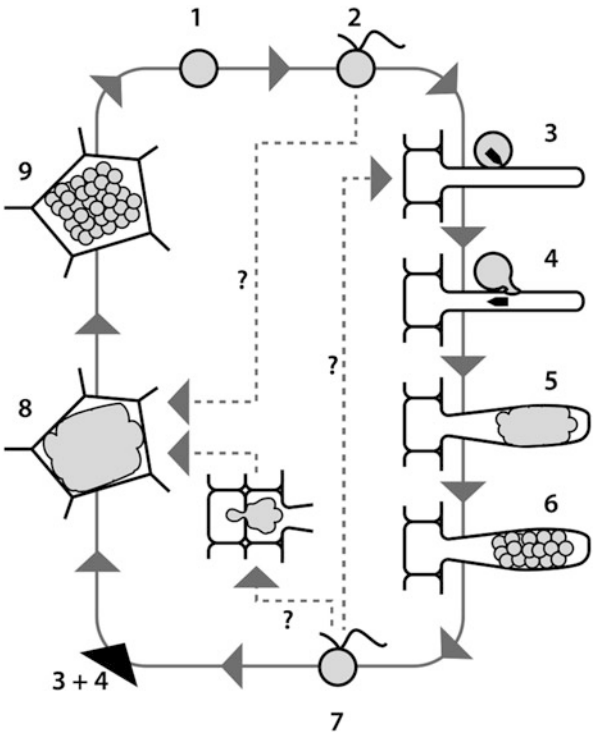

Fig. 1 A Phytomyxid life-cycle scheme drawn mostly from plasmodiophorid infection of crop plants. Variations to this life cycle may occur in some species such as among the marine phagomyxids. *1*, environmentally resistant resting spore; *2*, biflagellate primary zoospore; *3*, location of host cell by zoospore and commencement of encystment – for many plasmodiophorids, primary infection occurs in root hairs; *4*, cell penetration by Stachel followed by zoospore contents; *5*, development of multinucleate plasmodium; *6*, multilobed structure containing zoosporangia; *7*, secondary zoospore – reinfection of host cells occurs by encystment as in *3* and *4*, or via a myxamoeboid phase (dashed lines to 8); *8*, secondary plasmodium; *9*, resting spores or aggregates thereof. Dashed lines indicate uncertainty about direct progression to secondary infection mediated via primary zoospores or generation of new cycles of primary infection by secondary zoospores

swimming motion. On encountering the host, zoospores retract their flagellae and begin a characteristic infection process termed encystment. An infection apparatus develops within the zoospore, consisting of a tubular cavity (Rohr) containing a bullet-like structure (Stachel), with one end oriented in the direction of the host wall (Keskin and Fuchs 1969; Aist and Williams 1971). The Rohr rapidly contracts, and the Stachel penetrates the host wall followed by the unwalled, uninucleate protoplast of the parasite, which is presumably forced out by turgor pressure created by the expansion of a large vacuole in the encysted zoospore (Fig. 1).

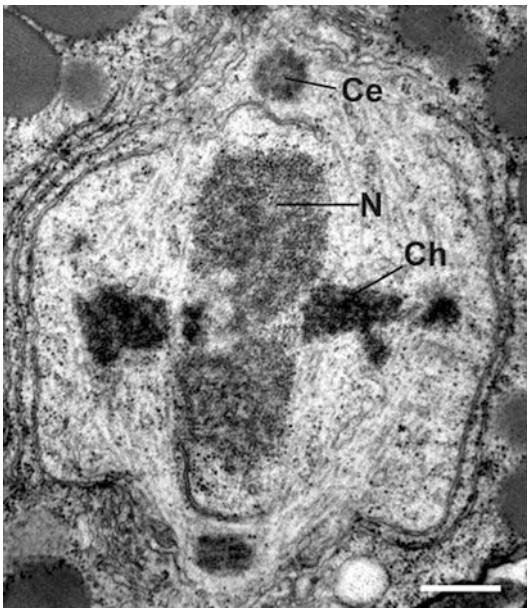

Fig. 2 Transmission electron micrograph of cruciform division in sporogenic plasmodium of *Plasmodiophora brassicae* on Chinese cabbage (*Brassica rapa*). *N* nucleolus, *Ce* centriole, *Ch* chromatin. Scale bar = 0.5 μM. Photograph James Braselton, Plasmodiophorid Homepage

Sporangial Plasmodia

Inside infected cells, the uninucleate protoplast matures into a zoosporangial plasmodium, with a 9–24 nm host-plasmodiophorid interface (Aist and Williams 1971; Braselton and Miller 1975; Miller and Dylewski 1983a). Synchronous mitotic divisions yield a multinucleate plasmodium (Dylewski and Miller 1983). These cruciform divisions are the major synapomorphy defining phytomyxids (Braselton and Miller 1975). At metaphase, chromatin aligns at the equator of the nucleus, perpendicular to the elongating, persistent nucleolus. A symmetrical cross is formed that can be seen by light microscopy (Fig. 2) (Dylewski et al. 1978; Garber and Aist 1979).

After the mitotic divisions, the plasmodium cleaves into a thin-walled multicelled structure in the infected cell (Fig. 3). Zoospore formation occurs as the protoplasm within each zoosporangium cleaves. *Secondary* zoospores from zoosporangia may be released outside of the host, into adjacent cells, or into the same cell. Conspicuous exit tubes may be formed between the zoosporangia and adjacent host cells (Littlefield et al. 1998).

Sporogenic Plasmodia

The sporogenic phase culminates in the formation of thick-walled resting spores (Fig. 4). At the cessation of sporogenic division, cleavage furrows appear and meiosis begins (Dylewski and Miller 1984). Nucleoli begin to disperse during

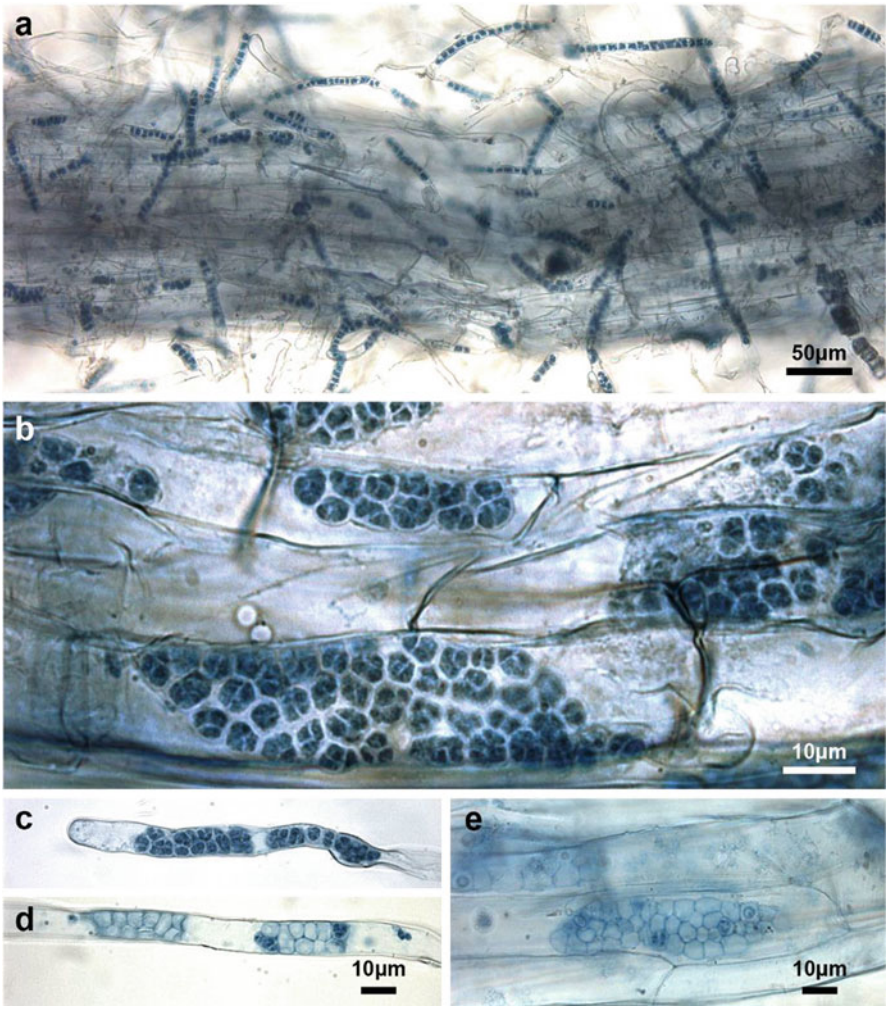

Fig. 3 *Spongospora subterranea* zoosporangia in trypan blue stained potato roots. Photographs Richard Falloon

prophase of meiosis I, rendering the nuclei less obvious in the plasmodium. It is believed that chromosome number is halved as a result of meiosis during resting spore formation (Dylewski 1990). Eventually, each nucleus is partitioned, forming binucleate resting spores. One nucleus presumably undergoes degeneration because all mature resting spores become uninucleate (Dylewski and Miller 1984).

Many phytomyxids have resting spores arranged in aggregate bodies called sporosori. For example, *Sorodiscus* sporosori are usually composed of two closely

pressed layers of resting spores, whereas those of *Membranosorus* occur in a single layer usually lining the inner periphery of the host cell (Fig. 5). *Spongospora subterranea* sporosori are particularly large and distinctive; approximately 200–700 resting spores are aggregated into spongelike structures of variable size (Falloon et al. 2011) (Fig. 5).

Sporogenic plasmodia become more abundant as the host ages. In several plasmodiophorid species, sporangial and sporogenic plasmodia are distinguishable by their occurrence in separate tissues. In *P. brassicae*, sporangial plasmodia develop in root hairs and epidermal cells, whereas sporogenic plasmodia are found in the root cortex and stele. In *S. veronicae*, sporosori are produced only in galls on shoots and not during root infections. In *S. subterranea*, zoosporangia occur soon after infection in root epidermal cells, while sporosori are formed later in root galls and tuber lesions. Although sporangial development typically precedes sporogenic development, both stages can be seen in the same tissue early in *Polymyxa* infection (Ledingham 1939). Primary zoospores may be capable of initiating both sporangial and sporogenic plasmodia in *P. brassicae* (Mithen and Magrath 1992; McDonald et al. 2014). The biochemical and developmental factors that determine the transition to sporogenic growth are not known. In cultures, the state of the culture medium appears to have an influence on the development path of *Woronina* plasmodia (Miller and Dylewski 1983b).

Sporogenic development is associated with growth of hypertrophic plant galls characteristic of several plasmodiophorid diseases. While sporogenic development is considered to be initiated via secondary zoospore infection, there are persistent

reports of direct penetration of the root cortex. Indeed, a myxamoeboid stage is nearly an accepted part of the plasmodiophorid life cycle, despite the exact nature of this stage remaining unclear (Mithen and Magrath 1992; Claxton et al. 1996; Kobelt et al. 2000; Asano and Kageyama 2006). Few genes encoding proteins with cellulose-binding domains, which might be involved in the cell wall modification needed to penetrate into new plant cells, were detected in the *P. brassicae* or *S. subterranea* transcriptomes (Schwelm et al. 2015b).

Nutrition

There are some unanswered questions about the degree of phagotrophy in phytomyxids. As the genus name suggests, ingestion of host material has been reported as a feature of nutrition in *Phagomyxa* (Karling 1944; Schnepf et al. 2000). On the other hand, during early sporangial growth of plasmodiophorids, pseudopodial-like extensions of protoplasm grow outward and partially surround host organelles and cytoplasm, but it has generally been agreed that these fail to completely surround host cytoplasm and that there is consequently no phagotrophic nutrition (Dylewski 1990).

Karyogamy

The occurrence of karyogamy in phytomyxids is not well understood. Protoplasm fusion was claimed to occur between haploid secondary zoospores or between the nuclei in plasmodia, prior to resting spore formation and the onset of meiosis (Ingram and Tommerup 1972). Potential karyogamy in sporogenic *P. brassicae* plasmodia has also been reported (Buczacki and Moxham 1980).

Atypical-Host Infection

An unusual feature of plasmodiophorids is their appearance in a wide range of hosts beyond those in which they complete a full life cycle. Primary plasmodia have been observed in the roots of such atypical plant hosts, with little or no evidence for progression to secondary plasmodia. For example, *S. subterranea* and *P. brassicae* have been observed in many plant species other than their respective *Solanum* and Brassicaceae hosts (Ludwig-Muller et al. 1999; Qu and Christ 2006). A model for atypical host infection is provided by the *Polymyxa-Arabidopsis thaliana* interaction (Desoignies et al. 2010). Frequent host shifts have occurred during the evolution of phytomyxids; whether these host shifts are related to promiscuous host infections at primary stages remains to be investigated (Neuhauser et al. 2014).

Maintenance and Cultivation

Collection and Isolation

Phytomyxids are "isolated" from soil or water samples through infection of their hosts. Plasmodiophorids may be collected from wild sources or from hosts deliberately planted in infested potted soils. Plant-infecting species of *Plasmodiophora* (Fig. 6), *Spongospora*, *Sorosphaerula*, *Sorodiscus*, and *Tetramyxa* produce obvious galls or hypertrophies that are easily collected from infected plants. *Spongospora subterranea* is most frequently collected from sporosori-filled scabs on potato tubers (Fig. 6). *Ligniera* and *Polymyxa* species must be found by microscopically examining the roots of hosts, which is time-consuming due to the lack of external symptoms (Fig. 4).

Woronina and *Octomyxa* spp. are typically attracted to hosts growing on seeds added to water or water amended with soil. Samples may be baited with specific oomycetes if available. Oomycete-infecting plasmodiophorids are then detected by light microscopy (Fig. 4).

Phagomyxid species are identified through microscopic surveys of marine heterokont hosts. *Phagomyxa odontellae* and *P. bellerocheae* are found infecting diatoms in marine phytoplankton samples (Fig. 7) (Schnepf 1994; Schnepf et al. 2000). *Maullinia* spp. can be collected from galls on marine brown algae macrophytes (Fig. 8). Resting spores were observed for *Maullinia* infecting *Durvillaea antarctica*, raising the possibility that this species may be maintained in a viable form within collections (Goecke et al. 2012).

Cultivation

Studies of the interactions between phytomyxids and their hosts are most tractable for *P. brassicae* which infects the model plant *Arabidopsis thaliana* (Fig. 6). For manipulating *P. brassicae*, spore suspensions are prepared by maceration and filtering of decayed galls (Castlebury et al. 1994). For new plant infection, the suspension is applied to soil surrounding plant seedlings. Temperature and pH are important for disease progression, with 20 °C and pH <7 being typical conditions for maximal

P. brassicae growth. Clubroot galls or *P. brassicae* spore suspensions may be kept frozen in a viable state for at least 3 years.

Sporosori samples from *S. subterranea* are prepared by scraping scabs from potato tubers followed by air drying and sieving. A solution-culture assay (Merz 1989) has been adopted for studying the potato-*S. subterranea* interaction.

Although phytomyxids cannot be cultured in the absence of their hosts, several publications have detailed the establishment of dual cultures of plasmodiophorids with plant cells. *Plasmodiophora brassicae* and *S. subterranea* have been grown in hormone-induced callus/cell cultures (Buczacki 1983; Asano and Kageyama 2006; Bulman et al. 2011). *Plasmodiophora brassicae*, *S. subterranea*, and *P. betae* have been grown with *Agrobacterium*-induced in vitro hairy root cultures (Mugnier 1987; Qu and Christ 2007).

Dual cultures of plasmodiophorids and oomycete hosts in water and "soft" agar media have been established for *W. pythii* and *W. cokeri* (Miller and Dylewski 1983a). Resting spores of *W. pythii* may be dried on filter paper and germinated by rehydration after up to 14 months at 6 °C (Miller and Dylewski 1983a). Laboratory co-cultures of *Maullinia ectocarpii* with a range of brown algae macrophytes have been established under controlled conditions (Maier et al. 2000).

Evolutionary History

Classification

Phytomyxids are likely to be at least 400 million years old based on fossil records (Taylor et al. 1992). For a long period, their taxonomic position was unstable, oscillating between fungi, slime molds, and protozoa (Barr 1981). The first ribosomal DNA sequence from *P. brassicae* provided evidence for a relationship between plasmodiophorids and Cercozoa (Cavalier-Smith and Chao 1997; Castlebury and Domier 1998). Assembly of sequences from a greater diversity of protists has confirmed that this grouping with Rhizaria (Nikolaev et al. 2004; Bass et al. 2005, 2009) and that Phagomyxida belong in Phytomyxea (Bulman et al. 2001). Plasmodiophorid polyubiquitin sequences were shown to have an unusual amino acid insertion, as do those from Cercozoa and Foraminifera (Archibald et al. 2003; Archibald and Keeling 2004). Phytomyxids fall within the subphylum Endomyxa that includes a mixture of free-living and parasitic organisms including vampyrellid amoebae (predators), *Filoreta* (bacterivores), Ascetosporea (parasites of marine invertebrates), and *Gromia* (Bass et al. 2009). Phylogenomic studies have mostly indicated that Endomyxa is a distinct clade (Burki et al. 2010; Sierra et al. 2013; Cavalier-Smith et al. 2015). The exact phylogenetic position of Phytomyxea relative to other endomyxans remains to be finalized, although ribosomal phylogenies point to vampyrellids as close relatives (Bass et al. 2009).

Phytomyxea genera were historically designated by the aggregation of resting spores in sporosori and by ultrastructure, with less emphasis placed on host affiliations. However, *S. nasturtii* was raised to species rank partly on the basis of its

significantly different host to *S. subterranea* (Dick 2001), while *W. cokeri* was moved to the genus *Woronina* harboring other oomycete parasites (Robbins and Braselton 1997). Across the last century, a large number of phytomyxids were described; many of the reported species appear to have been synonyms or were doubtful taxa, as reviewed in Karling (1942; 1968). A summary of some of these taxa is presented in Table 1. Although each phytomyxid genus could once be uniquely identified by spore arrangement and ultrastructure (Dylewski 1990), it is now clear that neither feature provides a firm framework for understanding within-group relatedness. As with the overall phylogenetic position of Phytomyxea, the internal relationships of the group have been radically altered by the advent of DNA techniques. Ribosomal small subunit RNA phylogenies showed large evolutionary distances between plasmodiophorid species that were largely indistinguishable by morphology. For example, *Spongospora subterranea* and *S. nasturtii* were found to be phylogenetically remote from one another (Bulman et al. 2001). Even more strikingly, *Plasmodiophora diplantherae* was shown to be a phagomyxid rather than plasmodiophorid (Neuhauser et al. 2014). Anonymous DNA sequencing coupled with specific PCR has now revealed many new distinct lineages, especially within Plasmodiophorida (Neuhauser et al. 2014); a selection of these environmental lineages is listed in Table 1. An intermixed cluster of *Polymyxa*, *Sorosphaerula*, and, to a lesser degree, *Ligniera* species was confirmed (Neuhauser et al. 2014). This group of genera appears ripe for taxonomic revision based on a combination of ecological and DNA data. Anonymous DNA sequences also indicated a significant diversity of lineages in the *Woronina* clade (Neuhauser et al. 2014). It will be highly informative to use molecular techniques to link these *Woronina*-like lineages with their, presumably, oomycete hosts. Phagomyxid lineages in marine ecosystems await exploration with the techniques of molecular ecology.

Paramyxida

22

Robert J. G. Lester and P. Mike Hine

Abstract

Paramyxidans are obligate parasites of marine invertebrates. They produce a characteristic delicate spore with one cell within a second cell. In some genera, these are enclosed within a third cell and even a fourth cell. Life cycles are generally unknown. In two *Marteilia* species that are major pathogens of oysters, there could be an alternate host in the life cycle.

Keywords

Paramyxida • *Marteilia* • *Marteilioides* • *Paramarteilia* • Oyster pathogen • Aber disease • QX disease

●●***Paramarteilia*** (*P. orchestiae, P. canceri, P. branchialis*)

Introduction

The Paramyxida currently comprise a small group of species that differ from other protistans in that their spores consist of several cells, one inside another, that arise from internal cleavage within a mother cell (Fig. 1). Paramyxidans are also commonly referred to as paramyxeans, a reflection of the unclear taxonomic status of the group (Ward et al. 2016). Known paramyxidans all develop within marine invertebrates: polychaetes, crustaceans, or mollusks.

Thirteen species are recognized (Table 1). There are at least 15 other records of paramyxidan-like organisms in marine invertebrates including an enigmatic form in a tunicate (Choi et al. 2006; Carrasco et al. 2012). Most records of the phylum are from Eurasia (Ward et al. 2016) though there are reports of paramyxids from Florida

Dig.gl. digestive gland
[a]Associated with mass mortalities

(Moyer et al. 1993) and Mexico (Grijalva-Chon et al. 2015). The Florida parasite destroyed local scallops suggesting it was an exotic introduction, and the *M. refringens* in Mexico probably originated from Europe. Three records of paramyxidans from the ovaries of oysters within ports but not elsewhere suggest that their distributions can be extended by shipping (Becker and Pauley 1968; Wolf 1977; Hine and Thorne 2000).

Paramyxidans develop within tissues of invertebrates both inside and outside tissue cells. Sporulation typically occurs in the digestive epithelium or gonad cells of the host. Three species, *Marteilia refringens*, *M. sydneyi*, and *M. (*syn. *Marteilioides) chungmuensis*, have had and continue to have devastating effects on oyster industries around the world. Most of what we know about the biology of paramyxidans come from studies on these three species.

Habitats and Ecology

The best known species, *Marteilia refringens,* sporulates within the tissues of *Ostrea edulis*. Infections occur throughout the summer. Sporulation takes place at temperatures over 17 °C, much of the epithelium of the digestive gland is destroyed and 50–90% of the oysters may die. The paramyxidan infection is the cause of "Aber

Disease" in *O. edulis* in Western Europe. As a result of its pathogenicity and that of *Bonamia ostreae*, a haplosporidian, *O. edulis* has been replaced by *C. gigas* in the most of the European oyster industry. The paramyxidan also infects and sporulates in *Mytilus edulis, M. galloprovincialis, Solen marginatus, Chamelea gallina*, *Ostrea stentina*, and possibly other *Ostrea* species. In *Mytilus* spp. it causes little significant mortality, apparently depending on the species and strain of host (Berthe et al. 2004). Infections in *M. galloprovincialis* inhibit gonad regeneration after the first spawning (Villalba et al. 1993). It shows considerable variability, the strain commonly found in mussels having been regarded as *M. maurini* (see Lopez-Flores et al. 2004, 2008).

Marteilia sydneyi develops in *Saccostrea glomerata* in Australia. The epithelium of the digestive gland becomes swollen with sporulating parasites, and heavily infected oysters die within 6 weeks (Wolf 1979). In southeast Queensland and northern New South Wales, the parasite infects over short periods in late summer (Lester 1986; Rubio et al. 2013). To avoid "QX Disease," as the infection is known, farmers empty estuarine leases in December (late spring) and restock in April (early autumn). In mid-New South Wales, epizootics are less regular but destroy most of the year's production when they occur.

Marteilia chungmuensis develops within the ovary of *C. gigas, Crassostrea nippona,* and *Saccostrea echinata*. In Japan it causes large nodules to form in the gonad of *C. gigas* rendering the oysters unmarketable (Ngo et al. 2003) (Fig. 2). Oysters develop disease only in the summer; low temperature inhibits the development of the infective stage in winter, although it is present all the year (Tun et al. 2008a). Infected oysters spawn later in the year than normal, and infected oocytes are sterile (Tun et al. 2008b). Those oysters that survive the winter lose their infection as they change to males. Like oysters with *M. refringens*, those infected by *M. chungmuensis* become watery from depleted glycogen reserves, though the paramyxidan is not very pathogenic (Tun et al. 2008b).

Paramarteilia orchestiae in the testes of male gammarids result in the crustaceans becoming females or intersex forms (Ginsburger-Vogel 1991). Crabs infected by the systemic *Paramarteilia canceri* are lethargic and have shrunken internal organs (Feist et al. 2009).

Characterization and Recognition

Life Cycle

In *Marteilia refringens*, *M. sydneyi*, and *M. chungmuensis*, initial stages occur within the tissues of the gills, palps, to a lesser extent mantle, and anterior gut. After entry the paramyxidans divide, and bicellular stages are liberated into the surrounding connective tissue and hemolymph spaces. Following systemic dissemination, the parasite infiltrates the target organ. In *M. sydneyi* the outer cell forms a nurse cell beneath the epithelial cells of a digestive tubule. Within this cell, daughter cells and eventually sporonts develop (Figs. 3, 4, and 5). A nurse cell has not been reported from *M. chungmuensis*, which develops in the ovary (Itoh et al. 2004).

Spores, enclosed within a propagule (sporont) singly or in pairs or groups depending on the species, are released with oyster feces or, in the case of *M. chungmuensis*, enclosed in an ovum and released through the genital canal (Tun et al. 2008b). The next stage in the life cycles is not clear. Though Comps and Joly (1980) found what appeared to be young stages of *M. refringens* in *M. galloprovincialis* after exposing them to a homogenate from infected *O. edulis*, the life cycles have been generally considered to be indirect. Attempts by Balouet et al. (1979) and others to infect oysters with *M. refringens* by feeding or injecting infected homogenized digestive gland, by cohabitation with infected stock or by introduction of oysters into the field after a disease event, failed to produce infections detectable by histology. Lester (1986) made the same observations with *M. sydneyi*. These negative results, together with the poor survival of *M. sydneyi* spores in seawater (Roubal et al. 1989; Wesche et al. 1999) compared to the long periods of

Fig. 3 Proposed development of *Marteilia sydneyi* in *Saccostrea glomerata*. (***A***) Initial replication in the gill and palp epithelium. (***B***) Disseminating cell enters subepithelium of digestive tubule to form nurse cell Nc. (***C***) Daughter cells (*Dc*) internally cleave primary cells (*Sc*) which then internally cleave 8–16 secondary cells (sporonts) each containing two multicellular spores (From Kleeman et al. 2002)

a year or more between disease outbreaks, led to a search for an alternate host. A non-specific DNA probe SMART2 has enabled researchers to visualize paramyxeans in putative alternate hosts particularly copepods (Audemard et al. 2004; Carrasco et al. 2008; Boyer et al. 2013; Arzul et al. 2014) and polychaetes (Adlard and Nolan 2015).

It is not certain that an alternate host is required. In a Mediterranean lagoon, infections by *M. refringens* were common in mussels, found by histology, and confirmed by PCR but were not detected, by histology, in oysters in the same area (Arzul et al. 2014). On the east coast of Australia, using PCR and in situ hybridization, *M. sydneyi* was shown to be present in *S. glomerata* in areas where it had never been detected by histology and which had no history of the disease (Adlard and Wesche 2005). Lester (1986) found that oysters with overt infections could survive the summer and may have been able to carry the disease through the winter. These

results have moved the research focus to the conditions that precipitate the rapid and extensive sporulation that kills the oysters.

High temperature has been associated with high prevalence of a number of paramyxidans. In northern France *M. refringens* is most prevalent in *O. edulis* during the summer when the temperature is over 17°C (Balouet et al. 1979; Audemard et al. 2004). In the Mediterranean it is abundant, in *M. galloprovincialis*, in early and late summer (Boyer et al. 2013). Prevalence of *M. chungmuensis, in C. gigas,* increased in summer (Imanaka et al. 2001), and mortality associated with *Marteilia conchillia*, in *Cerastoderma edule*, occurred when temperatures were up to 29 °C (Carrasco et al. 2015), though *Eomarteilia granula* in *Ruditapes philippinarum* was detected (by histology) more frequently in winter (Itoh et al. 2014).

For *M. sydneyi*, onset of disease has been linked to high temperatures and sudden changes in salinity (Lester 1986; Green et al. 2011; Rubio et al. 2013). Under normal conditions *S. glomerata* appear to be able to kill sporulating parasites and survive. Low salinity has been shown to inhibit defense mechanisms, but as low salinity is not invariably associated with disease other factors must be at play. Immunosuppression in *S. glomerata* has been demonstrated to occur with a range of factors such as extremes of temperature, physical agitation, magnesium chloride, and starvation. The environmental stressors needed to trigger a lethal outbreak of QX disease are currently unknown (Raftos et al. 2014).

Selective breeding of *S. glomerata* for QX resistance has been successful. Dove et al. (2013) found up to 72% survival by progeny in a QX outbreak after four generations of selection versus 3% survival in controls. Dang et al. (2011) observed 80% survival after five generations versus 14% in controls. The resistance appears to be from an enhanced ability to kill *M. sydneyi*, rather than block its entry, a capacity apparently linked to the high number of granulocytes in the hemolymph of resistant oysters (Dang et al. 2011). However, even with genetically bred resistant oysters, the resistance can be overwhelmed (Dang et al. 2013), and the continued susceptibility of local oysters in an area endemic for the disease suggests that the natural development of resistance may involve the loss of another capability (Thompson et al. 2015).

Paramarteilia orchestiae in amphipods of the genus *Orchestia* and an unknown paramyxidan in the amphipod *Echinogrammarus marinus* appear to be vertically transmitted (Ginsburger-Vogel 1991; Short et al. 2012).

Ultrastructure

During the sporulation of paramyxidans, primary cells (C1) bud endogenously to form secondary cells (C2-sporont), in which tertiary cells (C3) bud to form the outer spore wall in which further cells bud (C4–C6) (Fig. 6). Primary cells, tertiary cells of most species, and some spore cells (Larsson and Køie 2005) contain haplosporosomes, but secondary cells do not (Figs. 1, 6, and 7). Haplosporosomes have an external and an internal unit membrane, may contain DNA (Perkins 1968), have glycoproteins in the core and membranes with more glycoproteins in the outer membrane than the inner, and the outer has a lipid component (Azevedo and Corral

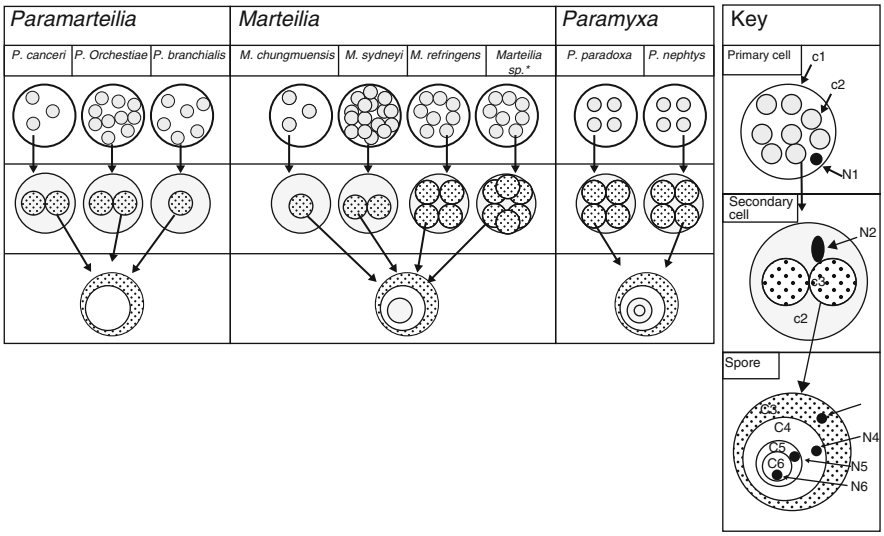

Fig. 6 Proposed division of the genera based on the number of cells in the spore. Marteilia sp.* is *Marteilia* sp. of Lopez and Darriba (2006). Numbered nuclei are shown in the key on the right (From Feist et al. 2009)

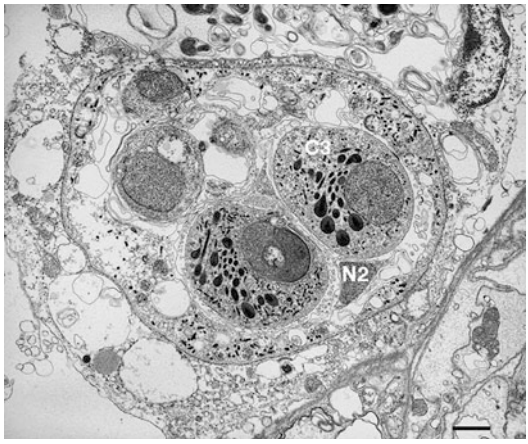

Fig. 7 *Paramarteilia canceri* early pansporoblast (sporont) containing secondary cells and tertiary cells (*C3*) with typical electron-dense bulbous haplosporosomes. The nucleus of the secondary cell (*N2*) is constrained to the periphery of the secondary cell and assumes a triangular appearance on cross section. Bar = 0.5 um

1985). In some haplosporidians, the outer membrane fuses with the parasite plasma membrane permitting exocytosis of the haplosporosome (Hine et al. 2002). Endogenous budding appears to occur by the linking up of cytoplasmic vesicles to form membranes (Perkins and Wolf 1976; Ginsburger-Vogel and Desportes 1979a, b; Anderson and Lester 1992; Larsson and Køie 2005). Primary and secondary cells become compressed during sporogony, the nuclei often appear triangular in cross section (Fig. 7).

The Primary Cell (C1)

Primary stem cells are often amoeboid (Comps et al. 1986; Kleeman et al. 2002) and contain many ribosomes, smooth endoplasmic reticulum (sER), and haplosporosomes, in all species. They may develop dendritic extensions used to nourish the cell (Kleeman et al. 2002). Multivesicular bodies (MVBs) have been reported from *Marteilia christenseni, M. sydneyi, Paramarteilia branchialis*, and *Paramarteilia* spp., but not *P. paradoxa, P. nephtys,* or *M. refringens* and may be involved in haplosporogenesis (Perkins and Wolf 1976). Mitochondria occur in the primary cells of *P. paradoxa* and *M. sydneyi* but have not been reported in other species. *Marteilia refringens* and *M. christenseni* primary cells have cytoplasmic striated platelike inclusions (Grizel et al. 1974; Comps 1983; Longshaw et al. 2001).

The Secondary Cell (C2) or Sporont

Secondary cells have many ribosomes and vesicles and may have mitochondria (Perkins and Wolf 1976; Ginsburger-Vogel and Desportes 1979b; Desportes 1981; Comps 1983; Anderson and Lester 1992), centrioles (Ginsburger-Vogel and Desportes 1979a; Comps et al. 1986; Larsson and Køie 2005; Feist et al. 2009), or cytoplasmic refringent granules (Perkins and Wolf 1976; Comps 1983; Itoh et al. 2014). Haplosporosomes are absent, but in *M. branchialis* (Anderson and Lester 1992), and possibly *M. chungmuensis* (Fig. 7 in Comps et al. 1986) they develop after nuclear division but before tertiary cell formation. In *P. nephtys* and *P. canceri*, there are perinuclear masses of dense material resembling those seen in early haplosporogenesis in haplosporidians (Larsson and Køie 2005; Feist et al. 2009; Hine et al. 2002). The C2 of *M. chungmuensis* and C3 of *M. branchialis* are encircled by layers of sER (Comps et al. 1986; Anderson and Lester 1992). In *M. refringens* and *M. sydneyi*, C2 persists as the wall of the propagule which is released from the oyster and which contains refringent granules and spores.

The Tertiary Cell (C3) or Spore Wall Cell

Tertiary cells usually contain ribosomes, sER, vesicles, and haplosporosomes, but seldom mitochondria (Perkins and Wolf 1976), and form the outer layer of the spore. Exceptions are *P. paradoxa* in which haplosporosomes only occur in C1 and C4 (Desportes 1981), and *P. nephtys* in which haplosporosomes occur in C1, C4, and C5 (Larsson and Køie 2005). Large haplosporosomes occur in C3 cells of *P. orchestiae* (see Ginsburger-Vogel and Desportes 1979b), and *P. canceri,* and in the latter are associated with many MVBs (Feist et al. 2009) (Figs. 7 and 8). In *P. nephtys*, after degeneration of C1 and C2, C3 forms a sac around the spores from material released

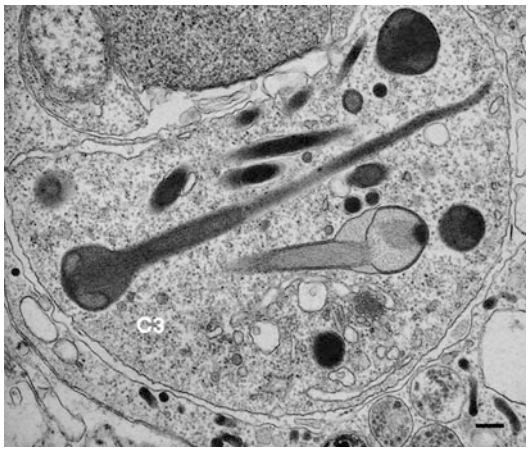

Fig. 8 *Paramarteilia canceri* tertiary (*C3*) cell with bulb-ended haplosporosomes. Bar = 0.2 um

from regularly arrayed ridges on its surface (Larsson and Køie 2005). The spore wall of *P. paradoxa* is underlain by a cytoskeleton of microtubules (Desportes 1981), possibly associated with cell division. Its spores lie in sacs comprising the residual membrane of the sporont (Desportes 1981). Subsequent shrinkage and appearance of fibrous material results in the formation of striated projections on the spore wall. The C3 of *E. granula* (Itoh et al. 2014; Ward et al. 2016) has a thick external wall, unlike other genera. In *M. refringens* central thin laminated structures are present within the C3 (Grizel et al. 1974). In *M. sydneyi* the C3 produces a thick layer of concentric membranes that surrounds the spore cells (Perkins and Wolf 1976). In *M. christenseni* the C3 forms a double membrane containing fine granular osmophilic material (Comps 1983).

Spore Cells (C4–C6)

C4 cells, sometimes called intermediate cells (Grizel et al. 1974; Perkins and Wolf 1976; Desportes 1981; Comps 1983; Larsson and Køie 2005), and their subsequent endogenous cells are rich in ribosomes and sER. They may include mitochondria and haplosporosomes, although these vary between species. In *E. granula, M. sydneyi*, and *M. christenseni*, flattened vermiform vesicles occur in intermediate cells, but only in C3 of *M. refringens* (Perkins and Wolf 1976; Comps 1983; Grizel et al. 1974). Larsson and Køie (2005) state that C4 and C5 of *P. nephtys* have haplosporosomes, which are spherical in C4 and rodlike in C5. The sporoplasms of *M. refringens* contain central thin laminated structures (Grizel et al. 1974). Otherwise, C4 onward are uniformly described as being small and dense with ribosomes, sER, and haplosporosomes and the nuclei having prominent nucleoli. The nuclei are usually round and dense, but in the inner sporoplasm of *P. paradoxa* they are horseshoe shaped (Desportes 1981).

Taxonomic Position of Paramyxidans

The taxonomy of the Paramyxida has frequently changed (Berthe et al. 2004), and the group has been recognized as a phylum (Desportes and Perkins 1990), separate from the Haplosporidia and the Myxosporea (Berthe et al. 2000), although they and haplosporidians have also been regarded as separate orders within the phylum Cercozoa (Cavalier-Smith and Chao 2003a, b). The relationship of paramyxidans with haplosporidians and myxosporeans has been studied because all three groups possess prominent cytoplasmic haplosporosomes (paramyxidans, haplosporidians) or sporoplasmosomes (myxosporeans), and myxosporeans, like paramyxidans, divide by endogeny. The occurrence of endogeny in the Paramyxida has led to the suggestion that they are intermediate between protists and multicellular organisms (Desportes 1984). Paramyxidan haplosporosomes resemble those of haplosporidians in the disappearance of haplosporosome-like bodies from early vegetative cells, to be reformed in the spore, and in the occurrence of invaginations in the nuclear surface and perinuclear dense granular material (Feist et al. 2009). Haplosporosomes in haplosporidian spores and sporoplasmosomes of myxosporeans develop from similar membranous structures. There is no apparent role for haplosporosomes in any of the three groups, except perhaps release and the lysis of surrounding cells in some haplosporidians and myxosporeans.

The suggestion by Cavalier-Smith and Chao (2003a, b) that *Marteilia refringens* is a haplosporidian is not supported by ultrastructure, spore formation, spore structure (Hine et al. 2009), or analysis of the small subunit ribosomal gene sequence (Berthe et al. 2000). Paramyxidans divide by endogeny and possess centrioles (Ginsburger-Vogel and Desportes 1979a), while haplosporidians do not undergo endogeny and appear to lack centrioles, although a reticulated structure in some haplosporidians may be a degenerate centriole (Hine et al. 2002).

Taxonomy Within the Paramyxida

The taxonomy of paramyxidans has been based on the pattern of endogenous cleaving of the primary or stem cell, giving rise to secondary cells, which become sporonts when further cleaving occurs to produce spores. However, the taxonomy is confusing as some authors follow cleaving patterns, primary cells giving rise to secondary cells that develop to tertiary cells, etc., while others regard the cleaving within secondary cells as sporulation, the secondary cell being a sporont. There is also confusion as to whether a primary stem cell gives rise to a single secondary cell within a cytoplasmic vacuole (Desportes 1981), and primary cells are less common than would be expected (Berthe et al. 2004), given current interpretations of development.

Definitions of genera have included:

Paramyxa Chatton, 1911: Primary cell produces two to four secondary cells or sporonts. Each sporont produces four tetracellular spores.

Paramyxoides Larsson and Køie 2005: Primary cell produces two to four secondary cells or sporonts. Each sporont produces four tetracellular fusiform spores.

Paramarteilia Ginsburger-Vogel and Desportes, 1979b: As *Marteilia* spp. but producing a bicellular spore.

Eomarteilia (syn. *Marteilia*) *granula* Itoh, Yamamoto, Kang, Choi, Green, Carrasco, Awaji, Chow 2014: Primary cell gives rise to eight secondary cells (sporangia), each containing four spores, comprising innermost, intermediate, and outermost cells.

Marteilia Grizel, Comps, Bonami, Cousserans, Duthoit and Le Pennec, 1974: Secondary cells (sporanges) each give rise to eight cells.

Marteilioides: (Comps et al. 1986): Production of one tertiary cell from each secondary cell. Differentiation of a tricellular spore from the sporont.

Paramyxa and *Paramyxoides* are similar in having two to four secondary cells, each of which produces four tetracellular spores, and both are parasites of the digestive tracts of polychaetes. However, *Paramyxoides* was distinguished from *Paramyxa* because the latter has rod-shaped spores with plugs at each end and the innermost cell (cell 4) contains haplosporosomes, while the former has fusiform spores, and cells 4 and 5 contain haplosporosomes (Larsson and Køie 2005). There is no formal definition of the genus *Marteilia* or the species *M. refringens,* only microscopic observations on tissue tropism and development, which showed that the secondary cell (sporont) produces eight cells (Grizel et al. 1974), while the congeneric *M. sydneyi* sporont produces 8–16 cells (Berthe et al. 2004). There is also disagreement over whether the secondary cell (Berthe et al. 2004) or the tertiary cell is the sporont (Desportes and Perkins 1990). The genus *Marteilioides* is defined as producing tricellular spores (Comps et al. 1986), but the congeneric *M. branchialis* produces bicellular spores (Anderson and Lester 1992).

A recent review of eukaryote taxonomy (Adl et al. 2012) defines the Paramyxida as having a bicellular spore, consisting of a parietal cell and one sporoplasm, without an orifice. The definition needs to be broadened to reflect the variation in sporogony observed in *Paramyxa* and *Paramyxoides,* which have tetracellular spores and *Marteilioides* with tricellular spores. In describing the stages, terms such as sporont, sporoplasm, and spore suggest function. When the function is unknown, C1–C6 have been used.

A proposal has been made to revise the taxonomy of paramyxidans with emphasis on the number of cells comprising the spore, the number of cells produced by secondary cells (sporonts), and the shape of the spores (Feist et al. 2009) (Fig. 6). This proposal gives emphasis to the spore cell number, the number of secondary cells, and similarity in host group and tissue tropism, resulting in only three genera. An analysis of known 18S sequences was not quite congruent with this classification. Ward et al. (2016) concluded that *Marteilia granula* was distinct from other *Marteilia* species and proposed the genus *Eomarteilia* for this species. Their analysis also suggested that the species *Marteilia chungmuensis* was close to the *Paramarteilia* clade despite having a more complex spore and suggested that *Marteilioides* should be retained for *M. chungmuensis*. No 18S sequence is currently available for *Marteilioides branchialis*. As 18S sequences are not invariably good discriminators of genera, it would be useful to have sequences from other parts of the genome to clarify relationships.

Classification

Paramyxida (Chatton 1911)

Sporulation results from series of internal cleavages within an amoeboid stem cell that germinates spores in tissues of invertebrate animals. Development characterized by production of offspring cells that remain inside the parent cell. Spores consist of several cells enclosed inside each other. Parasitic. Four genera in proposed revision of the phylum (Feist et al. 2009):

Paramyxa Each secondary cell produces four tertiary cells (spores), each of which contain three additional cells. Sporulate in polychaetes. The genus comprises two species, *P. paradoxa* and *P.* (*Paramyxoides*) *nephtys.*

Eomarteilia Each of the eight secondary cells produces four spores composed of three cells. Sporulation in *Ruditapes philippinarum.* Currently a monotypic genus, phylogenetically basal to *Marteilia* spp.

Marteilia Secondary cells produce variable number of tertiary cells, each of which contain a further two cells. Sporulate in mollusks. The genus comprises *M. refringens, M. sydneyi,* and *M.* (*Marteilioides*) *chungmuensis* (but see note above).

Paramarteilia Secondary cells produce variable number of tertiary cells, each of which contains a further single cell. Sporulate in mollusks and crustaceans. The genus comprises *P. orchestiae, P. canceri*, and *P.* (*Paramarteilia*) *branchialis.*

This scheme proposes that from the number of cells in the spore, *Paramyxoides* is congeneric with *Paramyxa*, that *M. branchialis* be transferred to the genus *Paramarteilia,* and that *M. chungmuensis* is a species of *Marteilia*.

P. paradoxa and *P. nephtys* are more similar to each other than to other known genera in their pattern of sporogony and in having elongated rather than spherical spores. However, in *P. paradoxa* the cytoskeleton, rodlike spores with terminal plugs in which transverse section are rosette like (Desportes 1981) and differ considerably from the ridges in the spore wall of C3, the sacs around spores, their fusiform shape and elongated striated projections in *P. nephtys* (see Larsson and Køie 2005). Retention of separate genera may be valid but as Larsson and Køie (2005) observe, they are probably con-familial.

In *Paramarteilia* spp., the C3 of *P. orchestiae* have large dense osmiophilic bodies (Ginsburger-Vogel and Desportes 1979b), but, in the C3 of *P. canceri,* bacilliform haplosporosomes develop from MVBs, and large elongated haplosporosomes with bulbous heads are present (Feist et al. 2009) (Figs. 7 and 8). In the C3 of *M. branchialis*, large (>300 nm in diameter) dense osmiophilic bodies and haplosporosomes are present (Anderson and Lester 1992), suggesting they may be congeneric with *Paramarteilia* spp. However, the C3 of *M. branchialis* (Anderson and Lester 1992) is encircled by layers of sER similar to those of *M. chungmuensis* (see Comps et al. 1986) and unlike other genera making the placement of *M. branchialis* in the genus *Paramarteilia* less certain.

Eomarteilia is distinguished by the thick wall in C3 and flattened vesicles in C4.

It appears that *Marteilia* spp. may be distinguished from other paramyxidan genera by the presence of flattened vermiform vesicles associated with the plasma

membrane of C3 in *M. refringens* or intermediate cells of *M. sydneyi* and *M. christenseni* (Grizel et al. 1974; Perkins and Wolf 1976; Comps 1983). It is unclear whether *M. chungmuensis* possesses similar vesicles, although the text of Comps et al. (1986) mentions "des trabécules vermiformes opaques aux électrons," none are visible in the electron micrographs.

Maintenance and Cultivation

These organisms require host cells in order to develop. The required cell lines are not yet available. Though Ginsberger-Vogel and Carre-Lecuyer (1976) were apparently able to infect gammarids by implanting tissue from an infected gammarid, it has not yet been possible to infect oysters in the laboratory by this method (Balouet et al. 1979; Lester 1986) or even to have early infections thrive in already infected oysters (Tun et al. 2008a; Lester unpubl.), possibly because the environmental stressors and/or nutritional requirements of the target tissues are not met in laboratory tanks.

Evolutionary History

The evolutionary history of paramyxidans depends on whether they belong in an order within the cercozoans (Cavalier-Smith and Chao 2003a, b) or are an independent phylum not closely related to other eukaryotes (Berthe et al. 2000). If the former is the case, they are rhizarians, a group comprising radiolarians and foraminiferans which have an abundant fossil record extending back to the early Cambrian. The fossil record of the cercozoan *Difflugia* extends back to the Neoproterozoic, 1,000–542 ± 1 million years ago (Finlay et al. 2004). However, while molecular studies have shown a close relationship between cercozoans and foraminiferans in the amino acid sequences of their α-tubulin, β-tubulin, and actin (Takashita et al. 2005), in their polyubiquitin (Archibald et al. 2003), and SSU rRNA (Berney and Pawlowski 2003) genes sequences, cercozoans are morphologically diverse, and no morphological feature distinguishes them from other protists. Their position within the Cercozoa is uncertain because they differ from all other protists in their SSU rRNA gene sequences (Berthe et al. 2000) and because they are multicellular (Desportes 1984). As they are soft bodied, there is no paramyxidan fossil record.

Haplosporidia

23

Carlos Azevedo and P. Mike Hine

Abstract

Haplosporidian species (phylum Haplosporidia Caullery & Mesnil, 1899) are a small group of four genera of sometimes pathogenic protozoan parasites usually with uninucleated spores. They are widely distributed in marine and freshwater invertebrates, although their status in Africa, much of Eurasia and Central and South America, is largely unknown. They infect molluscs including commercially important bivalves and other molluscs, annelids, crustaceans, ascidians, trematodes, turbellarians, and probably many invertebrate groups. The morphology, development, and ultrastructure of the four haplosporidian genera (*Haplosporidium*, *Minchinia*, *Urosporidium*, and *Bonamia*) are described using light, scanning, and transmission electron microscopy. Several new haplosporidian species have recently been described based on their genetic sequences, spore morphology, and ornamentation. Ultrastructural organization of the spores and the origin of the spore wall ornamentation are discussed. This phylum contains 52 described species and several unnamed species reported in the four genera. Life cycle stages involve exosporulation of the endosporoplasm to form multinucleate plasmodia and sporoblasts giving rise to the spores that are described from some species. The phylogenetic analysis based on SSU rRNA strongly supports that the genera *Minchinia*, *Urosporidium,* and *Bonamia* are monophyletic, while

the genus *Haplosporidium* is paraphyletic. The taxonomic positions and affinities between these genera within phylum Haplosporidia are discussed. The negative economic impact on the commercially important infected hosts is reported.

Introduction

General Characteristics

The phylum Haplosporidia (syn. Aplosporidia Caullery & Mesnel, 1899; Ascetospora Sprague, 1979; or Balanosporidia Sprague, 1979) is a protozoan group that infects several tissues/organs of different species of some invertebrate groups. These include molluscs (Arzul and Carnegie 2015), such as bivalves (Bower and McGladdery 2003; Burreson and Ford 2004), gastropods (Azevedo 1984; Azevedo et al. 2006; Burreson 2001; Vea and Siddall 2011; Ituarte et al. 2014), chitons (Ball 1980), arthropods (Newman et al. 1976; Larsson 1987; Dyková et al.

1988; Lipa and Hokkanen 1991; Marchand and Sprague 1979; Perkins 1975; Bower and Meyer 2002; Stentiford et al. 2004, 2013; Winters and Faisal 2014), annelids (Ormières 1980), platyhelminths (De Turk 1940; Zaika and Dolgikh 1963), echinoderms (La Haye et al. 1984), tunicates (Ormières and de Puytorac 1968), and other groups (see below). Some haplosporidians infect parasites in clams, cockles, oysters, and other invertebrates (Perkins 1971, 1979; Perkins et al. 1975; Carballal et al. 2005; Le et al. 2015).

They appear to infect mainly commercially important molluscs from freshwater, brackish, and marine environments, but this reflects research effort to date, and it is likely that they are ubiquitous in other invertebrate groups. Haplosporidians occur in different regions of the world (Azevedo 1984; Perkins 2000; Bower and Meyer 2002; Hine and Thorne 2002; Bower and McGladdery 2003; Burreson and Ford 2004; Ituarte et al. 2014), although their status in many regions (Africa, Central Eurasia, Central and South America) is largely or totally unknown. They are sometimes responsible for significant mortality in their hosts (Haskin et al. 1966; Diggles et al. 2002; Hine and Thorne 2002; Hine et al. 2002b; Renault et al. 2002; Burreson and Ford 2004; Cranfield et al. 2005; Bearham et al. 2008a, b, c).

Historically, the phylum Haplosporidia contained three genera: *Haplosporidium* Caullery & Mesnil, 1899; *Minchinia* (Lankester, 1895) Labbé, 1896, and *Urosporidium* Caullery & Mesnil, 1905 (Figs. 1a–c, 2a–i, and 3a–c). However, electron microscope and molecular phylogenetic studies support the inclusion of the genus *Bonamia* Pichot et al. 1980 within the phylum Haplosporidia (Fig. 3d, e) (Hine and Jones 1994; Hine et al. 2001; Reece et al. 2004; Carnegie et al. 2006). Another genus *Mikrocytos* Farley et al. 1988 comprised two species, *Mikrocytos mackini* and *Mikrocytos roughleyi*, which are not known to form spores, but *M. roughleyi* was later reclassified as a haplosporidian, *Bonamia roughleyi* (Carnegie et al. 2000; Cochennec-Laureau et al. 2003). However, a subsequent molecular study could not identify the organism as a separate species from *B. exitiosa* (Carnegie et al. 2014), and the disease, "winter mortality" with which *M. roughleyi* was associated, cannot be attributed to *B. exitiosa/roughleyi* clade (Engelsma et al. 2014; Spiers et al. 2014).

The phylum Haplosporidia at the present consist of 52 species in four genera (*Haplosporidium*, *Minchinia*, *Urosporidium*, and *Bonamia*) and several unnamed species. They form spores with an uninucleated endosporoplasm surrounded by the spore wall that has an orifice (micropyle) and a complex membranous system named spherulosome (formerly named spherule) (Azevedo and Corral 1985, 1989). The orifice is either covered by a hinged operculum on the other face of the orifice or occluded by a lingula that covers the inner edge of the orifice (Perkins 1971). Haplosporosomes are cytoplasmic inclusions of haplosporidian spores that characterize this taxonomic group. These structures are randomly distributed throughout the cytoplasm and are delimited by a membrane and characterized as being electron-dense organelles with variable morphology (Figs. 2d, h, i, and 3a, c). The spores of the genera *Haplosporidium* and *Minchinia* are similar, possessing an orifice covered by a hinged operculum differentiated from spore wall, differing in the presence or absence of "ornaments" attached to the spore wall (Fig. 2a–d). The lack of uniform terms to describe these structures has caused some taxonomic confusion (Azevedo

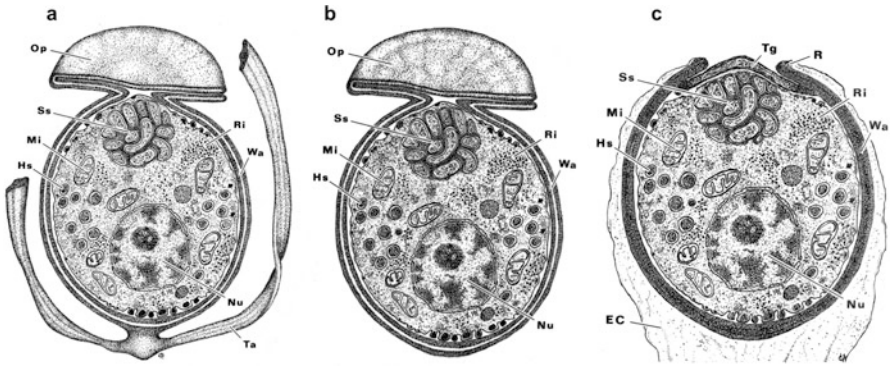

Fig. 1 Schematic drawings showing the morphological and taxonomic differences among the spores of the three genera of the phylum Haplosporidia: (**a**) *Haplosporidium lusitanicum* showing a spore with two tails, as ornaments of the spore wall, and the operculum; (**b**) *Minchinia* sp. showing a spore with the operculum without any ornaments; (**c**) *Urosporidium* sp. showing a spore with the apical orifice of the spore closed by a flap of wall material and the epispore cytoplasm extending posteriorly into an ephemeral tapering extension. *Abbreviations*: *Op* operculum, *Ss* spherulosome, *Mi* mitochondria, *Hs* haplosporosomes, *Ta* tail, *Nu* nucleus, *Wa* spore wall, *Ri* ribosomes, *EC* epispore cytoplasm, *R* rim, *Tg* lingula

2001; Azevedo et al. 2006; Burreson 2001; McGovern and Burreson 1990; Burreson and Reece 2006).

At the present, it is difficult to characterize and define Haplosporidia. Some species, particularly those of crustaceans (Newman et al. 1976; Dyková et al. 1988; Bower and Meyer 2002; Stentiford et al. 2004, 2013; Nunan et al. 2007) and some *Bonamia* spp. (Pichot et al. 1980; Hine et al. 2001), lack spores, and bodies similar to the characteristic haplosporosomes are not recognizable in some species (Bower and Meyer 2002; Stentiford et al. 2004).

Literature and History of Knowledge

Over a century ago, two French researchers, Maurice Caullery and Félix Mesnil in 1899, created the genus *Aplosporidium* to contain the species *A. scolopli* and *A. heterocirri*, two sporozoan parasites of marine annelids. They proposed the genus *Aplosporidium* that was considered an incorrect transliteration according to the Article 32 of the International Code of Zoological Nomenclature. Later, the correct transliteration was applied and thereby altered to the new name *Haplosporidium* (Sprague 1963b). The phylum Haplosporidia consists of four genera: *Haplosporidium*, *Minchinia*, *Urosporidium*, and *Bonamia* (Burreson and Ford 2004). The status of the two major genera, *Haplosporidium* and *Minchinia*, continues to be confused and is a source of disagreement between some authors (Azevedo et al. 1999, 2003; Perkins 2000; Burreson 2001).

Perkins); (**d**) The uninucleate infective stage of *B. exitiosa* showing the central nucleus with a nucleolus, mitochondria, spherical haplosporosomes, endoplasmic reticulum, and lipid droplets; (**e**) Detail of a spore of *Bonamia* enclosed in a hemocyte showing the nucleus and the cytoplasmatic organelles (Courtesy of Elsevier). *Abbreviations*: (*) external epispore cytoplasm, *Wa* spore wall, *Op* operculum, *Ss* spherulosome, *Hs* haplosporosomes, (**) endospore, *M* mitochondria, *ER* endoplasmic reticulum, *L* lipid droplet, *HC* hemocyte, *Nu* nucleus, *R* rim, *Tg* lingula

Fig. 2 (continued) spore wall, spherulosome, and haplosporosomes; (**i**) A spore of *H. armoricanum* showing the wall, the anastomosing spherulosome beneath the hinged lid, a basal nucleus, and elongated, axe-head-shaped haplosporosomes in between. The bundle of microfilaments is a common feature of unknown function in the spores of some *Haplosporidium* spp. *Abbreviations*: *Ta* tails, *Op* operculum, *Ss* spherulosome, *Hs* haplosporosomes, *Nu* nucleus, *Wa* spore wall, *EC* epispore cytoplasm, (*) exosporoplasm, (*arrows*) exosporoplasm membrane

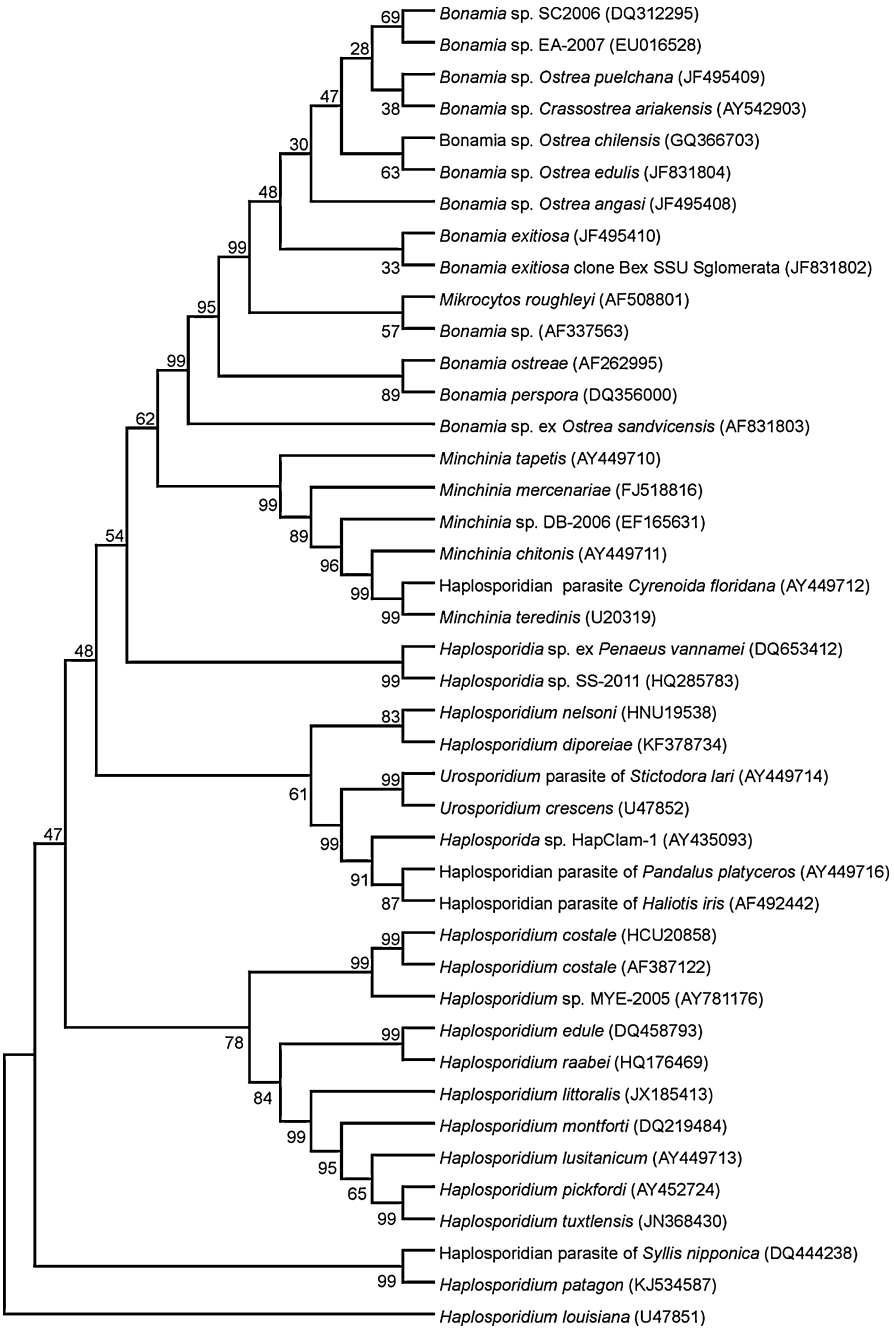
Much attention has been given to spore ornamentation (variously termed filaments, tails, projections, extensions, folds, wrappings, bifurcated slender projections, and epispore extensions) in the different descriptions (Perkins and van Banning 1981; Azevedo and Corral 1985; McGovern and Burreson 1990; Comps and Tigé 1997; Azevedo et al. 1999; Burreson 2001; Hine and Thorne 2002; Azevedo et al. 2003, 2006; Carnegie et al. 2006; Bearham et al. 2008a; Molloy et al. 2012). They were regarded as the principal taxonomic feature distinguishing the genera *Haplosporidium, Minchinia,* and *Bonamia perspora* (Burreson 2001; Burreson and Reece 2006), but a molecular study (Burreson and Reece 2006) showed no correlation between ornamentation and phylogeny, and it appears that they are not taxonomically important. This is not surprising given that *Haplosporidium* is a paraphyletic genus (Flores et al. 1996; Burreson and Ford 2004; Hine et al. 2007), containing *Haplosporidium*-like orphan species, such as *H. parisi* (Ormières 1980) and *H. ascidiarum* (Ciancio et al. 1999) that are ultrastructurally different and probably belong in separate genera. Unfortunately the type *Haplosporidium*, *H. scolopli*, is inadequately described, there being no molecular tools or electron microscopy in 1899, and until rediscovered and adequately described, other *Haplosporidium*-like species cannot be distinguished from it. Consequently, generalizations cannot be made about the spore ornamentation of all current *Haplosporidium* spp. The spores of *Minchinia* spp. are devoid of ornaments (Azevedo et al. 1999; Burreson and Reece 2006). However, an unnamed *Minchinia* sp. has epispore cytoplasmic extensions, unattached to the spore wall and comprising microtubules (Comps and Tigé 1997), but these structures are considered to be ephemeral, disappearing during the spore maturation process (Azevedo et al. 1999; McGovern and Burreson 1990).

Phylogeny

Several studies on haplosporidians include phylogenetic trees (Reece and Stokes 2003; Burreson and Ford 2004; Reece et al. 2004; Azevedo et al. 2006; Carnegie et al. 2006; Nunan et al. 2007; Molloy et al. 2012; Burki et al. 2013; Stentiford et al. 2013; Engelsma et al. 2014; Ituarte et al. 2014; Sierra et al. 2015) which differ in details depending on how they are constructed (Table 1). A study using group-specific PCR primers on eDNA samples revealed several distinct novel clades, novel lineages within known clades, and seasonal and habit-related patterns in assemblage composition (Hartikainen et al. 2014). Planktonic stages and host-free stages were also detected, in these highly divergent and diverse lineages.

These trees are consistent in (a) the basal position of the spot prawn (*Pandalus*) parasite (SPP) and New Zealand abalone parasite (Reece and Stokes 2003; Reece et al. 2004; Hartikainen et al. 2014); (b) more derived but intermediate positions of *Urosporidium* spp., *H. nelsoni*, and *H. louisiana*; (c) the integrity of *Minchinia* spp. and *Bonamia* spp., which are sister clades (Engelsma et al. 2014; Hartikainen et al. 2014); and (d) the phylogenetic closeness of gastropod *Haplosporidium* spp. A "core" group of *Haplosporidium* spp. comprises *H. lusitanicum*, *H. pickfordi*

Table 1 Maximum likelihood tree of the SSU rRNA sequences of different species of phylum Haplosporidia. Numbers on the branches are bootstrap percent values on 500 replicates trees. There were a total of 1712 positions in the final dataset. GenBank accession numbers in parentheses after the species name



(Fig. 4g), *H. tuxtelensis*, *H. montforti*, and *H. littoralis*, while *H. edule* and *H. raabei* cluster together (Hartikainen et al. 2014). *H. nelsoni* is not included in the "core" group.

Phylogenetically, *Bonamia perspora* and *B. ostreae* are more closely related to each other than to *B. exitiosa*, while a *Bonamia* sp. in *Dendostrea sandvicensis* in Hawaii is basal to the other *Bonamia* spp. (Hill et al. 2014).

According to recent phylogenetic studies, rhizarian (supergroup Rhizaria) parasites evolved from homoplastic processes occurring both in the animal and plant lineages. The first comprises the Ascetospora, intracellular parasites that infect marine invertebrates and that form a monophyletic clade in which all haplosporidian species are included (Burki et al. 2013; Sierra et al. 2015).

Practical Importance

Haplosporidians infect and cause disease in commercially important oysters, such as *Crassostrea virginica* (Perkins 1968, 1969; Ford and Haskin 1982), *Crassostrea gigas* (Comps and Pichot 1991; Renault et al. 2002), *Ostrea edulis* (Pichot et al. 1980; Hine et al. 2007), *Ostrea chilensis* (Hine 1991; Cranfield et al. 2005; Lane et al. 2016), *Ostrea puelchana* (Kroeck and Montes 2005), and *Saccostrea cucullata* (Hine and Thorne 2002; Bearham et al. 2008b). They also infect pearl oysters (Hine and Thorne 1998; Bearham et al. 2008a), clams (Azevedo 2001; Ford et al. 2009), cockles (Azevedo et al. 2003), mussels (Comps and Tigé 1997), and abalone (Diggles et al. 2002; Azevedo et al. 2006, 2007; Balseiro et al. 2006). In economic terms, *C. virginica* (Ford and Haskin 1982), *O. edulis* (Tigé et al. 1986), and *O. chilensis* (Cranfield et al. 2005) have suffered the biggest impacts. There may be indirect impacts, such as the discoloration of nematodes infected with *Urosporidium spisuli* in clams, making them unattractive to consumers (Perkins et al. 1975).

There is evidence that haplosporidians of clams, *M. tapetis* and *M. mercenaria*, may be associated with epizootics (Hartikainen et al. 2014).

Commercially important shrimp, *Penaeus vannamei* (Dyková et al. 1988; Nunan et al. 2007), and a crab (Newman et al. 1976) are also infected with haplosporidians, with losses in *P. vannamei* culture in Indonesia estimated at >US$ 5 m over 5 years (Utari et al. 2012).

Characterization and Recognition

General Appearance

Phylogenetically Basal Haplosporidians

The phylogenetically basal haplosporidian of the spot prawn (*Pandalus*) parasite (Reece et al. 2004) infecting and castrating *Pandalus platyceros* comprises multinucleate plasmodia that divide into uninucleate trophonts, some of which contain a

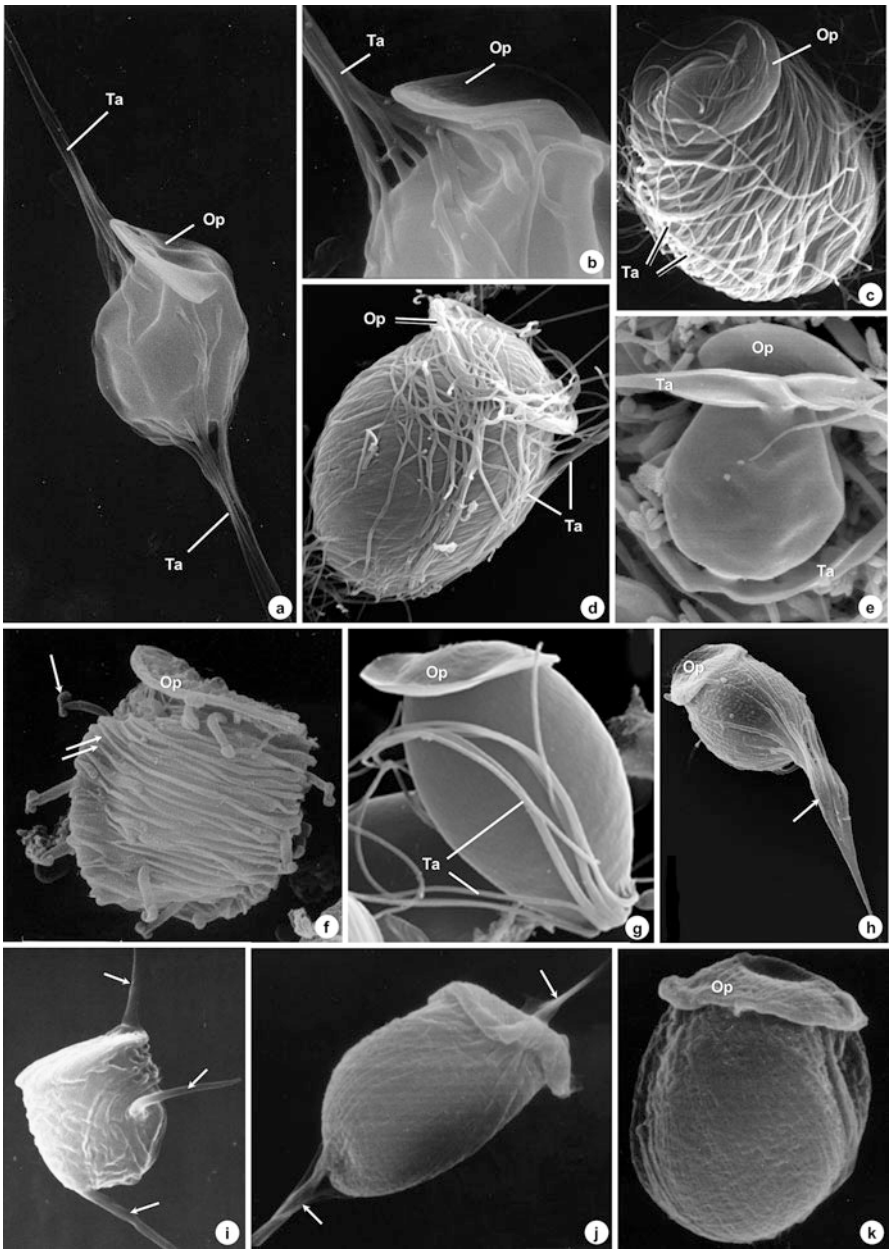


Fig. 4 Scanning electron micrographs of aspects of spores of some haplosporidian species: (**a**, **b**) *Haplosporidium armoricanum* showing some details of the external morphology evidence of tails and operculum (Courtesy of Springer); (**c**) *H. louisiana* showing a complex network of the tail and operculum (Courtesy of E. M. Burreson); (**d**) *H. nelsoni* (Courtesy of E. M. Burreson; Permission of Allen Press); (**e**) *H. montforti*: spore showing the tails and operculum (Courtesy of Elsevier);

dense basophilic inclusions. Ultrastructurally single-membraned peanut-shaped bodies containing tiny tubules cluster around the nucleus; there are plasmalemma extensions resembling ectoplasmic nets and large round to oval cytoplasmic inclusions, sometimes with a light periphery and darker core. Characteristic haplosporosomes are not present (Bower and Meyer 2002).

Conversely, the phylogenetically basal New Zealand abalone parasite (Reece and Stokes 2003) infecting *Haliotis iris* (Diggles et al. 2002; Hine et al. 2002b), has characteristic haplosporosomes formed from material in indentations on the nuclear surface, which is processed through Golgi to the *trans*-Golgi network where haplosporosomes form. These then either pass to the plasma membrane where the outer haplosporosome membrane fuses with the plasma membrane to release the core, or they are degraded in autophagic-crinophagic vacuoles in the cytoplasm. Released cores may also be internalized and degraded in these vacuoles (Hine et al. 2002b). Spores are unknown, observations being restricted to one outbreak of disease in one abalone farm. It is noticeable that currently molecular phylogenies place the spot prawn parasite and the New Zealand abalone parasite together at the base of haplosporidian phylogeny, despite them being so different that other than basic eukaryotic structure and organelles they appear to have nothing in common.

Haplosporidium – The principal characteristics of this genus are spores with an apical-hinged operculum (Fig. 2c–f) and a variety of extensions externally (tails, filaments, extensions, wrapping, folds, and epispore extensions) (Fig. 2c, d, g) formed by the same material of the spore wall. The number of ornaments is variable according to the different species. The internal uninucleated endosporoplasm contains a spherulosome (structure formerly designated by the name "spherule"), generally located at the apical region of the spore, several haplosporosomes, and mitochondria (Fig. 2h, i). However, a parasite of shore crabs (*Carcinus maenas*), *Haplosporidium littoralis* (Stentiford et al. 2013) does not appear to form spores (Stentiford et al. 2004). The occurrence of ultrastructural features reported up to 2009 has been compared (Fig. 2i) (Hine et al. 2009).

Haplosporidium louisiana (Sprague 1963b) (Figs. 4d, e) infects crabs, *Panopeus herbstii* in the USA, and a very similar species, *Minchinia cadomensis* (Marchand and Sprague 1979) infects crabs, *Rhithropanopeus harrisii* in France. They are probably conspecific and regarded as *H. louisiana.* This species is phylogenetically basal to other *Haplosporidium* spp. (see above) and differs from them in

haplosporogenesis occurring in plasmodia from amorphous electron-dense masses formed by nuclear membrane-bound Golgi, which contain membrane-bound vesicles that by budding into the cytoplasm acquire a second membrane to form classic haplosporosomes (Perkins 1975, 1979). Spores are ~12 × 8 μm, with a spherulosome which produces striated formative bodies from which haplosporosomes form by budding.

Haplosporidium nelsoni parasitizes *Crassostrea virginica* and *Crassostrea gigas*, the former in eastern North America and the Gulf of Mexico, the latter in western North America, Europe (France, Spain, Ireland), and east Asia (Japan, China, South Korea) which was probably the origin of North American and European infections.

Haplosporidium costale infects oysters (*Crassostrea virginica* and *Crassostrea gigas*) on the eastern coast of the USA (Perkins 1969), France (Comps and Pichot 1991), and China (Wang et al. 2010).

Haplosporidium lusitanicum (Azevedo 1984) parasitizes the gills and visceral tissues of *Helcion pellucidus* (Mollusca, Gastropoda). Spores are ellipsoidal ~3.0 × 2.1 μm and surrounded by a proteinaceous wall ~0.1 μm thick (Figs. 1a, and 2d, e, h, i). In the basal region, the wall is thicker and gives rise to two long tape-like proteinaceous filaments (or tails), each ~112 μm long (Fig. 2c, d, g). The apical zone of the spore wall is modified into a complex opercular system covering a circular orifice (micropyle) ~0.5 μm in diameter (Fig. 2d, e, h).

Haplosporidium armoricanum (Azevedo et al. 1999) (syn. *Minchinia armoricana* (van Banning 1977) parasitizes the oyster *Ostrea edulis.* It was transferred to *Haplosporidium* on the basis that it has filaments originating from the spore wall. The ellipsoid spores are about 5.0 μm long and 3.1 μm wide with an operculum and two long epispore cytoplasm extensions (ECE) attached eccentrically at opposite ends of the spores (Figs. 2i, 3a, and 4b). The base of each ECE is attached to the spore wall by a bundle of 9–13 cylindrical fibers arising from the spore wall (Figs. 2i, 4b, and 5a). Each of these filaments is about 130 μm long. Spores may have a spherulosome and Golgi attached to the nucleus (Hine et al. 2007).

Haplosporidium montforti (Azevedo et al. 2006, 2007) infects the connective tissue, gill, digestive gland, and foot muscle of the abalone, *Haliotis tuberculata*, imported from Ireland and experimentally grown in Galicia, Spain. The spores are spherical to slightly ellipsoidal (2.4 ± 0.5 × 2.3 ± 0.6 μm). The apical pole of the spore wall is modified into a complex opercular system covering a circular orifice that measures about 0.5 μm across. The operculum is connected to the spore wall by a hinge. The spore wall is about 110 nm thick, with four filaments (or tails) (20–28 μm long). The cross-sections through the base of these filaments are T-like and X-like (Figs. 2f, 4e, and 5b). Internally, the uninucleated endosporoplasm contained typical haplosporidian structures, such as haplosporosomes, a spherulosome, and mitochondria with vesicular cristae (Fig. 5b).

Haplosporidium edule (Azevedo et al. 2003) parasitizes the digestive gland tissues of the cockle *Cerastoderma edule* in Galicia (northwest Spain) and has tape-like filaments (Figs. 4f and 5c). The spores are ovoid to ellipsoidal ~3.2 × 2.2 μm with the apical wall modified into a complex opercular system covering the micropyle. The spore wall 0.1–0.12 μm thick is composed of three

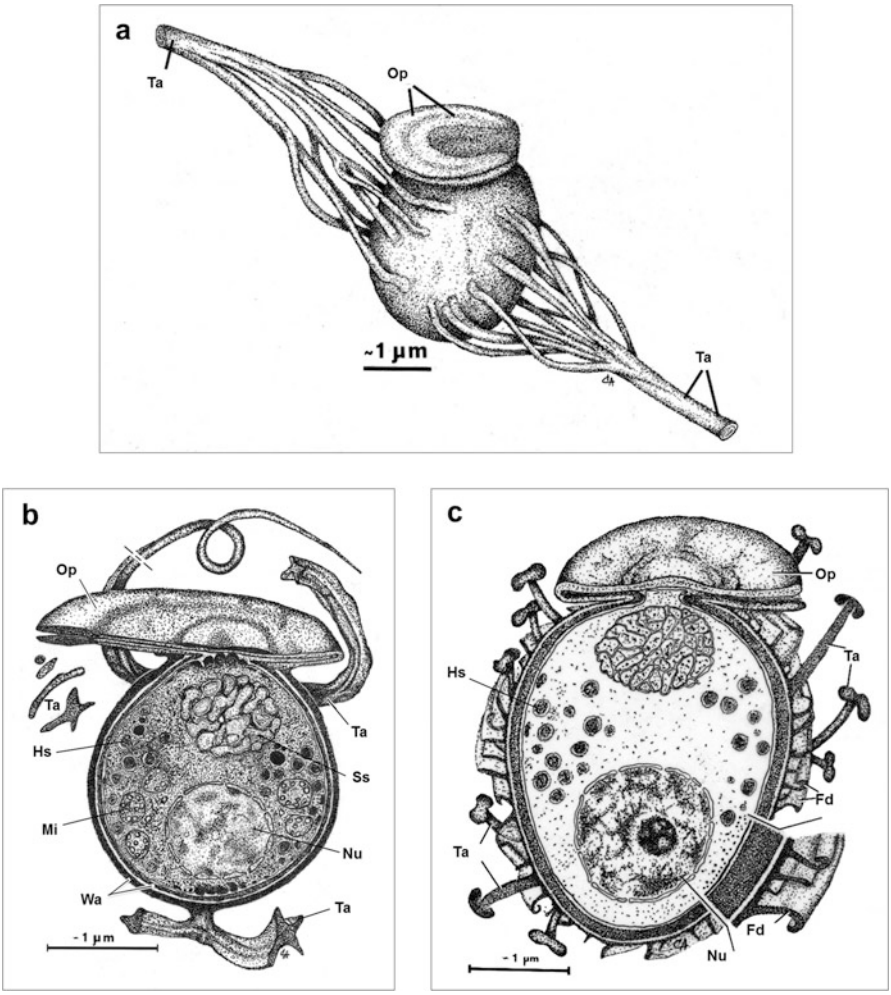

Fig. 5 Schematic drawings of spore of some haplosporidian species showing the external and internal organization: (**a**) *H. armoricanum* (Courtesy of Elsevier); (**b**) *H. montforti* (Courtesy of Elsevier); (**c**) *H. edule* (Courtesy of Springer). *Abbreviations*: *Op* Operculum, *Ta* Tails, *Ss* Spherulosome, *Hs* Haplosporosomes, *Mi* Mitochondria, *Wa* Spore wall, *Nu* Nucleus, *Fd* Folds

layers. The outermost has numerous folds surrounding the periphery of the spores. Several slender projections having two short opposite, dilated branches emerge between the folds (Fig. 4f). The inner endoplasm contains similar structures as those described in *H. lusitanicum*.

Haplosporidium littoralis (Stentiford et al. 2013) is a parasite of green crabs (*Carcinus maenas*) that is only known from multinucleate plasmodia that divide by cytokinesis to form uninucleate stages that undergo karyokinesis to form more plasmodia (Stentiford et al. 2004). Haplosporosomes are arrayed around the nuclear

membrane. Not only spores, but even the initial stages of sporogenesis, are not observed. Haplosporidians of blue crabs (*Callinectes sapidus*) (Newman et al. 1976) and *Penaeus vannamei* (Dyková et al. 1988; Nunan et al. 2007) also comprise uninucleate stages and multinucleate plasmodia with haplosporosomes arrayed around the nuclear membrane, with no evidence of sporogenesis. Therefore, *H. littoralis* and the two unnamed species may represent a group of crustacean haplosporidians that appear to be different from *H. louisiana*, which has spores.

Minchinia – This genus is characterized by having mature spores without any ornaments. The endosporoplasm of *Minchinia* structurally resembles *Haplosporidium* spp., having a spherulosome, haplosporosomes, and mitochondria (Fig. 3a). The immature spores when observed free may present an epispore (exospore) cytoplasm forming an ephemeral extension that disappears in the final phase of spore maturation (Fig. 4h–k).

Minchinia tapetis (Azevedo 2001) (formerly described as *Haplosporidium tapetis*) was described parasitizing the clam *Tapes decussatus* gill. The internal organization of *Minchinia* spore was similar to that *Haplosporidium*, however, without spore ornamentations (Figs. 3a, b, and 4k). The immature spores may show the presence of an ephemeral surrounding epispore cytoplasm that disappears during the final phase of maturation (Fig. 4j, k).

Urosporidium – The spores of this genus are characterized by flask-shaped spores, with a cap covering the orifice (Figs. 1c and 3c). The spores of different species are spherical to ellipsoidal or oval, measuring 3.0–5.5 μm in width and 3.0–6.0 μm in length. Some spores have extrasporal ornamentations deriving from the epispore cytoplasm (Le et al. 2015). Epispore extensions may be fibrous (Anderson et al. 1993; Le et al. 2015), have a dense core (Perkins et al. 1975), have ribbons and extensions (Carballal et al. 2005), or contain microtubules (Ormières et al. 1973). The endosporoplasm of these spores is similar to those of *Haplosporidium* spp. (Fig. 1a–c), except the equivalent of a spherulosome may occur as scattered cisternae throughout the sporoplasm (Perkins 1971; Perkins et al. 1975) or as parallel cisternae underlying the plasma membrane, the spherulosome having no fixed position in relation to the apical orifice (Anderson et al. 1993).

Bonamia – The cells of *Bonamia* spp. measure 2–5 μm in diameter and are intrahemocytic within the connective tissue of the mantle and gills and in the vascular sinuses near the digestive gland, intestine, and stomach (Fig. 3d, e). The cells of *B. ostreae* are smaller (2–3 μm), and in tissue smears the nucleus appears eccentric, whereas in *B. exitiosa* smears, the nucleus is central, giving a "fried egg" appearance.

This genus comprises three species which infect oysters, of which one species, *B. perspora*, forms spores and the other two species, *B. ostreae* and *B. exitiosa*, are not known to form spores. Another organism, originally described as *Mikrocytos roughleyi* (Farley et al. 1988), was transferred to the genus *Bonamia* (Cochennec-Laureau et al. 2003), but this is probably not a valid classification, and it may be a form of *B. exitiosa* (Carnegie et al. 2014). *B. perspora* infects small oysters, *Ostreola equestris* (type host), in North Carolina, USA (Carnegie et al. 2006).

Bonamia ostreae infects *Ostrea edulis* on the eastern and western coasts of the USA and is present in several Western European countries (France, Ireland, Italy, the

Netherlands, Portugal, Spain, and the UK). It has recently been reported from New Zealand (Lane et al. 2016), which is the first report from the Southern Hemisphere. It is thought to have originated from eastern North America, moved to the US west coast in infected oysters, and then moved from there to France in infected oysters in 1978–1979, resulting in massive European epizootics. *B. ostreae* has probably also infected *O. chilensis* (Grizel et al. 1983), *O. puelchana* (Pascual et al. 1991), and *O. angasi* (Bougrier et al. 1986) when introduced live into France. It can establish mild infections in *C. ariakensis*.

Bonamia exitiosa infects *Ostrea chilensis* (type host) in New Zealand (Fig. 3d), *O. angasi* in Australia, *O. puelchana* and *O. stentina* in Argentina, *O. stentina* from SE USA and the Mediterranean, *O. edulis* in Spain, and a related species parasitizes *O. chilensis* in Chile. It also infects *Crassostrea ariakensis* at the port of Morehead City Bay in North Carolina, USA (Audemard et al. 2014), but only in the vicinity of the port (Bishop et al. 2006). This finding and the origin of an epizootic of *B. exitiosa* in an oyster (*O. puelchana*) next to a bunkering wharf for international shipping in San Antonio Bay, Argentina (Kroeck and Montes 2005), strongly suggests that this parasite has been spread by international shipping.

Ultrastructure

The Haplosporidia were originally regarded as spore-forming species (Fig. 1a–c), but *B. ostreae* and *B. exitiosa* were reported infecting oysters in the absence of spores. Despite this, their uninucleate and multinucleate stages containing typical haplosporosomes closely resemble the presporogonic stages of spore-forming haplosporidians, and they are recognized as such (Carnegie et al. 2000). Uninucleate and multinucleate stages with typical haplosporosomes, but without spores, have also been reported from crabs (Newman et al. 1976) and shrimps (Dyková et al. 1988). Two other crustacean-infecting haplosporidians, the phylogenetically basal spot prawn parasite (Reece et al. 2004) and *H. littoralis*, which is phylogenetically close to *Haplosporidium* spp. from gastropods (Stentiford et al. 2013), also do not appear to form spores, but *H. littoralis* has dense vesicles among which some may have an inner membrane suggestive of haplosporosomes (Stentiford et al. 2004), and the basal spot prawn parasite lacks haplosporosomes (Bower and Meyer 2002).

Plasmodial Stages

Uninucleate stages (Fig. 3d) contain a usually central nucleus, with or without intranuclear microtubules, Golgi that often arises from the nuclear membrane (Perkins 1968, 1969, 1971, 1975; Perkins et al. 1975; Hine 1991; Hine and Wesney 1992, 1994a; Hine et al. 2001, 2007, 2009; Carnegie et al. 2006) and is associated with a *trans*-Golgi network from which haplosporosomes form (Perkins 1968, 1969, 1975, 1979; Hine 1991; Hine and Wesney 1992, 1994a, b; Hine et al. 2001; Carnegie et al. 2006), mitochondria, and smooth endoplasmic reticulum. In *H. nelsoni* dense

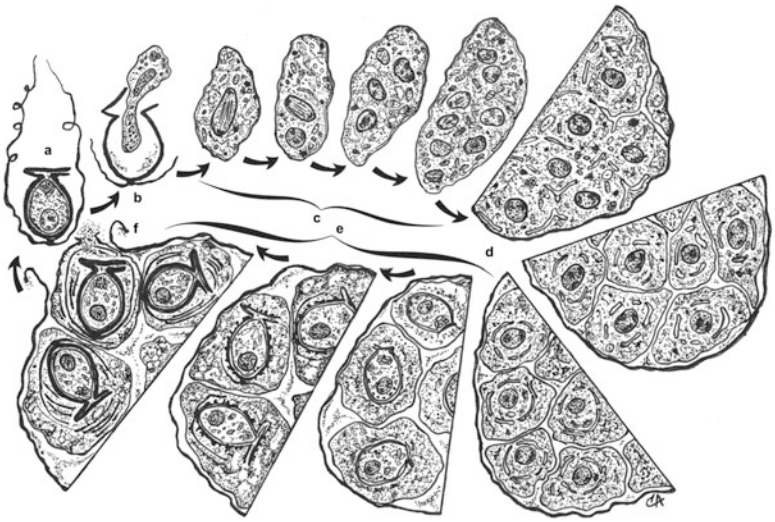

Fig. 6 Schematic drawing of the life cycle (spores → plasmodium → sporontes → sporoblasts → to 100 spores) of *Haplosporidium lusitanicum:* (*a*) free mature spore; (*b*) excystment of the spore thought the micropile; (*c*) sequential phases of the plasmodial development after penetration on the host, characterized by sequential nucleokineses originating a plasmodium with some hundreds of nuclei; (*d*) development of several cisternae around the nuclei, each of one give rise to a nucleate cell (sporont); (*d–f*) sporoblasts within the sporocyst and sequential phases of sporogenesis during which each sporoblast gives rise to a spore, when mature is released from the sporocyst by rupture of its wall

cytoplasmic formative inclusions give rise to haplosporosomes (Perkins 1968, 1979). In haplosporidians infecting crustaceans, the haplosporosomes may cluster around the nucleus (Newman et al. 1976; Dyková et al. 1988; Stentiford et al. 2013). The nucleus divides by binary fission (Figs. 6 and 7c), sometimes to form diplokarya (Fig. 7d). (Perkins 1968, 1969, 1971), and multiple divisions result in a multinucleate plasmodium (Azevedo et al. 1985) (Figs. 6 and 7a–e). Formation of diplokarya may indicate the beginning of sporogony.

The multinucleate plasmodia undergo irregular multiple fission (plasmotomy) to yield daughter cells – the sporonts (Figs. 6 and 7a–e). In the next phase, a very irregular membranous system and some Golgi complexes begin to differentiate in the cytoplasm, among the plasmodial nuclei. Each nucleus and a portion of surrounding cytoplasm are encircled by a limiting membrane which arises from fusion of Golgi vesicles (Fig. 8a, b). In sporonts, several hundred sporoblasts are thus formed (Fig. 8c, d). Sporoblastogenesis is characterized by a gradual thickening of the sporoblast membrane which becomes the spore wall (Fig. 8d and inset). During the thickening of the wall, the pre-operculum appears and later differentiates into an operculum, while in the endosporoplasm, the spherulosome and haplosporosomes begin their formation. Sporogenesis occurs during the development of the spore wall, and in spores with ornaments, their development begins. Later, each sporoblast differentiates into immature spores (Fig. 8e) (Azevedo et al. 1985, 2007). Spore

The sporoblasts are surrounded by an irregular sporocyst wall (*arrows*); (**d**) Aspect of the initial process of spore wall formation showing several blisters of dense material (*arrows*):

maturation occurs during the degradation of the episporoplasm, rupture of the sporocyst, and liberation of the mature spores (Fig. 6).

The spores of the paraphyletic *Haplosporidium* spp., *Minchinia* spp., and *Bonamia perspora* are similar (Burreson and Ford 2004; Carnegie et al. 2006), having an oval to ellipsoidal shape, with an apical pore covered by a hinged operculum. The spores range in size from about 3–8 × 2–5 μm. The spore ornaments are not of taxonomic significance (Burreson and Reece 2006), except that *Minchinia* spp. lack spore ornaments and epispore cytoplasm is never attached to the spore wall. Internally, the endosporoplasm contains haplosporosomes, mitochondria, the spherulosome, and Golgi equivalent. *Urosporidium* spp. have spores without an operculum but instead an internal flap of wall material covering the spore wall orifice. The spore wall does not have ornaments (Figs. 1c and 3c).

When the mature spores are free or within the same host (Perkins 1975, 1979; Ball 1980; Desportes and Nashed 1983; Azevedo 1984; Hine and Thorne 2002), excystment of endosporoplasm occurs through the micropyle of the spore (Figs. 6 and 7a) (Azevedo and Corral 1989).

Life Cycle

The life cycles of spore-forming species are unknown despite attempts to determine the life cycle of *H. nelsoni* (Burreson et al. 1997). The developmental cycle of *H. lusitanicum* (Fig. 6) may represent the sequential phases in the majority of haplosporidian species, but there is no evidence that *H. lusitanicum* transmits directly between chiton (*Helcion pellucidus*) hosts. *Bonamia perspora*, unlike other *Bonamia* spp., forms spores, and *H. littoralis,* unlike other spore-forming *Haplosporidium* spp., does not. While utilization of more than one host has its advantages (dispersal, survival, reservoir hosts), it also has the disadvantage of relying on all hosts to be available. Direct transmission by species that do not form spores is of benefit when the host species is abundant, with contiguous populations, but not when hosts are scattered or the parasite has to be dormant to survive.

Life cycles may have a degree of plasticity, depending on environmental conditions. New Zealand *B. exitiosa* has large amoeboid stages (Hine and Wesney 1994a), not reported from other *B. exitiosa*, and diplokaryotic stages and plasmodia with slightly thickened membranes suggestive of early sporogony, although further development has not been observed. Under unfavorable conditions, *H. littoralis* may form spores but under favorable conditions may not need to sporulate and may

Fig. 8 (continued) inset – details of the process (Courtesy of Elsevier); (**e**) An immature spore showing a nucleus, pre-spherulosome, mitochondria, and the spore wall with the operculum (Courtesy of Elsevier). *Abbreviations*: *Sb* sporoblasts, *Nu* nucleus, *Ss* pre-spherulosome, *Mi* mitochondria, *Wa* spore wall, *pOp* pre-operculum, *Op* operculum

transmit directly. Even when sporulation occurs, direct uninucleate or plasmodial transmission may also be possible.

An environmental DNA (eDNA) study (Hartikainen et al. 2014) found evidence of *H. edule*, *M. tapetis*, and *B. exitiosa* in planktonic samples, suggesting these species may utilize plankton in their life cycles, although *B. exitiosa* also transmits directly (Hine et al. 2002a). *B. ostreae* also infects planktonic larvae of its oyster host (Arzul et al. 2011). The eDNA study found similar and novel haplosporidian sequences in benthic and planktonic samples from Europe, Panama, and South Africa (Hartikainen et al. 2014), suggesting ubiquitous infection in invertebrates including zooplankton globally.

Systematics

Overall Phylogenetic Position

The protistan phylum Haplosporidia is composed of histozoic parasites of great variety of freshwater and marine invertebrate.

Systematics

The taxonomy of the phylum Haplosporidia is not well yet established. In this document, it was decided to present one of the most consensual taxonomies of this group that includes the Haplosporidia:

Protista (kingdom)
Rhizaria (supergroup)
Cercozoa
Ascetospora
Haplosporidia Caullery & Mesnil, 1899 (phylum)
Haplospora Caullery, 1953 (class)
Haplosporida Caullery & Mesnil, 1899 (order)
- Haplosporiidae (family)
  - *Haplosporidium* (with 34 species)
  - *Minchinia* (with 6 species)
  - *Bonamia* (with 3 species)
- Urosporiidae (family)
  - *Urosporidium* (with 9 species)

Evolutionary History

There is no fossil record of haplosporidians. However, molecular phylogenies show that haplosporidians are cercozoans (Cavalier-Smith and Chao 2003), related to Foraminifera and Radiolaria, which evolved in the early Cambrian (Pawlowski et al. 2003). Like foraminiferans and radiolarians, the basal haplosporidian SPP

(Reece et al. 2004) has ectoplasmic extensions. Haplosporidians may also therefore date back to the Cambrian.

List of the Haplosporidian Species

Aplosporidium Caullery & Mesnil, 1899 (name later altered to *Haplosporidium*)

- *A. scolopli* Caullery & Mesnil, 1899 (later altered to *Haplosporidium scolopli*)
- *A. heterocirri* Caullery & Mesnil, 1899 (later altered to *Haplosporidium heterocirri*);

Anurosporidium Caullery & Chappellier, 1906 (later altered to *Urosporidium*)

- *A. pelseneeri* Caullery & Chappellier, 1906 (later altered to *Urosporidium pelseneeri*)

Haplosporidium Caullery & Mesnil, 1899

1. *H. scolopli* (Caullery and Mesnil 1899) (formerly described as *Aplosporidium*)
2. *H. heterocirri* (Caullery and Mesnil 1899) (formerly described as *Aplosporidium*) (altered to *Minchinia* and later newly transferred to the genus *Haplosporidium*)
3. *H. marchouxi* (Caullery and Mesnil 1905)
4. *H. potamillae* (Caullery and Mesnil 1905)
5. *H. vejdovskii* (Caullery and Mesnil 1905)
6. *H. limnodrili* (Granata 1914)
7. *H. nemertis* (Debaisieux 1920)
8. *H. caulleryi* (Mercier and Poisson 1922)
9. *H. mytilovum* (Field 1924)
10. *H. ascidiarum* (Duboscq and Warrant 1923)
11. *H. cernosvitovi* (Jírovec 1936)
    - *H. tapetis* (Vilela 1951) (later transferred to *Minchinia*)
12. *H. pickfordi* (Barrow 1961)
13. *H. costale* (Wood and Andrews 1962)
14. *H. louisiana* (Sprague 1963b) (*syn. H. cadomensis* Marchand and Sprague 1979) (formerly described as *Minchinia*)
15. *H. nelsoni* (Haskin et al. 1966) (formerly described as *Minchinia*)
16. *H. tumefacientis* (Taylor 1966)
17. *H. simulii* (Beaudoin and Wills 1968)
18. *H. macobdellae* (Jennings and Gibson 1968)
    - *H. cadomensis* (Marchand and Sprague 1970) (*Syn. H. louisiana* Sprague 1963b) (formerly described as *Minchinia*)
19. *H. prostomae* (Gibson and Moore 1979)
20. *H. parisi* (Ormières 1980)

21. *H. comatulae* (La Haye et al. 1984)
22. *H. lusitanicum* (Azevedo 1984)

Cryptophyta (Cryptomonads)

24

Kerstin Hoef-Emden and John M. Archibald

Abstract

Cryptomonads are small (~5–50 μm) biflagellate protists found in diverse freshwater, brackish, and marine habitats. They are characterized by a distinct cellular asymmetry and the presence of extrusive organelles called ejectosomes. Many cryptomonads are photosynthetic; their plastids are diverse in pigmentation and coloration. Plastid-bearing cryptomonads are noteworthy in their possession of a "nucleomorph," a residual nucleus of secondary endosymbiotic origin. Members of the cryptomonad genus *Goniomonas* lack plastids and ingest bacteria for nutrition. Mixotrophic cryptomonads may also exist, and loss of photosynthesis has given rise to colorless, heterotrophic, leucoplast-bearing species on multiple occasions. Cryptomonad taxonomy was traditionally based on morphology and now includes consideration of ultrastructural features such as the cell shape, the periplast structure, the type of cell invagination present (furrow-gullet system), the flagellar apparatus architecture, and the presence-absence of pyrenoids. However, molecular sequence data suggest that morphology is of limited taxonomic utility at the level of species identification. Cellular dimorphisms have been found within clonal cultures, supporting the notion that cryptomonads are capable of sexual reproduction. Approximately 20 genera and >100 species of cryptomonads have been described, although their true diversity and abundance in nature is unknown.

- - ***Goniomonas***

Introduction

General Characteristics

The cryptomonads (= cryptophytes = Cryptophyceae) are a delineated protist phylum. Most species are photosynthetic and motile (Figs. 1, 2, and 3); palmelloid forms are also known. The latter tend to form colonies invested in multiple mucilaginous sheaths. Some are known to form thick-walled cysts (Fig. 4). Cryptomonads are easily recognized with their flattened asymmetric cells, distinctive swimming motion, refractile ejectosomes (a kind of extrusome), and distinctive ultrastructure (Figs. 1, 5, 6, 7, 8, 9, 10, 11, and 12). Cryptomonad plastids contain chlorophylls *a* and c_2 as well as a proteinaceous phycobiliprotein as a second light-harvesting complex and are unusual in that a remnant nucleus of endosymbiotic origin lies in close association with the organelle (Fig. 11; see "Electron Microscopy" section below).

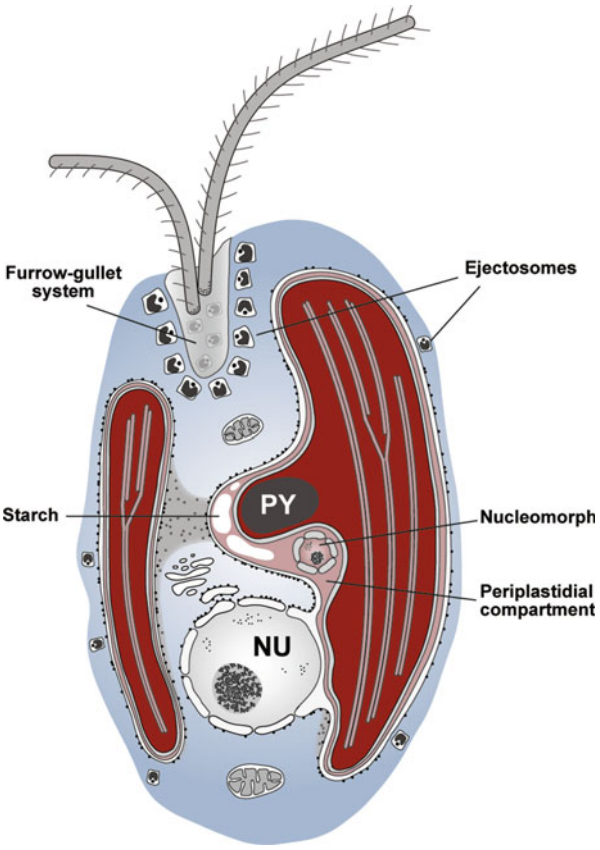

Fig. 1 Drawing of a generic cryptomonad cell. Most cryptomonads possess a single bilobed plastid surrounded by four membranes. The outermost plastid membrane is continuous with the endomembrane system and is studded with ribosomes. Abbreviations: *NU* nucleus, *PY* pyrenoid

It is often difficult to distinguish different cryptomonad genera from one another. Many taxonomically informative characters require electron microscopical methods and/or spectrophotometric analysis. Unidentified dimorphic life histories in some genera have resulted in an inconsistent systematics, and a lack of species-specific characters hampers identification of species by morphology. In several cryptomonad genera, species identification may be possible only with molecular signatures.

Occurrence

Cryptomonads are ubiquitous in marine, brackish, and freshwater habitats (Klaveness 1988), though it is currently not possible to determine the distribution of cryptomonad taxa on a global scale. Recent research has shown that even in well-sampled regions and habitats, the true diversity of cryptomonads has not yet been uncovered (von der Heyden et al. 2004; Hoef-Emden 2007; Lane and Archibald 2008; Shalchian-Tabrizi et al. 2008). Cryptomonads tend to be quite fragile; their numbers may therefore be underestimated in field collections.

Literature

No exhaustive monographs are available for cryptomonads. Traditional morphology-based classification schemes for cryptomonads are inconsistent (Deane et al. 2002; Hoef-Emden et al. 2002; Hoef-Emden and Melkonian 2003; Hoef-Emden 2005, 2007; Lane and Archibald 2008). Most of the literature addressing cryptomonad species or genera has relied on morphological characters alone and is therefore outdated. The most recent comprehensive keys for species identification were assembled by Huber-Pestalozzi (1950; freshwater taxa, in German), Butcher (1967; marine taxa), and Starmach (1974; freshwater taxa, in Polish). Although some genera have subsequently been revised or synonymized, classification schemes of cryptomonad genera based on ultrastructural characters nevertheless provide a good overview of cryptomonad cell biology (Clay et al. 1999; Kugrens and Clay 2002; Novarino 2003).

History of Knowledge

The name-giving genus *Cryptomonas* was erected by Ehrenberg in 1831. He described the first cryptomonad species in 1832 (Ehrenberg 1832), and figures

Fig. 3 *Cryptomonas borealis*, epitype strain CCAC 0113. Same cell as in Fig. 2, but with plane of focus in the cell middle, showing the ejectosome-lined gullet. *V* contractile vacuole

were published as colorized copper-plate engravings 6 years later (Ehrenberg 1838). The Ehrenberg Collection, which includes C. G. Ehrenberg's original watercolor drawings, manuscripts, and specimens, is maintained at the Museum für Naturkunde of the Humboldt University at Berlin (http://www.naturkundemuseum-berlin.de/en/collections/palaeontology/ehrenberg-collection/, last accessed 2016-01-15; Lazarus and Jahn 1998).

Practical Importance

Although cryptomonads have not yet been exploited commercially on a large scale, they are nontoxic, are easy to mass-cultivate, contain polyunsaturated fatty acids among other lipids, and are therefore used as food for copepods in fish farming (Brown et al. 1997; Knuckey et al. 2005). Cryptomonad biliprotein pigments may be used as fluorescent dyes (Telford et al. 2001; Sekar and Chandramohan 2008). Govorunova et al. found genes for channelrhodopsin proteins with seven transmembrane helices in the genome of the model cryptophyte *Guillardia theta* (Govorunova et al. 2015). When expressed in human embryonic kidney cells, these rhodopsins proved to be anion-specific (Cl^-) light-gated channels that can be used as

optogenetic tools in neuroscience research for the hyperpolarization of cells. Cryptophyte channelrhodopsins may thus prove useful as antagonists of chlorophyte Ca^{2+}-specific channelrhodopsins, which have already been established as tools to depolarize neural cells.

Habitats and Ecology

Photosynthetic cryptomonads belong to the phytoplankton community of essentially every body of water one can imagine, be it marine, brackish, or limnic; only the phagotrophic and aplastidic genus *Goniomonas* seems to be benthic (Skuja 1948; Klaveness 1988; Patterson and Simpson 1996; Bernard et al. 2000). Cryptomonads have been found in cold, temperate, and tropical waters; in offshore and coastal water samples; in rock pools, tide pools, freshwater lakes, ponds, puddles, and rain barrels; and even in snow and hypersaline lakes (Butcher 1967; Javornický and Hindák 1970; Klaveness 1988; Hill 1991a; Alcocer et al. 1998; Garibotti et al. 2003; Hoef-Emden 2007; Phlips et al. 2008). It is almost impossible to draw a water sample that does not contain at least a few cryptomonad cells. Cryptomonads are present throughout the year and are often reported as one of the most prominent or even the dominant algal group at certain times of the year (Alcocer et al. 1998; Garibotti et al. 2003; Phlips et al. 2008). Species of the genus *Cryptomonas* probably represent the most abundant

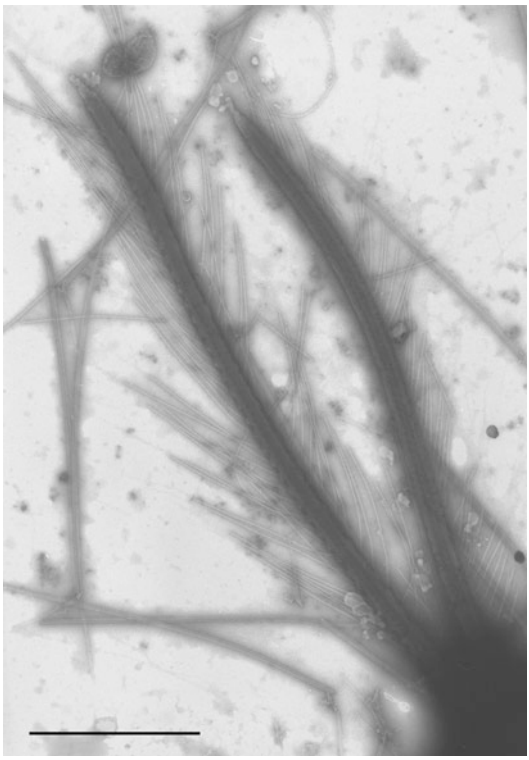

Fig. 5 Whole mount preparation of *Cryptomonas commutata* flagella (cryptomorph strain CCAC 0109). The longer flagellum has two opposite rows of flagellar hairs, the shorter one only one row. The straight structures scattered across the image are discharged ejectosomes. Uranyl acetate stain, negative contrast. Scale bar = 2 μm

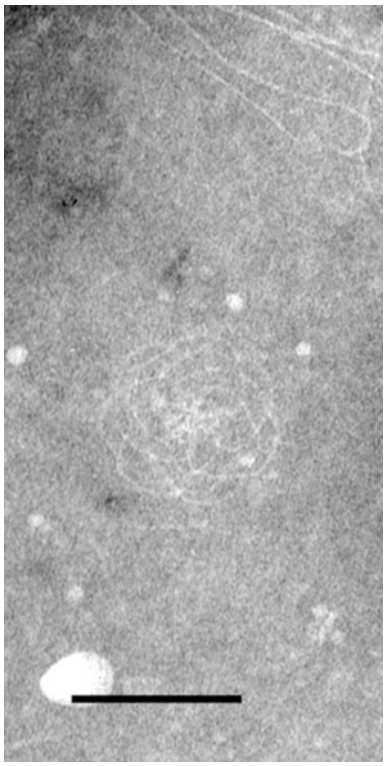

Fig. 7 Whole mount preparation of a Rosulate scale of *Rhodomonas* sp. strain CCAC 1090 B. Thin fibrils from the tip of a nearby flagellum are visible on the *top right*. Stained with methylamine tungstate, negative contrast. Scale bar = 125 nm

cryptomonads in freshwater, often forming dense populations close to the chemocline of lakes. They have been reported to migrate vertically in the water column down to the anoxic environment at night and up to the epilimnion during the day (Gasol et al. 1992; Gervais 1997; Camacho et al. 2001). Cryptomonads constitute a major component of aquatic food chains as nontoxic prey for planktonic ciliate, dinoflagellate, or copepod predators (Pedrós-Alió et al. 1995; Weisse and Kirchhoff 1997; Roberts and Laybourn-Parry 1999; Tirok and Gaedke 2007). Vertical migration and the formation of palmellae – accumulations of flagellated cells embedded in mucus – may represent predator avoidance strategies (Klaveness 1988). However, it has been hypothesized that cryptomonads stay close to the chemocline at night to take up nutrients such as phosphorus (Camacho et al. 2001). To survive unfavorable environmental conditions, *Cryptomonas* species may produce globular and thick-walled cysts as resting stages (Lichtlé 1979, 1980). Cryptomonads not only suffer from predation but can also be invaded by intracellular parasites (Brugerolle and Mignot 1979; Ettl and Moestrup 1980; Brugerolle 2002).

Photosynthetic cryptomonads are important primary producers in aqueous habitats, not only due to their ubiquitous presence and abundance but also as low-light specialists. Using biliproteins as light-harvesting complexes, compensation points of cryptomonad photosynthesis have been found at light intensities below 30 μmol

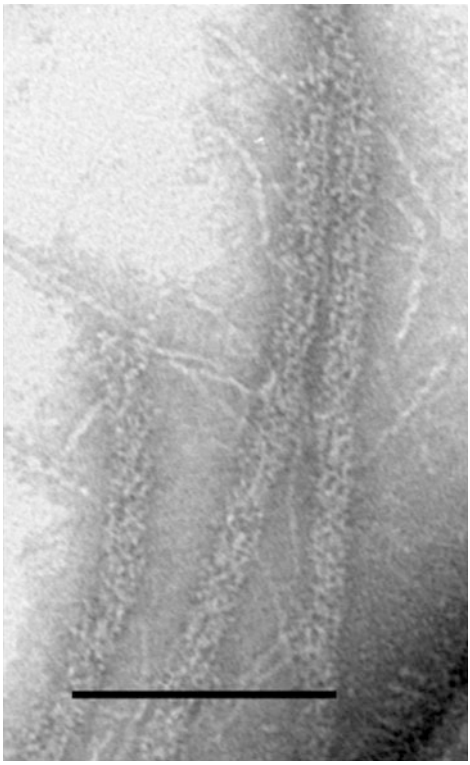

Fig. 8 Whole mount preparation of a "spiked" flagellum of *Goniomonas truncata* strain M0871. The granular surface structure of the "spikes" resembles that of flagellar hairs of plastid-containing cryptomonads. Short fibrils are attached to the "spikes." Uranyl acetate stain, negative contrast. Scale bar = 100 nm

photons m^{-2} s^{-1} (Gervais 1997; Hammer et al. 2002). In addition, the absorption spectrum of the biliproteins fills the "green gap" between the blue and red light absorption maxima of the chlorophylls. This enables cryptomonads to utilize the green light passing through layers of other algae (Doust et al. 2006).

Several reports indicate that plastid-containing cryptomonads may be mixotrophic. A marine strain of *"Chroomonas" salina* (subsequently renamed to *Rhodomonas salina*) was shown to be capable of growth in darkness at extremely high glycerol concentrations of 0.5 M (Antia et al. 1969). The observation that loss of photosynthesis has evolved at least three times independently from photosynthetic *Cryptomonas* ancestors further supports the notion of mixotrophy in photosynthetic cryptomonads (Hoef-Emden 2005). At least some strains of *Cryptomonas paramecium* (formerly subsumed under the genus *Chilomonas* together with the two other unrelated leucoplast-containing lineages; Hoef-Emden and Melkonian 2003; Hoef-Emden 2005) can grow axenically in media with organic additives (e.g., strain CCAC 0056; refer to the websites of the culture collections CCAC and CCAP for media recipes). While no cytostome has yet been observed in plastid-containing cryptomonads (unlike the phagotrophic genus *Goniomonas*), uptake of bacteria has been observed (Tranvik et al. 1989). According to Kugrens and Lee, bacteria entered the cells of a freshwater *Chroomonas* via the contractile vacuole (Kugrens and Lee 1990).

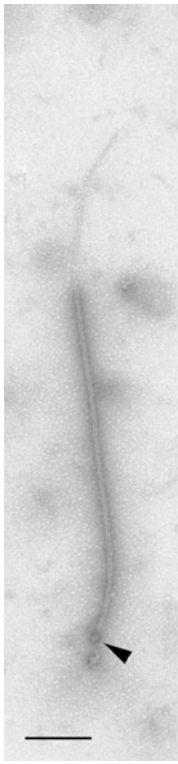

Fig. 9 Whole mount preparation of a detached flagellar hair of a *Cryptomonas obovoidea* flagellum (strain CCAC 0106 B). Flagellar hairs from the longer flagellum are attached to the axoneme by a globular structure (*arrow head*). Hairs from the shorter flagellum do not possess a globular attachment site and have a shorter shaft and two unequal filaments instead of only one terminal filament. Uranyl acetate stain, negative contrast. Scale bar = 250 nm

Other studies refute bacterivory or consider these bacteria to be merely endocytic (Schnepf and Melkonian 1990; Gervais 1997). Bacteria, however, may settle on the surface of *Cryptomonas* cells causing modifications in cell shape (Klaveness 1982).

Some cryptomonads are highly adaptable to different salinities. A *Chroomonas* species from South African habitats has been reported to grow in marine as well as freshwater media (Meyer and Pienaar 1984a). A vacuolar region in the apex of these cells transformed into a contractile vacuole in freshwater and vice versa. A more detailed study by Hoef-Emden (2014) confirmed most of the observations of Meyer and Pienaar. However, the contractile vacuole did not stop operation at levels of marine salinity; it just worked more slowly and with a small diameter (Hoef-Emden 2014). All close relatives of the African isolate were euryhaline and in one representative culture of the clade, CCAP 978/08, the osmolyte produced under brackish to marine conditions proved to be floridoside, an osmoprotectant known otherwise from red algae (Hoef-Emden 2014).

Several phagotrophic dinoflagellates – *Dinophysis* spp., *Nusuttodinium acidotum*, *N. aeruginosum*, and *Pfiesteria piscicida* – and the ciliate *Myrionecta rubra* (formerly *Mesodinium rubrum*) mimic a photosynthetic lifestyle by engulfing cryptomonads and taking advantage of their photosynthetic organelles for days at a time before completely digesting them (Schnepf et al. 1989; Fields and Rhodes

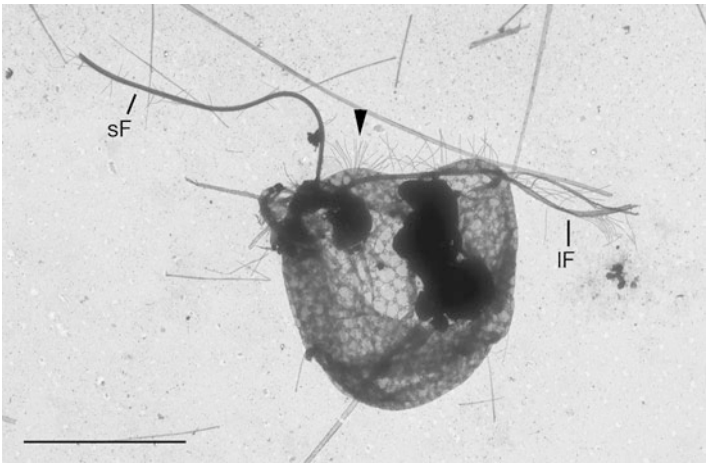

Fig. 10 Whole mount preparation of an isolated inner periplast component (IPC) of cryptomonad strain CCAP 979/35 (cryptomorph of either *Cryptomonas curvata* or *C. pyrenoidifera*). The IPC consists of poly- to hexagonal plates with ejectosome discharge holes between the corners of the plates. The dark globules inside of the periplast are starch grains. The IPC has been isolated with a microtubule-stabilizing buffer usually used to isolate cytoskeletons. The axonemes of the two flagella are therefore sometimes preserved during the isolation procedure. The axoneme of the shorter flagellum (*sF*) is sparsely covered by some of the remaining flagellar hairs. Almost all hairs are still attached to the axoneme of the longer flagellum (*lF*). The tuft of hairs at the base of the longer flagellum is also still present (*arrow head*). Fragments of discharged ejectosomes are scattered around the IPC. Uranyl acetate stain, negative contrast. Scale bar = 10 μm

1991; Lewitus et al. 1999; Gustafson et al. 2000; Takishita et al. 2002; Minnhagen and Janson 2006; Onuma and Horiguchi 2015). This phenomenon is referred to as kleptoplastidy. *Dinophysis* spp., *Pfiesteria piscicida*, and *Myrionecta rubra* form blooms under optimal environmental conditions, which is especially problematic in the case of *Dinophysis* spp. and *Pfiesteria piscicida*, as they produce dangerous toxins (Rao et al. 1993; Burkholder and Glasgow 1997).

Characterization and Recognition

Light Microscopy

Cell sizes of plastid-containing cryptomonads range from below 5 μm (*Hemiselmis* species) up to 50 μm (*Cryptomonas curvata* campylomorphs). The cells show a marked asymmetry and may be twisted along their longitudinal axis. The apex often is shifted to the left side of the cell (Figs. 2 and 3), whereas the two unequal flagella insert subapically or laterally and to the right side of the cell in the vestibulum of an invagination, the furrow-gullet system (Figs. 2 and 3; Klaveness 1985; Clay and Kugrens 1999; Hoef-Emden and Melkonian 2003). The furrow-gullet system defines

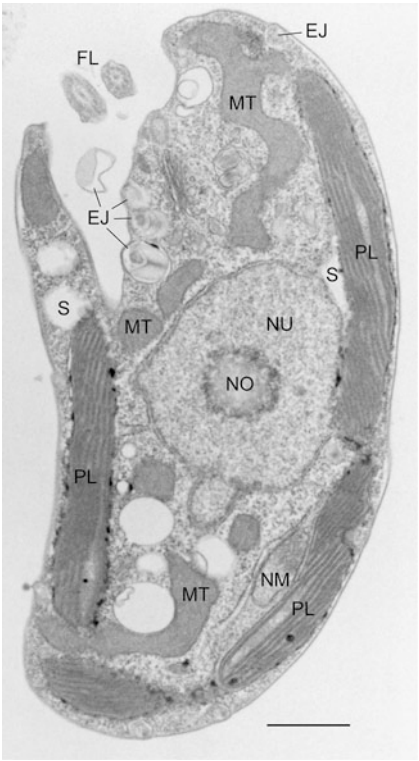

Fig. 11 Transmission electron micrograph of the cryptomonad *Guillardia theta* strain CCMP327 sectioned approximately longitudinally. The flagella (*FL*) and one of the large gullet-associated ejectosomes (*EJ*) are shown in the cross section. Periplast-associated ejectosomes are also apparent. Starch (*S*) deposits are located in the periplastidial compartment and, depending on the plane of section, can be difficult to distinguish from lipid-containing vesicles in the cytoplasm. Additional abbreviations: *NU* nucleus, *NO* nucleolus, *NM* nucleomorph, *PL* plastid, *MT* mitochondrion. Scale bar = 1 μm

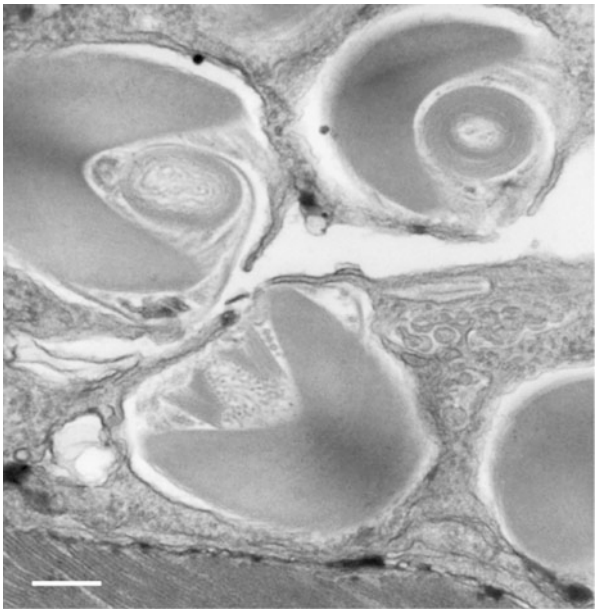

Fig. 12 Transmission electron micrograph showing large gullet ejectosomes of *Cryptomonas* sp. strain CCAP 979/52. Scale bar = 200 nm

the ventral side of the cryptomonad cell. In the cross section the cells have a rounded to elliptical outline. In *Cryptomonas* the broad side views usually correspond to ventral and dorsal sides of the cell. Large explosive organelles, termed ejecto- or ejectisomes, line the furrow-gullet system (Figs. 2 and 3). Although the term ejectisome was introduced by Anderson (1962) and is still seen in the literature; the corrected spelling ejectosome is used throughout this text (since both parts of the term are of Greek origin, the letter "o" must be used to connect them).

One striking feature of cryptomonads is the astounding variety of colors they exhibit. Due to the presence of different types of blue or red biliproteins (albeit with only one type per cell/clonal culture; Hill and Rowan 1989), in combination with chlorophylls *a* and c_2 and the carotenoid alloxanthin, cryptomonad plastids may display shades from chocolate brown to olive brown, bright brown, tomato red, brick red, blue green, and sky blue (Butcher 1967; Clay et al. 1999). Cryptomonads usually contain only one H-shaped plastid per cell. In most cryptomonad genera, the bridge connecting the two plastid lobes is broad and contains a single pyrenoid, whereas it is very thin or – perhaps prior to cell division – absent in *Cryptomonas* species (Hollande 1942; Ettl 1980; Klaveness 1985; Hill 1991a, b; Hoef-Emden and Melkonian 2003). In genera/species with two separate plastids or with very thin connections between the plastid lobes, pyrenoids are either absent or distributed pairwise at the inner sides of the two lobes (Taylor and Lee 1971; Hill 1991a; Hoef-Emden and Melkonian 2003). In some *Chroomonas* species, an eyespot consisting of carotene globules is present in the plastid close to the pyrenoid (Erata et al. 1995; Clay et al. 1999). Cryptomonads mainly use starch as their energy storage material, but lipids can also be used (Pringsheim 1968; Santore 1985; Deschamps et al. 2006). Whereas lipid vesicles are found in the cytosol, starch is produced in the periplastidial compartment (see Electron Microscopy section below). Under suboptimal growth conditions, the starch grains accumulate on the surface of the plastid and – due to a more or less regular pattern – may be mistaken for many small plastids or even periplast plates in surface view (Fig. 2; Pringsheim 1944).

In most cryptomonads, the longer flagellum serves as an anteriorly directed locomotoric flagellum, which pulls the cell behind. The cell rotates about its longitudinal axis during forward swimming, emphasizing the characteristic compression and asymmetry. Upon irritation, the forward swimming motion may be interrupted by abrupt directional changes accompanied by sharp backward jerking movements (first noticed by Ehrenberg 1838). The latter may be the result of discharge of ejectosomes.

Several cryptomonad species form palmellae (Pringsheim 1968; Klaveness 1985). A palmella is an agglomeration of flagellated cells embedded in mucus, which may grow to macroscopically visible size. The flagellates divide within the mucus, but may escape from it easily (Pringsheim 1968). In the genus *Chroomonas*, palmellae may be quite robust and virtually undissolvable. In a study of osmotolerance in *Chroomonas* species thriving in tide pools, it was hypothesized that these palmellae may also serve to protect against desiccation (Hoef-Emden 2014). Flagellar insertion sites in the embedded cells are retracted into the gullet region, resulting in a branched gullet (Meyer and Pienaar 1984a). In members of the

genus *Cryptomonas*, cells can be mobilized from palmellae simply by placing a cover slip on a drop of culture. Some species (in *Cryptomonas* seemingly only cryptomorphs; see Taxonomy section below) may produce cysts as resting stages upon starvation and/or high light intensities (Lichtlé 1979, 1980; Hoef-Emden and Melkonian 2003). A thick cell wall consisting of concentric layers protects the globular starch-laden cyst, which shows no internal structures such as furrow-gullet system or ejectosomes (Fig. 4). Even after several months in nutrient-depleted cultures, cysts may still germinate after being transferred to fresh culture medium (Lichtlé 1979, 1980; Hoef-Emden and Melkonian 2003).

The aplastidic and phagotrophic genus *Goniomonas* differs in cell shape, organization of the cell, and swimming behavior from plastid-containing cryptomonads (see also Electron Microscopy). *Goniomonas* cells are markedly flattened with an obliquely truncate anterior. Parallel to the truncate anterior, a single straight line or ring of ejectosomes traverses the apical part of the cell (Larsen and Patterson 1990; Lee et al. 2005). Light microscopically visible striations on the cell surface may correspond to periplast plates (Hill 1991c). Goniomonads engulf bacteria and usually they prefer gliding along substrates to swimming freely in the water column.

Electron Microscopy

Cell periphery. Cryptomonads lack true cell walls. The cells are bounded by the periplast, composed of proteinaceous inner and surface layers that sandwich the plasma membrane that can be best examined by freeze-fracture techniques and scanning electron microscopy. The inner periplast component (IPC) may consist of hexagonal, polygonal, rectangular, or elongate plates or may be continuous and sheetlike (Fig. 10 shows polygonal IPC plates). The surface is covered by congruent plates, rosulate scales, and/or a fibrous coat (the surface periplast component = SPC; Table 1; Fig. 7). In sectioned material, the IPC appears either as a separate layer or closely appressed to the plasma membrane; retention of the external layer is sensitive to the fixation procedure. Evidence from freeze-fracture studies of members of the genus *Cryptomonas* (Brett and Wetherbee 1986) indicates that there are two types of fibrous coats, one of which is associated with rosulate body scales. Scales have also been observed in association with flagella (Pennick 1981; Santore 1983). The periplast plates tend to decrease in size toward the posterior of the cell; they do not extend into the vestibulum or the furrow-gullet region.

Furrow-gullet system. The cryptomonad furrow-gullet system can be usually localized by the presence of large ejectosomes (see below) lining this cell invagination (Figs. 2, 3, and 11). The identification of the type of furrow-gullet system in most smaller cryptomonads requires electron microscopical methods. Among other characters, different types of furrow-gullet systems have been used to differentiate genera (Table 1; closed tubular gullet vs. slit-like opening along entire length of cell invagination = furrow vs. combination of furrow and gullet vs. shallow groove). In the genus *Cryptomonas*, which possesses a furrow extending into a more or less pronounced tubular gullet, the furrow can open and close (Kugrens et al. 1986;

Table 1 Cryptomonad genera

Genus	Type of biliprotein	Position of the nucleomorph	Furrow-Gullet system	IPC	SPC	Rhizostyle	Other features
Chroomonas	PC630 or PC645	Free	Gullet or branched gullet	Longitudinal rows of stepped rectangular plates or hexagonal plates	Fibrils, plates	None[1]	Thylakoids traverse pyrenoid matrix, eyespot may be present
Cryptomonas[2]	PE566 or leucoplast	Free	Combination	Polygonal plates (CR) or sheet (CA)	Fibrils, rosulate scales	Non-keeled (CR) or keeled (CA)	Dimorphic; deeply bilobed plastid, ev. with one or more pairs of pyrenoids
Falcomonas	PC569	Free	Furrow	Polygonal plates	Plates with fibrillar margins, few rosulate scales	No information available	Pyrenoid bisected by periplastidial cytoplasmic extension
Geminigera	PE545	Embedded in nucleus	Combination	Sheet	Fibrils, rosulate scales	Keeled	Deeply bilobed plastid with two pyrenoids
Goniomonas	No plastid	-	Groove + cytopharynx	Large longitudinal plates	Longitudinal plates	Non-keeled, short	Flagella with "spikes" and long fibrils
Guillardia	PE545	Free	Gullet	Sheet	Large longitudinal plates	Non-keeled[3]	
Hanusia	PE545	Free	Furrow	Sheet	Rosulate scales	Keeled	
Hemiselmis	PC615, PC630, PC577 or PE555	Free	Short gullet	Hexagonal plates	Hexagonal plates, fibrils	None[1]	Thylakoids traverse pyrenoid matrix

(*continued*)

Table 1 (continued)

Genus	Type of biliprotein	Position of the nucleomorph	Furrow-Gullet system	IPC	SPC	Rhizostyle	Other features
Komma	PC645	Free	Gullet	Hexagonal plates	Hexagonal plates, rosulate scales	No information available	No thylakoids in pyrenoid matrix
Plagioselmis	PE545	Free	Furrow	Hexagonal plates	Hexagonal plates, tail without plates	Non-keeled	
Proteomonas	PE545	Free	Furrow	Polygonal plates (1n), sheet (2n)	Fibrils, rosulate scales (1n + 2n)	Non-keeled (1n), keeled (2n)	Dimorphic
Rhinomonas	PE545	Embedded	Gullet	Polygonal plates	Polygonal plates, fibrils	None[1]	
Rhodomonas	PE545	Embedded	Combination	Rectangular plates	Fibrils, rosulate scales	Keeled	
Storeatula	PE545	Embedded	Gullet	Sheet	Fibrils	Keeled	
Teleaulax	PE545	Free	Furrow	Sheet	Fibrils, rosulate scales	Keeled	

Notes: Genera sorted in alphabetical order. Ultrastructural characters and biliproteins according to Mignot (1965), Mignot et al. (1968), Dodge (1969), Roberts et al. (1981), Grim and Staehelin (1984), Santore (1984; *Rhodomonas* = *Pyrenomonas*), Brett and Wetherbee (1986); Hill and Wetherbee (1986, 1988, 1989, 1990), Wetherbee et al. (1986); Kugrens and Lee (1987, 1991), Hill (1991a, b, c), Novarino et al. (1994), Deane et al. (1998), Clay and Kugrens (1999), Clay et al. (1999); Hoef-Emden and Melkonian (2003), Novarino (2003), Hoef-Emden (2008), Lane and Archibald (2008). Potential candidates for alternative morphotypes according to phylogenetic analyses: *Rhinomonas*, *Rhodomonas*, and *Storeatula* (synapomorphy of this clade = nucleomorph embedded in pyrenoid matrix); *Geminigera*, *Plagioselmis*, and *Teleaulax* (Deane et al. 2002; Hoef-Emden et al. 2002; Hoef-Emden 2008). (1n), *Proteomonas* haplomorph; (2n), *Proteomonas* diplomorph; combination, slit-like opening (furrow) extending into a closed tubular gullet; embedded, nucleomorph embedded in pyrenoid matrix; *IPC*, inner periplast component; keeled, keeled rhizostyle (posteriorly directed microtubular root of the flagellar root system) with winglike appendages; *PC*, phycocyanin; *PE*, phycoerythrin; *SPC*, surface periplast component. Some additionally described features such as ligulae or other details of furrows or midventral bands have not been listed. [1]According to Clay et al. (1999); [2]includes the synonymized "*Campylomonas*," "*Chilomonas*," "*Cryptochrysis*," and "*Pseudocryptomonas*" (Hoef-Emden and Melkonian 2003; Hoef-Emden 2005, 2007); [3]according to Gillott and Gibbs (1983), but keeled according to Clay et al. (1999)

Melkonian et al. 1992). The cells probably achieve this by contracting two bands of centrin that run longitudinally along the left and right margins of the furrow and may correspond to the rim fibers of Gillott and Gibbs (Gillott and Gibbs 1983; Melkonian et al. 1992). Furrows may differ in the presence/absence of delicate structures such as vestibular ligulae or rim folds (Kugrens et al. 1986). In all cryptomonads, freshwater, brackish, or marine, a contractile vacuole appears to occupy the apical pole of the cell and empties into the vestibulum (Fig. 3; Patterson and Hausmann 1981; Hoef-Emden 2014).

Ejectosomes. Cryptomonads possess unique explosive organelles, termed ejectosomes (Figs. 2, 3, 11, and 12). Small ejectosomes are located underneath the periplast, either at the corners between IPC plates or equally distributed in strains with sheetlike IPCs (Fig. 11). Larger light microscopically visible ejectosomes line the furrow-gullet system (Figs. 2, 3, and 11). An undischarged ejectosome is a tightly coiled, tapered ribbon that is wound with the wider end toward the outside; a smaller coil is attached to it and lies in the depression of the larger one (Morrall and Greenwood 1980; Fig. 12). Prior to release, ejectosomes are enclosed within vesicles. When discharged, the ribbon unfurls, with the shorter segment forming a beaklike tip on the longer. The edges of the ribbon tend to curl inward, producing circular and c-shaped profiles in the cross section. Yamagishi et al. examined the proteins of purified ejectosomes and found sequence similarities to the product of *reb*B, a component of the ejectile R-bodies in the gammaproteobacterium *Caedibacter taeniospiralis*, which lives as an endosymbiont in the ciliate *Paramecium* (Yamagishi et al. 2012). The ejectosome proteins, termed ejectisins, proved to be extremely resistant to high concentrations of detergent, to freezing and thawing cycles, and to reducing chemicals (Ammermann et al. 2013).

Flagella and flagellar apparatus. The slightly unequal flagella of plastid-containing cryptomonads emerge near the base of the vestibulum and bear rows of bipartite flagellar hairs closely resembling and possibly being related to stramenopile mastigonemes. Flagellar hairs of cryptomonads consist of a shaft with thin terminal filaments, but do not have a proximately tapering basis like mastigonemes. Instead, the flagellar hairs of the longer flagellum are attached to the axoneme with a globular structure, whereas the flagellar hairs of the shorter flagellum are not and seem to detach more easily (Hibberd et al. 1971; Figs. 8 and 9). Kugrens et al. observed six different patterns of distribution of flagellar hairs in cryptomonad strains (Kugrens et al. 1987). Some strains showed the "classical" two rows of flagellar hairs on the longer flagellum, whereas the shorter one bore a single row (Fig. 5). In other strains, each flagellum was covered by only one row of flagellar hairs, sometimes together with thin filaments, or only the longer flagellum had one row of hairs. According to Kugrens et al. (1987), two flagella with only one row of flagellar hairs have been observed in *Cryptomonas* strains with a sheetlike IPC (campylomorphs; see Taxonomy below), whereas the classical two-row/one-row combination was found in *Cryptomonas* strains with periplast plates (cryptomorphs) and in some *Chroomonas* species (Kugrens et al. 1987; Fig. 5). This indicates a correlation of flagellar hair pattern with the alternating morphotypes in *Cryptomonas.* A tuft of flagellar hairs was present on a swelling near the base of the longer flagellum in a cryptomonad

strain with "classical" flagellar hair pattern (Hibberd et al. 1971; Fig. 10). In addition to the flagellar hairs, fine filaments and rosulate scales 12–14 nm in diameter may be associated with the flagellar surface (Pennick 1981; Santore 1983; Fig. 7).

The axoneme has a typical 9 + 2 arrangement; fibrous or amorphous material is sometimes present on the side of the axoneme. The transition region, located external to the cell body, is composed of two to several platelike partitions (Gillott and Gibbs 1983; Santore 1982; Roberts et al. 1981; Roberts 1984; Hibberd et al. 1971; Mignot et al. 1968). The central pair of axoneme microtubules terminates at the distal partition, which extends out to the plasma membrane. One to three proximal partitions may be present; these span only the central portion of the axoneme. There is no evidence of a transitional helix such as those found in other chlorophyll *c*-containing algal classes (Hibberd 1979). The basal bodies are oriented at a slight angle to each other and are connected by two bands, at least one of which is striated (Mignot et al. 1968; Roberts et al. 1981; Gillott and Gibbs 1983). In addition to these connections, some components of the flagellar rootlets pass between the basal bodies (Gillott and Gibbs 1983; Roberts et al. 1981; Roberts 1984).

The most prominent flagellum-related structures are the rhizostyle and the compound rootlet. The rhizostyle is a posteriorly directed microtubular structure. It originates alongside one of the basal bodies and extends deep into the cell, passing near the nucleus in some species, although no physical connections with the nuclear envelope have been found (Gillott and Gibbs 1983; Roberts et al. 1981). In many cryptomonads, e.g., a colorless *Cryptomonas* sp. (Roberts et al. 1981; Mignot et al. 1968), *Rhodomonas* sp. (Mignot et al. 1968), and *Hanusia phi* (Gillott and Gibbs 1983), each of the rhizostyle microtubules bears a winglike lamellar projection. These characteristic wings are absent in other taxa, e.g., *Guillardia theta* (Gillott and Gibbs 1983). In the genera *Proteomonas* (Hill and Wetherbee 1986) and *Cryptomonas* (Hill 1991a; alternative morphotype described as a distinct genus *Campylomonas*), the absence or presence of winglike extensions is correlated with alternating life histories. In both genera, the morphotype with a sheetlike periplast contains a rhizostyle with winglike extensions, whereas in the morphotype with polygonal periplast plates, the rhizostyle is without wings (Hill and Wetherbee 1986; Hill 1991a).

The compound rootlet is made up of microtubules associated with a striated fibrous band. The microtubules of the compound rootlet originate near the rhizostyle and pass between the basal bodies; the striated fiber component attaches to the opposite side of both basal bodies. This rootlet extends laterally, passing between the vacuolar region and the plasma membrane. Two other microtubular structures are commonly associated with the basal bodies. One microtubular rootlet, which may be very short, originates near the rhizostyle and extends anteriorly. A second microtubular structure, variously termed the lateral (Gillott and Gibbs 1983) or curved (Roberts et al. 1981) rootlet, extends dorsolaterally. A mitochondrion-associated lamellar rootlet has been found in several *Cryptomonas* strains (Roberts et al. 1981; Roberts 1984). Anti-centrin antibodies have been used to label four different parts of the *Cryptomonas* cytoskeleton (Melkonian et al. 1992). Apart from the rim fibers of

the left and right furrow margins, centrin was observed to run as a thin band along the microtubular rhizostyle, to interconnect the two basal bodies, possibly corresponding to the striated band of Gillott and Gibbs (1983), and to connect the basal bodies to the vestibulum (Melkonian et al. 1992).

The fluid dynamics of flagella in diverse protists has been examined and modeled mathematically. In flagella with two opposite rows of stiff flagellar hairs, a sinusoidal beating pattern in plane with the flagellar hairs results in a reversal of thrust (Sleigh 1991). Thus, the flagellum pulls the cell behind. In cells with only one row of stiff flagellar hairs attached to the longer flagellum, this system does not work. In Brennen and Winet (1977), a *Chilomonas* species (i.e., a heterotrophic *Cryptomonas* with a sheetlike IPC) was observed to possess a helical flagellar beat, which may account for the presence of a flagellum with only one row of stiff flagellar hairs. The differences between the flagellar root systems, i.e., a long rhizostyle with winglike extensions versus a shorter non-decorated rhizostyle, thus may be related to different arrangements of stiff flagellar hairs and beating modes of the longer flagellum.

Nucleus. The cryptomonad nucleus occupies much of the antapical half of the cell. It contains both light and darkly staining regions, the latter often closely associated with the nuclear periphery (Fig. 11). A nucleolus may or may not be visible. The outer membrane of the nuclear envelope is contiguous with the outermost plastid membrane (Fig. 1), as is the case for many other chlorophyll c-pigmented algae (see below).

Plastid and periplastidial space. Cryptomonad plastids are unusual in both their pigment composition and ultrastructure. They contain a complex plastid derived by secondary endosymbiosis. Four membranes enclose the plastid: the inner pair ensheathes the plastid stroma and the outer pair forms the plastid endoplasmic reticulum (Fig. 1). The four-membrane configuration is common in chlorophyll *c*-containing algae. However, unlike other groups of algae, the outer membranes are not uniformly appressed to the plastid membranes. In the cryptomonads, there is an expanded space between the plastid endoplasmic reticulum and the plastid envelope on its inward face (Figs. 1 and 11). This periplastidial compartment contains 80S ribosomes, starch grains, and the nucleomorph. The nucleomorph is an unusual, double-membrane-bounded structure that contains a fibrillogranular region and dense bodies (Fig. 11). The nucleomorph has been shown to be a vestigial nucleus belonging to a red algal endosymbiont (see "Evolutionary History" section below). That hypothesis is supported by the demonstration of nucleoprotein within this organelle with cytochemical staining (Gillott and Gibbs 1980), fluorescence (Ludwig and Gibbs 1985), and, more recently, genome sequencing (Douglas et al. 2001; Lane et al. 2007; Tanifuji et al. 2011; Moore et al. 2012). The position of the nucleomorph within the cell varies: it can reside between the pyrenoid and nucleus (e.g., *Cryptomonas*) or be embedded within a groove in the pyrenoid (e.g., *Storeatula*) (Clay et al. 1999).

The thylakoids of cryptomonads are most often paired (Fig. 11), although single thylakoids as well as large stacks have also been observed. They do not, however, form structured grana. Pyrenoids are usually covered by a cap of starch, but the pyrenoid matrix and starch grains are separated by the two inner plastid membranes.

In *Chroomonas* and *Hemiselmis* species, thylakoids traverse the pyrenoid matrix (Santore 1982, 1987; Meyer and Pienaar 1984a; Hill 1991b). The Cryptophyceae are characterized by the presence of chlorophylls *a* and c_2, one type of either a red or a blue phycobiliprotein, carotenes, and alloxanthin as a major xanthophyll (Pennington et al. 1985; Lichtlé et al. 1987; Hill and Rowan 1989). Only one type of biliprotein is present in a single species. The chlorophylls *a* and c_2 operate as photosynthetic pigments in a light-harvesting complex that is – as in other algae and in land plants – embedded in the thylakoid membrane contacting the photocenters from the side of the thylakoids (Lichtlé et al. 1987; Kereïche et al. 2008). The biliprotein is not part of phycobilisomes as in red algae, glaucophytes, or *Cyanobacteria*, but comprises a fully functional low-molecular-weight second light-harvesting complex inside of the thylakoid lumen (Gantt et al. 1971; Lichtlé et al. 1987; Vesk et al. 1992; Doust et al. 2006).

Mitochondrion. Cryptomonads contain a single, large vermiform or branched mitochondrion, which extends throughout the cytoplasm (Fig. 11) and contains flattened fingerlike cristae (Santore and Greenwood 1977; Roberts et al. 1981; Roberts 1984; Hill and Wetherbee 1986).

Members of the genus Goniomonas. *Goniomonas* differs from all other cryptomonads in numerous important aspects. These include a different cell shape and ultrastructure, the lack of a plastid, a benthic lifestyle, and a phagotrophic mode of nutrition. *Goniomonas* has distinctly flattened cells with a groove running along the truncate anterior. The flagella insert apically in the vestibulum of the groove and a conical infundibulum or cytopharynx advances close to the groove into the cell (Mignot 1965; Kugrens and Lee 1991; Kim and Archibald 2013). Whereas in plastid-containing cryptomonads, the broad side mostly corresponds to a ventral or dorsal view, i.e., the cells are dorsoventrally compressed, *Goniomonas* cells are typically compressed in a left-right lateral plane. The small side of the truncate anterior thus corresponds to the ventral side; the opposite side closer to the basal bodies corresponds to the dorsal side, whereas the broad views with cytopharynx or flagellar insertion represent the left or right sides, respectively. The structure of the flagellar apparatus supports this notion. The non-winged rhizostyle originates from the basal body closer to the presumed dorsal side (Mignot et al. 1968). However, instead of passing by the nucleus as in the plastid-containing cryptomonads, the comparably short rhizostyle tapers off and vanishes anteriorly and dorsally close to the nucleus (Mignot et al. 1968). Similar to the plastid-containing cryptomonads, a striated band connects the two basal bodies (Mignot et al. 1968). A larger microtubular root originating from the basal body closer to the ventral side follows the cytopharynx into the cell (Mignot et al. 1968). Some additional rootlets accompany the groove margins. Equivalents to the dorsolateral or the compound striated/microtubular roots of the plastid-bearing cryptomonads have not been found (Mignot et al. 1968). The large ejectosomes along the groove and the small ejectosomes underneath the periplast are similar in structure to the ejectosomes of the plastid-containing cryptomonads (Mignot 1965). The *Goniomonas* periplast consists of elongate plates (Kugrens and Lee 1991). The nucleus is found dorsally and posteriorly (Mignot 1965; Kugrens and Lee 1991; Kim and Archibald 2013). The nuclear

envelope is continuous with the endoplasmic reticulum (Mignot 1965), and food vacuoles with ingested bacteria are scattered in the cytoplasm (Mignot 1965; Kugrens and Lee 1991). In cells of the freshwater species *Goniomonas truncata*, a contractile vacuole empties into the distal part of the groove (Mignot 1965). Very long thin filaments cover both flagella of *Goniomonas truncata*; one flagellum bears one row of curved spikes (Kugrens et al. 1987; Figs. 6 and 8). The similarities in granular structure of the shafts of flagellar hairs and spikes indicate that the spikes may be highly modified flagellar hairs (Fig. 8). Overall, the differences in flagellar surface structure between *Goniomonas* and plastid-containing cryptomonads may be due to differences in lifestyle (i.e., benthic vs. pelagic).

Reproduction and Life Cycle

Cryptomonads normally reproduce asexually by mitosis and cytokinesis of the motile cells. Although neither meiosis nor fertilization has been reported in any cryptomonad, some researchers have presented direct or indirect evidence for sexual reproduction in this class, and meiosis-related genes were found in the nuclear genome of *Guillardia theta* (Curtis et al. 2012). Friederike Wawrik provided the first reports of cryptomonad cell fusions, including the formation of zygotes in field samples (Wawrik 1969, 1971, 1979). An ultrastructural study describing cell fusion in a *Chroomonas* strain is also available (Kugrens and Lee 1988). The described processes of cell fusion differ markedly. In a *Cryptomonas* species, Wawrik observed the formation of a thin tube between the apices of two cells, the addition of a second tube resulting in a ring formation, and then transformation into a globular zygote (Wawrik 1969). In the same publication, she described the fusion of two cells at the apex without tube or ring formation in a second *Cryptomonas* species (Wawrik 1969) and a similar process in *Chroomonas acuta* from an Austrian field sample 2 years later (Wawrik 1971). In a later publication and in the study of Kugrens and Lee, however, the cells of an unnamed *Cryptomonas* species and of a strain of *Chroomonas acuta* were shown to have fused asymmetrically (Wawrik 1979; Kugrens and Lee 1988). One cell touched the midventral side of another cell with its antapical tip, leading to cell fusion. All reports, however, were congruent in that the gametes remained motile during the fusion process, resulting in four-flagella stages prior to formation of the zygote.

Observations of cellular dimorphisms in clonal cultures lend further support to the notion of sexual reproduction in cryptomonads (Hill and Wetherbee 1986; Hoef-Emden and Melkonian 2003). Microspectrophotometric measurements of relative nuclear DNA content indicated that the two morphotypes of *Proteomonas sulcata* may correspond to haploid and diploid stages (Hill and Wetherbee 1986). Phylogenetic trees inferred from DNA sequences of nuclear and/or nucleomorph ribosomal operons have provided indirect evidence that dimorphic life histories may be an ancestral character state in plastid-containing cryptomonads (Deane et al. 2002; Hoef-Emden et al. 2002; Hoef-Emden and Melkonian 2003; Hoef-Emden 2007; Majaneva et al. 2014). Apart from the revised genus *Cryptomonas*, within at least

two additional distantly related clades, genera defined on the basis of ultrastructure do not form monophyletic groups and are instead intermingled with one another.

Cryptomonads continue to swim during the mitotic division cycle. Divisions occur predominantly during the second half of the night (Oakley and Dodge 1976; Oakley and Bisalputra 1977; McKerracher and Gibbs 1982; Meyer and Pienaar 1984b; Perasso et al. 1992). Progress of cytokinesis is delayed or arrested completely upon exposure to light during microscopical observation (Oakley and Bisalputra 1977; Meyer and Pienaar 1984b). Only 10 min may suffice to go through mitotic cell division (Oakley and Bisalputra 1977). Peculiarly, the cell polarities of the daughter cells invert during cytokinesis. The former apex of the mother cell turns into the antapices of the daughter cells (shown for a *Cryptomonas* and a *Komma* strain; Perasso et al. 1993). During this process, the mother cell divides longitudinally, starting with a cleavage furrow anteriorly at the ventral site, which extends to the apex. The two basal bodies and flagellar apparatuses migrate along the two future ventral sites, following the growing cleavage furrow down to the former antapex until they reach the new apices of the daughter cells. Thereafter the cells separate completely (Perasso et al. 1993).

The ultrastructural details of mitosis have been examined in several cryptomonad strains (Oakley and Dodge 1976 [*Chroomonas salina* = *Rhodomonas salina*]; Oakley and Bisalputra 1977 ["*Cryptomonas*" sp. the authors examined a marine strain, but *Cryptomonas* is known today to be exclusively freshwater]; McKerracher and Gibbs 1982 [*Cryptomonas* sp. θ = *Guillardia theta*]; Meyer and Pienaar 1984b [*Chroomonas africana*]; Meyer 1987; for changes in taxonomy see below). The plastid divides prior to mitosis by constriction of the bridge connecting the two lobes of the organelle; both daughter plastids stay attached to endoplasmic reticulum (ER) (McKerracher and Gibbs 1982). In a *Chroomonas* species with an eyespot, the carotene globules entered the pyrenoid prior to plastid division and became segregated into two groups upon dissection of the pyrenoid matrix (Meyer 1987). Cryptomonads do not contain probasal bodies, thus, at first basal bodies and flagella duplicate. According to Perasso et al. (1992), the mature older basal body belongs to the longer dorsal locomotoric flagellum. Upon duplication, the ventral trailing flagellum matures to a locomotoric flagellum, whereas both new basal bodies give rise to new trailing flagella and associated flagellar roots (Perasso et al. 1992). The nucleus migrates to the apical part of the cell, and thereafter the nuclear envelope disintegrates (Oakley and Dodge 1976; Oakley and Bisalputra 1977; Meyer and Pienaar 1984b). During metaphase, a plate of condensed chromatin penetrated by small tunnels for spindle microtubules forms, but no individual chromosomes have been observed. The metaphase plate separates into two anaphase plates that move into the vicinity of the plastid-ER complexes, where during telophase the nuclear envelopes reassemble. Mitotic spindle formation starts at approximately the same time as the basal bodies duplicate. Microtubules originate from amorphous material and flagellar rootlets surrounding the basal bodies and grow toward the nucleus (Oakley 1978). The two flagella pairs move apart, each one associated with a Golgi apparatus (McKerracher and Gibbs 1982). At metaphase, the spindle adopts the shape of a compact barrel (Oakley and Bisalputra 1977; Oakley 1978; McKerracher

and Gibbs 1982; Meyer and Pienaar 1984b). The microtubules of the mitotic spindle either traverse the metaphase plate through the tunnels or contact the chromatin without visible kinetochores. At telophase, the microtubules disappear. In *Chroomonas africana* and *Guillardia theta*, fragments of the nuclear envelope were observed to border the mitotic spindle at its longitudinal sides and remain in contact with the plastid-ER complexes during mitosis (McKerracher and Gibbs 1982; Meyer and Pienaar 1984b). Cytokinesis in cryptomonads starts in meta- or anaphase apparently without participation of microtubular structures (Oakley and Dodge 1976; Oakley and Bisalputra 1977). Instead a thin layer of amorphous material has been observed underneath the periplast at the cleavage site (Oakley and Bisalputra 1977).

Nucleomorph division has been examined in *Guillardia theta*, two photosynthetic *Cryptomonas* strains, the leucoplast-containing *Cryptomonas paramecium* strain CCAP 977/2a, and in a marine strain assigned the species name *Plagioselmis punctata* (McKerracher and Gibbs 1982; Morrall and Greenwood 1982). In *Guillardia theta*, nucleomorph division takes place after duplication of the basal bodies (McKerracher and Gibbs 1982). Nucleomorphs undergo a closed mitosis, i.e., the nucleomorph envelopes remain intact. Prior to segregation the nucleomorph constricts in the middle adopting the shape of a dumbbell (McKerracher and Gibbs 1982). Both studies agree in that no microtubules appear to be involved in mitosis of the cryptomonad nucleomorph. Nevertheless, genes for α-, β-, and γ-tubulins have been found in the nucleomorph genome, indicating that some cytoskeletal elements are required in the periplastidial compartment (Keeling et al. 1999). Alignment and partitioning of electron-dense globular to rod-shaped particles – putative heterochromatic regions – seem to be steered by thin fibrillar material observed to connect the particles among each other and to the nucleomorph envelope (Morrall and Greenwood 1982). During mitosis of the nucleomorph, the elongated electron-dense particles arrange in parallel displaying a paracrystalline structure in the cross section (Morrall and Greenwood 1982). The complete absence of a mitotic spindle indicates that the mechanisms underlying nucleomorph division may be quite different from a "normal" mitosis. Nevertheless, some similarities to red algal nuclei still seem to exist, such as the presence of electron-dense particles and the fibrillar material embedded in the chromatin (Morrall and Greenwood 1982). This is potentially significant, given that the cryptomonad nucleomorph and plastid are derived from a red algal endosymbiont (see below).

Hirakawa and Ishida examined ploidy levels of the four different genomes in *Guillardia theta*. Whereas the nuclear genome of the model cryptophyte was haploid, the nucleomorph was tetraploid. Multiple genomic copies were found in the mitochondrion (ca. 24–43) and in the plastid (ca. 130–260) (Hirakawa and Ishida 2014). The process of DNA synthesis in these complex cells must be strictly choreographed. In the host cell nucleus of *Pyrenomonas helgolandii* strain SAG 28.87, DNA synthesis was shown to take place during the light until the onset of darkness and lasted 8–10 h (Sato et al. 2014). The nucleomorph DNA was doubled 2–4 h after the start of the dark period within ~2 h. The plastid divided first, followed by the nucleomorph. Mitosis of the nucleus occurred thereafter, followed by division

of the two outer plastid membranes and cytokinesis (Sato et al. 2014). Concerning the synthesis of cryptophyte organellar DNA, results consistent with those of previous studies in embryophytes were found. DNA synthesis of mitochondria and plastids was not synchronized, but rather found to occur throughout the cell cycle (Sato et al. 2014).

Taxonomy

As in most protist groups, the first cryptomonad genera and species were described using field material and light microscopically visible morphological characters, assuming that morphological characters were stable and differences in morphology would reflect species limits. Even prior to the establishment of electron microscopical methods, examinations of clonal cultures raised doubts concerning consistency in cryptomonad systematics (Butcher 1967; Pringsheim 1968; Klaveness 1985). Pringsheim examined several clonal strains of the freshwater genus *Cryptomonas* and expressed concern over a lack of distinct morphological characters and almost continuous transitional forms obviating the establishment of a reliable morphospecies concept (Pringsheim 1968). Butcher and Pringsheim emphasized the unreliability of color for classification (*Rhodomonas* = red cryptomonads, *Chroomonas* = blue cryptomonads, *Cryptomonas* = brownish cryptomonads with a combination of furrow and gullet; Butcher 1967; Pringsheim 1968). These authors observed that cell colors can change dramatically in a culture upon starvation. Butcher therefore abandoned cell color as a genus-specific criterion and entirely reorganized cryptomonad classification using the structure of the furrow-gullet system as major diagnostic criterion (Butcher 1967). As a consequence, cryptomonads formerly classified as *Rhodomonas* were reassigned to the genera *Cryptomonas* or *Chroomonas.* Several studies, however, demonstrated that at least eight different types of biliprotein can be produced by cryptomonads and that each clonal strain contains only one type, which is stable within a culture (Hill and Rowan 1989; Glazer and Wedemayer 1995; Hoef-Emden 2008). Therefore, Butcher's classification did not hold, but still causes some confusion in naming of strains in older literature and in culture collections.

In the 1960s, electron microscopical techniques developed and were used to unveil the fine-scale features of cryptomonad ultrastructure. As a consequence, genera within the cryptomonads have been distinguished by their type of biliprotein, the number and shape of their plastids, the position of the nucleomorph, pyrenoid structure, flagellar apparatus, morphology of the furrow-gullet system, and ultrastructure of the periplast (starting with Santore 1984; Clay et al. 1999; Kugrens and Clay 2002; Novarino 2003). Since most of these characters have been examined in clonal cultures, they are deemed to be stable. However, in 1986, a clonal strain, described as a new genus and species *Proteomonas sulcata*, was found to possess two different morphotypes (Hill and Wetherbee 1986). Both morphotypes shared the same type of biliprotein, phycoerythrin 545, but differed significantly in ultrastructure. The larger cells had sheetlike inner periplast components and keeled

rhizostyles, whereas the inner periplast components of the smaller cells consisted of hexagonal plates, and the rhizostyles of these cells were non-keeled. Microspectrophotometric measurements showed that the nuclei of the smaller cells contained only half of the DNA of the larger cells. Hill and Wetherbee therefore termed the different morphotypes diplomorph and haplomorph and suggested the presence of a dimorphic life history with sexual reproduction (Hill and Wetherbee 1986).

Molecular phylogenetic analyses using nuclear and nucleomorph ribosomal RNA genes demonstrated inconsistencies in several of the ultrastructurally defined cryptomonad genera. Genera were para- or polyphyletic, or strains assigned to two different genera proved to be genetically identical or almost identical in phylogenetic analyses (e.g., *Rhinomonas* and *Storeatula* strains or *Cryptomonas* and *Campylomonas*; Marin et al. 1998; Deane et al. 2002; Hoef-Emden et al. 2002; Hoef-Emden and Melkonian 2003). The genus *Cryptomonas* proved to be restricted to freshwater, to encompass only species with phycoerythrin 566 or with leucoplasts, and to be dimorphic (Hoef-Emden and Melkonian 2003). The situation in *Cryptomonas* and "*Campylomonas*" was similar to *Proteomonas sulcata*. *Cryptomonas* is a morphotype with polygonal periplast plates, whereas *Campylomonas* corresponds to the diplomorph with a sheetlike inner periplast component (Hill and Wetherbee 1986; Hoef-Emden and Melkonian 2003). Since DNA content of the *Cryptomonas* cells has not been determined and since the two morphotypes do not always differ in size, the terms crypto- and campylomorph have been adopted, instead of haplo- and diplomorph (Hoef-Emden and Melkonian 2003). Similar pairs of "genera" likely representing different morphotypes within a life cycle can be found in other cryptophyte clades: *Rhinomonas* and *Rhodomonas* (both with IPC plates) versus *Storeatula* (sheetlike IPC; Majaneva et al. 2014) and *Plagioselmis* (IPC plates) versus *Geminigera* and *Teleaulax* (sheetlike IPC; Shalchian-Tabrizi et al. 2008). Previous reports and evidence for dimorphism in several genera suggest that the biological species concept does apply to cryptomonads, although the inductors of sexual reproduction are unknown (see Reproduction and Life Cycle section). As of June 2015, only two genera, *Cryptomonas* and *Hemiselmis*, have been examined in greater detail by combining light and electron microscopical methods with molecular phylogenetic analyses and have been revised accordingly (Hoef-Emden and Melkonian 2003; Hoef-Emden 2007; Lane and Archibald 2008). In all three revisions, Pringsheim's observation of a low resolution of morphological characters at species level could be confirmed (Pringsheim 1968; Hoef-Emden and Melkonian 2003; Hoef-Emden 2007; Lane and Archibald 2008). In both *Cryptomonas* and *Hemiselmis*, genetic diversity appears to outweigh morphological diversity, resulting in cryptic species complexes probably encompassing several biological species. In *Cryptomonas*, morphological characters could also be misleading due to differences in the cell shapes within a strain and among strains that are genetically identical even in the highly variable internal transcribed spacer 2 of the nuclear ribosomal operon (Hoef-Emden 2007).

Problems with defining the boundaries of a genus have also been encountered in *Chroomonas*. By tradition, *Chroomonas* was said to contain a PC630 or PC645 biliprotein, to have a tubular gullet, and to be surrounded by a periplast consisting of

rectangular plates (Clay et al. 1999). An SEM examination of the original specimen of the type species, *Chroomonas nordstedtii*, revealed a periplast consisting of hexagonal periplast plates, which raises doubts over the current genus description (Novarino 2003). In addition, the genus *Chroomonas* proved to be paraphyletic in phylogenetic analyses with *Hemiselmis* and *Komma* being nested within it (Hoef-Emden 2008, 2014).

Various cryptomonad genera and their characters are listed in Table 1 according to their current classification status.

Maintenance and Cultivation

Cryptomonads are present in most samples taken from still waters. If cryptomonad cells are rare, enriching a sample with culture medium often helps to increase cell numbers. Since cryptomonads have no cell wall only palmella-forming taxa have proven capable of growth on agar. The isolation method of choice is the capillary technique. Capillaries are produced by heating glass Pasteur pipettes over a flame, stretching them and breaking them at their thinnest point. With these capillaries, single cells are identified and isolated under a – preferably inverted – microscope and washed by transferring each cell repeatedly into fresh drops of medium, ultimately placing the cell in a vessel with culture medium (a titer plate with culture medium-filled wells or small petri dishes). This method is difficult or impossible to apply if the cells are of nanoplanktonic size. If cryptomonads occur at a greater abundance, serial dilution techniques may be successful to obtain clonal cultures. Otherwise fluorescence-activated cell sorting (FACS) can be used to sort photosynthetic cryptomonads according to the fluorescence maximum of their biliprotein (Sensen et al. 1993). FACS is expensive but efficient and can be used to establish axenic cultures (Surek and Melkonian 2004).

Most cryptomonads can easily be grown in one of the standard culture media, such as WARIS and BBM (freshwater) or ASP-12, ESM, f/2, and ASP (marine; see recipes on the CCAC, CCAP, CCMP, NIES, and SAG websites). Cryptomonads need vitamins, but a standard cocktail containing vitamin B_{12}, niacin amide (nicotinic acid amide), biotin, and thiamine will suffice for most strains. Axenic cultures of photosynthetic freshwater cryptomonads may not grow without soil extract in the culture medium (1 mL per L may suffice). Sodium glycerophosphate and soil extract are often required additives for marine isolates. The phagotrophic *Goniomonas* species are more difficult to isolate and maintain. Success probably depends on whether or not their prey organisms, e.g., bacteria, are transferred by accident together with the cells and are able to grow in the culture medium. Otherwise prey has to be provided together with the culture media. Leucoplast-containing *Cryptomonas* species may be less difficult. They can be grown at first in biphasic soil-water media with a piece of pea or lentil, but some also grow in WARIS with soil extract, at least if they are not axenic. Axenic strains require some organic additives, such as a pea or lentil or bacterial growth media.

Many marine cryptomonad strains grow equally well in marine or brackish water media, but differences in temperature optima have to be considered for different isolates. Arctic or antarctic isolates often do not survive warming up to even 15 °C, whereas isolates from warmer regions may not divide at lower temperatures. Thus, when isolating cells for establishing new cultures, growth temperatures should at first approximate those of the respective habitat. Experiments concerning temperature tolerance may be done subsequently. Cryptophytes generally prefer larger surface to depth ratios in culture vessels, i.e., cultures become denser in petri dishes than in small Erlenmeyer flasks or glass tubes. Although the delicate nature of cryptomonad cells can cause problems, they can be easily grown at a large scale in aerated mass cultures. Rates of cell division and achievable cell densities, however, differ considerably among strains. Small-celled *Cryptomonas* and *Hemiselmis* strains divide at a faster rate than large *Cryptomonas ovata* cells or the campylomorphs of *Cryptomonas curvata. Chroomonas* strains that are extensively palmelloid do not lend themselves to cell counting and may grow comparably slowly, yielding low-density cultures.

Evolutionary History

Cryptomonads appear to be absent from the fossil record, presumably because they lack silica- or calcium carbonate-containing surface structures amenable to preservation. Attempts to discern how the different cryptomonad lineages relate to one another and, more generally, where cryptomonads belong on the eukaryotic tree of life have traditionally relied on morphological, ultrastructural, and biochemical data. With the advent of gene and whole genome sequencing, molecular approaches to cryptomonad systematics are now also widely used. Given that plastid-containing cryptomonads acquired photosynthesis by secondary endosymbiosis, a process whereby a non-photosynthetic eukaryote engulfs an unrelated eukaryotic phototroph and retains its plastid (Gould et al. 2008; Archibald 2012), the origin of both the host and endosymbiont components of cryptomonad cells must be accounted for.

The cryptomonad host cell has been allied with a wide variety of algae over the years, including the glaucocystophytes, dinoflagellates, and rhodophytes (see Edwards (1976) and references therein for early views on large-scale algal systematics). Cavalier-Smith (1986) placed the Cryptophyta in the kingdom Chromista together with the Haptophyta and Heterokonta, based on their shared presence of chlorophyll *c*-pigmented plastids and similar plastid ultrastructure. As is the case in cryptomonads, the haptophytes and photosynthetic heterokonts have plastids that are surrounded by four membranes. In each of these three groups, the outermost plastid membrane is contiguous with the host cell's endomembrane system, an arrangement historically referred to as the chloroplast (or plastid) endoplasmic reticulum (Gibbs 1979). Cavalier-Smith (1986) proposed that the cryptomonad, haptophyte, and heterokont plastids are the product of a single secondary endosymbiosis in their common ancestor, and that these three groups are each other's closest relatives. Molecular phylogenetic analyses of plastid and (in the case of cryptomonads)

nucleomorph gene sequences have shown convincingly that cryptomonad, haptophyte, and heterokont plastids are each red algal in origin (e.g., Douglas and Penny 1999; Douglas et al. 2001; Sánchez Puerta et al. 2005; Oudot-Le Secq et al. 2007).

Cryptophytes inherited several traits from the red algal ancestor of their plastids. The periplastidial space surrounding the complex cryptophyte plastid probably corresponds to the former cytosol of the engulfed red alga, since it contains starch grains and eukaryotic ribosomes. The starch metabolism in this compartment is also powered by UDP, as in red algae (Viola et al. 2001; Deschamps et al. 2006). Floridoside (α-D-galactopyranosyl 1 → 2′-glycerol) is the red algal equivalent to sucrose in Viridiplantae: it serves as the major soluble carbon pool and acts together with its relative isofloridoside as an osmolyte to counter salt stress (Hagemann and Pade 2015). In two algae with complex plastids of red algal ancestry, the stramenopile alga *Poterioochromonas malhamensis* (isofloridoside) and the cryptophyte *Chroomonas* sp. CCAP 978/08 (floridoside), these red algal-derived products have been shown to serve as osmoprotectants (Kauss 1981; Hoef-Emden 2014).

Many of the genes of the former red alga have been transferred to the nucleus, e.g., the *cpe*A genes for the α subunits of the biliprotein (Broughton et al. 2006). Cells with complex plastids require a sophisticated addressing system to correctly target nucleus-encoded proteins to their respective compartments or membranes and the targeting systems present in the model cryptophyte *Guillardia theta* and the model diatom *Phaeodactylum tricornutum* are compatible with each other. Gene products that have to cross five membranes such as the α subunit of the biliprotein (the plastid ER membrane, periplastidial membrane, outer plastid membrane, inner plastid membrane, and finally thylakoid membrane) depend on the presence of an N-terminal tripartite topogenic signal (Gould et al. 2007). Targeting of such cryptophyte proteins was demonstrated in the transformable *P. tricornutum.* First, the signal peptide directs translation through the plastid-ER membrane. An AXAF motif at the cleavage site between the signal and transit peptide marks the protein for import into the plastid lumen. If a twin arginine motif follows the transit peptide, the protein will end up in the thylakoid lumen (Gould et al. 2007). Since only some biliprotein α subunits possess a twin arginine motif, Gould et al. hypothesized that the two plastid-encoded β subunits, one α subunit with a twin arginine motif and another without, obtain their tetrapyrrole chromophores in the plastid stroma and come together to form the biliprotein. The fully assembled biliprotein is then imported via a twin arginine transporter into the thylakoid, guided by the twin arginine motif in one of the subunits. As in other plastids of primary and secondary endosymbiotic origin, cryptophyte plastids use TIC (*t*ranslocator of the *i*nner *c*hloroplast membrane) and probably also TOC (translocator of the outer chloroplast membrane) for protein import. The nature of the transporter for the periplastidial membrane has provided insight into the processes of integration between two eukaryotic cells. Specifically, it was identified as being derived from the ERAD-L of the red alga (*e*ndoplasmic *r*eticulum-*a*ssociated *d*egradation system for *l*uminal proteins). Instead of exporting defective proteins from the ER for degradation, its

direction of transport was reversed and now serves to import proteins into the periplastidial space. The modified ERAD-L was termed SELMA (*s*ymbiont-derived *E*RAD-*l*ike *ma*chinery; Gould et al. 2007).

A specific relationship between the plastids (and by extension, the host cells) of chromists and alveolates (i.e., dinoflagellates, apicomplexans, and ciliates) has also been proposed (Cavalier-Smith 1999). Many dinoflagellate algae as well as some apicomplexan parasites (e.g., the malaria parasite *Plasmodium*) possess plastids of red algal ancestry, and the so-called "chromalveolate" hypothesis posits that their red algal plastids share a common origin with those of cryptomonads, heterokonts, and haptophytes. A wide range of molecular, biochemical, and ultrastructural data has been brought to bear on this question, including consideration of plastid ultrastructure and pigmentation (see above), the nature of the plastid protein import apparatus in the organisms in question, and comparative analyses of plastid and nuclear genes and genomes from a broad range of photosynthetic and non-photosynthetic taxa (Sánchez Puerta and Delwiche 2008). It remains to be seen whether some or all of the plastids in cryptomonads, haptophytes, heterokonts, dinoflagellates, and apicomplexans share a common endosymbiotic origin (Baurain et al. 2010; Archibald 2012; Keeling 2013; Gould et al. 2015). Large-scale phylogenomic analyses of nuclear genes refute the hypothesis of a monophyletic origin of cryptomonads and haptophytes with the other chromalveolate lineages (e.g., Patron et al. 2007; Burki et al. 2008, 2012; Baurain et al. 2010). Comparative phylogenomic analyses and statistical analyses of gene sets indicate that the complex plastids of heterokonts, cryptomonads, and haptophytes may be the products of serial endosymbioses (Baurain et al. 2010; Stiller et al. 2014). The precise origin(s) of the red algal endosymbiont(s) in the three chromist lineages is unclear, as no particular modern-day rhodophyte lineage has emerged as an obvious sister of the plastids of cryptomonads and other chlorophyll *c*-containing algal groups.

Cryptomonads may also be specifically related to katablepharids, a ubiquitous lineage of marine and freshwater heterotrophic flagellates. Katablepharids lack plastids, but they share vague similarities with cryptomonads, including the presence of both large and small ejectosomes (the former being associated with the feeding apparatus; they differ from cryptomonad ejectosomes in that no small ribbon is attached to the large one) and two thick, unequal, subapically inserted flagella (Lee and Kugrens 1991; Lee et al. 1991). Molecular phylogenies are consistent with a distant relationship between cryptomonads and katablepharids (e.g., Okamoto and Inouye 2005; Okamoto et al. 2009; Burki et al. 2012; Yabuki et al. 2014). Under a model of serial endosymbiosis, the phagotrophic cryptomonad *Goniomonas* and the related katablepharids were ancestrally non-photosynthetic, i.e., they never possessed plastids. In contrast, under the chromalveolate hypothesis, these lineages would have evolved from plastid-bearing lineages and lost their photosynthetic organelles secondarily.

Within cryptomonad diversity, there is a clear distinction between lineages with plastids (e.g., *Chroomonas*, *Cryptomonas*, *Guillardia*, *Rhodomonas*) and those without, the latter being represented by the genus *Goniomonas* (Fig. 13). Beyond the presence or absence of a plastid, these two cryptomonad types differ from one

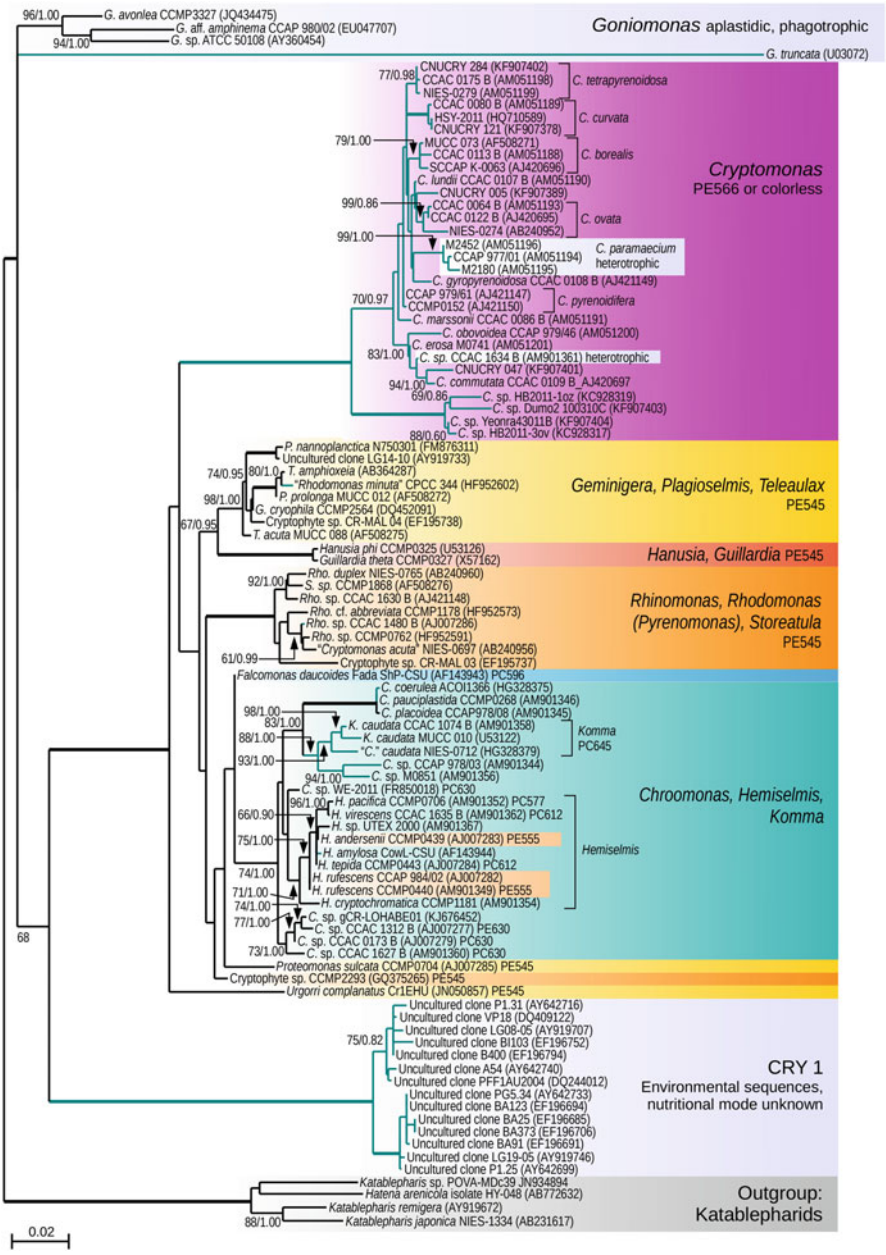

Fig. 13 Rooted maximum likelihood tree of the cryptomonads inferred from nuclear small subunit ribosomal (SSU rRNA) genes. The closest related sister group of the cryptomonads, the katablepharids, have been used as an outgroup. The plastid-containing cryptomonads form a monophyletic clade. In most subclades of the plastid-containing cryptomonads, the type of biliprotein is congruent – although not clade specific – with the respective subclade. The

another in terms of their ultrastructure (see "Characterization and Recognition" section above), and molecular sequence analyses (e.g., McFadden et al. 1994; von der Heyden et al. 2004; Kim and Archibald 2013) strongly support the hypothesis that *Goniomonas* is evolutionarily distinct from all other cryptomonads (Fig. 13).

Cryptomonad biliproteins originate from the phycobilisomes of the former red algal endosymbiont and have proven to be useful evolutionary markers within the group. Phycobilisomes consist of three types of biliproteins. Phycoerythrins and phycocyanins are organized in disk-shaped tri- or hexaheterodimers and are interconnected by linker proteins to form rods (Adir 2005). Together with three central units of allophycocyanin, several rods comprise one phycobilisome. These high-molecular light-harvesting complexes transfer energy to the photosystems from the outside the thylakoids (Adir 2005). In cryptomonads, the phycobilisomes have disassembled and disappeared almost entirely in the course of evolution. Only one type of biliprotein, the formerly peripheral phycoerythrin, has been retained (Apt et al. 1995). Its structure changed to an $\alpha\alpha'\beta\beta$ heterodimer and it moved into the lumen of the thylakoids (Gantt et al. 1971; Vesk et al. 1992; Glazer and Wedemayer 1995). The genes for the α subunits have been transferred to the nucleus, whereas the gene for the β subunit is still plastid-encoded (Jenkins et al. 1990; Douglas and Penny 1999; Broughton et al. 2006). The β subunit is highly conserved in amino acid sequence, despite the highly modified structure, localization, and function of the cryptomonad biliprotein. The α subunits, however, are so diverged that their origin has remained elusive (Apt et al. 1995; Wilk et al. 1999). The different types of biliproteins in cryptomonads evolved by exchange of the linear tetrapyrrole chromophores. Thus, the so-called cryptomonad "phycocyanins" are by origin phycoerythrins that mimic blue phycocyanins (Glazer and Wedemayer 1995). Eight types are currently known, three types of phycoerythrin (plus one slight modification) and five types of phycocyanin (Hill and Rowan 1989; Hoef-Emden 2008). They are named according to the approximate wavelengths of their respective absorption maxima.

Currently, seven distinct evolutionary lineages are known within the plastid-containing cryptomonads, two of which are represented by only one culture (*Proteomonas sulcata* and *Falcomonas daucoides*; Fig. 13). Of the different types of biliprotein, the phycoerythrins are largely congruent with clades in phylogenetic trees, but mostly not clade specific (Marin et al. 1998; Deane et al. 2002; Hoef-Emden et al. 2002; Hoef-Emden and Melkonian 2003; Fig. 13). The orange-red phycoerythrin 545 is found in four different lineages (Fig. 13). The purple

Fig. 13 (continued) phycocyanins are an exception. In several clades, mixtures of two to three genera indicate inconsistencies in systematics probably caused by dimorphic life histories. 104 taxa, 1450 positions, evolutionary model GTR + CAT with final gamma optimization, support values from *left* to *right*, ML bootstrap (1000 replicates), posterior probabilities from Bayesian analysis (six million generations, GTR + Γ6); *bold* branches, 100% BS support and PP 1.00. *Turquoise* branches represent freshwater taxa. Abbreviations: *PC* phycocyanin, *PE* phycoerythrin. Scale bar = substitutions per site

phycoerythrin 566 is exclusive to the genus *Cryptomonas*, although several independent lineages with leucoplasts have evolved within this group (Hoef-Emden and Melkonian 2003; Hoef-Emden 2005). Phycocyanins are found in only two lineages, *Falcomonas daucoides* and a highly diverse clade comprising the genera *Chroomonas*, *Hemiselmis*, and *Komma* (Hoef-Emden 2008; Lane and Archibald 2008; Fig. 13). In the latter clade biliproteins displayed a complex pattern of evolution in phylogenetic trees (Hoef-Emden 2008; Lane and Archibald 2008). Within the genus *Hemiselmis*, a third type of phycoerythrin, PE 555, has evolved from phycocyanin 615 (Hoef-Emden 2008; Lane and Archibald 2008). X-ray crystallography and 2D electronic spectroscopy demonstrated structural and functional differences between types of biliproteins that may be congruent with cryptophyte lineages. In a *Rhodomonas* and a *Chroomonas* species, the biliprotein was found to be in a closed conformation, i.e., the two boat-shaped subunits (αβ and α′β) are closely attached at their inner sides, allowing for energy transfer by quantum coherence. In contrast, in examined *Hemiselmis* species, the two subunits do not interact in this manner, hampering this kind of energy transfer (Collini et al. 2010; Harrop et al. 2014). It is possible that open-state biliproteins are a synapomorphy of the *Hemiselmis* clade.

Ultrastructural characters that are related to dimorphic life histories such as, e.g., the type of periplast, are not congruent with clades in phylogenetic trees in at least three cryptophyte lineages (*Cryptomonas*, the *Rhinomonas/Rhodomonas/Storeatula* clade, and the *Geminigera/Plagioselmis/Teleaulax* clade) (Marin et al. 1998; Deane et al. 2002; Hoef-Emden et al. 2002; Hoef-Emden and Melkonian 2003; Shalchian-Tabrizi et al. 2008; Majaneva et al. 2014; Fig. 13). Members of the *Rhinomonas/Rhodomonas/Storeatula* clade share a synapomorphic feature, i.e., their nucleomorphs are found in a periplastidial tongue embedded in the pyrenoid matrix (Hill and Wetherbee 1989; Hill 1991a). Another synapomorphy may be shared by the phycocyanin-containing genera *Chroomonas*, *Hemiselmis*, and *Komma.* In examined representatives of these taxa, thylakoids traverse the pyrenoid matrix (Santore 1982, 1987; Meyer and Pienaar 1984a; Hill 1991b).

Abstract

Haptophyta are predominantly planktonic and phototrophic organisms that have their main distribution in marine environments worldwide. They are a major component of the microbial ecosystem, some form massive blooms and some are toxic. Haptophytes are significant players in the global carbonate cycle through photosynthesis and calcification. They are characterized by the

haptonema, a third appendage used for attachment and food handling, two similar flagella, two golden-brown chloroplasts, and organic body scales that serve in species identification. Coccolithophores have calcified scales termed coccoliths. Phylogenetically Haptophyta form a well-defined group and are divided into two classes Pavlovophyceae and Coccolithophyceae (Prymnesiophyceae). Currently, about 330 species are described. Environmental DNA sequencing shows high haptophyte diversity in the marine pico- and nanoplankton, of which many likely represent novel species and lineages. Haptophyte diversity is believed to have peaked in the past and their presence is documented in the fossil record back to the Triassic, approximately 225 million years ago. Some biomolecules of haptophyte origin are extraordinarily resistant to decay and are thus used by geologists as sedimentary proxies of past climatic conditions.

Introduction

The division Haptophyta is a group of unicellular algae that are predominately marine, although there are a few freshwater and terrestrial records. Haptophyte nutrition is mainly phototrophic, but many exhibit phagotrophy and some are exclusively heterotrophic. Haptophytes usually appear yellow-brown at high population densities (in culture or blooms) because of accessory carotenoid pigments. Most haptophytes occur as solitary motile or nonmotile forms, but a few form colonies or short filaments. The cells are usually covered with scales of varying degrees of complexity ranging from elaborate calcified structures termed "coccoliths" that are usually visible in light microscopy to ornamented unmineralized organic scales, many of which can only be observed in electron microscopy. Scales and coccoliths are used in species identification (e.g., Bendif et al. 2011, Chrétiennot-Dinet et al. 2014, and http://ina.tmsoc.org/Nannotax3). Motile forms usually possess two equal (isokont) or subequal flagella, which can beat similarly (homodynamic) or differently (heterodynamic). The two flagella are similar in microanatomy and do not have superficial structures except in the class Pavlovophyceae, where they are markedly different in length and are covered by knob scales and fine hairs. Haptophytes possess a unique structure called a haptonema, a filiform organelle associated with the flagella, but different in structure. The name of the division is based on the name of this organelle (from the Greek, hapsis meaning touch).

The Haptophyta includes some 80 extant genera with approximately 330 species in two classes, the Coccolithophyceae (Prymnesiophyceae) with around 76 genera and 318 species (Jordan et al. 2004) and the Pavlovophyceae with 4 genera and 13 species (Bendif et al. 2011). Its members often form an important component of oceanic and coastal plankton and several species are known to form blooms; some of them toxic. Coccolithophores have been recognized in sedimentary rocks and ocean sediments since the early nineteenth century (Ehrenberg 1836) from their calcified scales called "coccoliths" (Huxley 1858). Haptophyte diversity probably peaked in the past, as documented in the coccolith fossil record that extends back to the late Triassic, ca. 225 million years ago.

Habitats and Ecology

Habitats

Haptophytes are found worldwide as common components of coastal and oceanic habitats, and most genera have representatives in the marine plankton. They constitute a considerable percentage of the numbers and biomass of nanoplankton (2–20 μm) (Marchant and Thomsen 1994; Thomsen et al. 1994; Masquelier et al. 2011) as well as in the picoplankton (<3 μm) (Thomsen 1986; Liu et al. 2009; Jardillier et al. 2010; Kirkham et al. 2011). Few estimates have been made, however, of the fraction of production attributable to haptophytes, partly because of the difficulty in identifying and quantifying them in preserved samples. Molecular methods have been instrumental in revealing haptophyte diversity and distribution. Environmental sequencing of clone libraries have repeatedly shown a large diversity including haptophyte clades with no cultured representatives (e.g., Moon-van der Staay et al. 2000; Liu et al. 2009; Shi et al. 2009; Cuvelier et al. 2010), an indication of a large hidden biodiversity in the group. The use of high-throughput sequencing (HTS) has revealed unprecedented haptophyte diversity in marine waters with most of the OTUs (operational taxonomic units) with best match to an environmental sequence, of which some may represent novel taxa from class to species levels (Bittner et al. 2013; Egge et al. 2015a).

Many species are euryhaline, such as the pavlovophyte *Diacronema vlkianum* and the toxic and economically important *Prymnesium* species, *P. parvum* (Green 1975; Green and Hibberd 1977; Green et al. 1982; Larsen 1999). It also grows epipsammically in sand and may thrive in ponds, lakes, and river basins with slightly elevated salinity (Edvardsen and Imai 2006; Johnsen et al. 2010; Southard et al. 2010). Filamentous and palmelloid forms of taxa such as *Ruttnera* and *Chrysotila* (see Andersen et al. 2014, 2015 for update on taxonomy) occur in the splash zone of marine cliffs and are found on damp, usually basic substrates, such as chalk cliffs, and limestone walls (Green and Parke 1975b). Coccolithophores in the related genera *Jomonlithus*, *Ochrosphaera*, and *Hymnenomonas* are typically found in nearshore coastal zones and estuaries.

Only a few genera and about 15 species have been reported from freshwater environments (Preisig 2002; Nicholls 2014). Freshwater records include reports of *Hymenomonas roseola* (Manton and Peterfi 1969), several *Prymnesium*, and *Chrysochromulina*. Freshwater phylotypes belonging to both classes have been revealed by 18 S rDNA environmental sequences (Shalchian-Tabrizi et al. 2011). Some Prymnesiales thrive in and under ice (Hällfors and Niemi 1974; Takahashi 1981).

Several species of *Phaeocystis* occur as symbionts of the widespread and abundant zooplanktonic acantharians (Decelle et al. 2012), and haptophytes have also been found in symbiosis with polycystine radiolarians (Febvre and Febvre-Chevalier 1979; Anderson et al. 1983) and foraminifers (Gast et al. 2000). A haptophyte with affinities to *Braarudosphaera* harbors a nitrogen-fixing cyanobacterium (Thompson et al. 2012). Several members of Prymnesiales and the motile stage of *Emiliania*

huxleyi and *Coccolithus pelagicus* phagocytize bacteria, artificial particles, or other algae (Parke et al. 1955; Jones et al. 1994; Tillmann 1998; Rokitta et al. 2011). Many coccolithophores, for example, species of *Balaniger*, *Ericiolus*, *Pappomonas*, and *Trigonaspis*, have been reported to be heterotrophic (Marchant and Thomsen 1994; Thomsen et al. 1994, 1995). Growth of some haptophytes is stimulated by the uptake of dissolved organic compounds (Pintner and Provasoli 1968; Antia 1980).

Biogeography

Investigations of the distribution and community structure of coccolithophores have been conducted since Lohmann (1912), who was probably the first to examine the oceanic distribution of extant coccolithophores. In Winter et al. (1994), rough biogeographic coccolithophore zones were established largely based on two pioneering oceanic transect studies in the Atlantic (McIntyre and Bé 1967) and the Pacific (Okada and Honjo 1973). Hagino and Young (2015) reviewed recent literature and defined eight coccolithophore floras based on the dominance of one (*E. huxleyi*, *G. oceanica*, or *U. irregularis*) and common occurrence of accompanying taxa. Their compilation supports the latitudinal zonal distributions of the Atlantic (McIntyre and Bé 1967; Winter et al. 1994), but highlights that floras of the equatorial Pacific are also subdivided along east–west gradients, likely corresponding to nutrient content (Hagino and Young 2015).

Distinct floral assemblages are found in the subarctic, temperate, subtropical, tropical, and subantarctic biogeographic zones, largely associated with major ocean current systems. Species diversity generally increases from polar to subtropical–tropical regions, where distinct vertical zonations are often related to (permanent) stratification and deep light penetration of oligotrophic surface waters. The majority of species are restricted to either an upper photic (0–80 m) or a lower photic (120–220 m) zone. The intermediate zone (80–120 m) may contain species from the assemblages above and below. Holococcolithophores are often found in relation with (seasonal) surface water stratification (Cros and Estrada 2013).

The lower photic zones are dominated by *Florisphaera profunda* (with occurrences of *Algirosphaera* spp. and *Gladiolithus* spp.) in temperate to tropical waters, whereas these deeper-dwelling taxa are absent in subpolar–polar waters (Hagino and Young 2015). Placolith-bearing taxa occur in the upper and intermediate photic zones. *Emiliania huxleyi* dominates the upper photic zone in all temperate to polar waters, as well as the equatorial Atlantic and eastern equatorial Pacific. Assemblages with *Umbellosphaera irregularis* are found in the oligotrophic Atlantic subtropical gyres and western equatorial Pacific. Notably, *Gephyrocapsa*-dominated assemblages have been, to date, only reported from the equatorial Indo-Pacific regions and western Pacific coastal waters (Hagino and Young 2015).

The open waters of the Arctic host *Coccolithus pelagicus*, *Calciopappus caudatus*, *Algirosphaera robusta*, and *Emiliania huxleyi* (Winter et al. 1994), and several representatives from the partially calcified genera, such as *Pappomonas*,

Papposphaera, and *Wigwamma*, are also present (Thomsen et al. 1991; Thomsen et al. 1994). The latter group is most abundant in coastal Arctic waters and is sometimes even observed in ice (Marchant and Thomsen 1994; Winter et al. 1994).

In Antarctic waters, common species of the Papposphaeraceae include *Papposphaera*, *Pappomonas*, *Trigonaspis*, and *Wigwamma* (Marchant and Thomsen 1994; Winter et al. 1994), and more than 20 species have been identified including *E. huxleyi* and several species of *Gephyrocapsa*. The abundance and diversity of Southern Ocean coccolithophores decreases poleward (Findlay et al. 2005). The presence of considerable concentrations (>1000 cells/L) of *E. huxleyi* in all sectors of the Southern Ocean and far south of the Antarctic Polar Front (Winter et al. 2014) affirms the eurythermal character of this species.

Less is known about the distribution of members of the Prymnesiales, such as *Chrysochromulina, Chrysocampanula*, *Haptolina*, *Dicrateria*, and *Prymnesium* species, because species identification usually requires electron microscopy examination or genetic methods, and in many instances species delimitation is difficult. Investigations of the Prymnesiales have been carried out in most regions of the world (Leadbeater 1972; Leadbeater 1974; Estep et al. 1984; Hoepffner and Haas 1990; Gao et al. 1991; Marchant and Thomsen 1994; Jensen 1998; LeRoi and Hallegraeff 2004; LeRoi and Hallegraeff 2006), but with present knowledge of species delimitation and their geographical distribution, a reasonable biogeography of the different Prymnesiales species cannot be outlined. Many species such as *Chrysocampanula spinifera*, *Chrysochromulina acantha*, *C. leadbeateri*, *C. simplex*, *C. mantoniae*, *Dicrateria rotunda*, *Haptolina ericina*, and *H. hirta* are reported from areas stretching from the sub-Arctic to the Antarctic and would in this sense be considered cosmopolitan. It has been claimed by de Vargas et al. (2007) that species we recognize as cosmopolitan and display a high genetic and/or ecological plasticity are in fact sibling species within morphological superspecies. The morphological variation in many species as for instance *C. leadbeateri* and *C. simplex* is considerable, and the different morphotypes may in the future prove to constitute sibling species or even different species. Very few of the species of this order have been reported to have their distribution restricted to certain geographical areas of the world. Of those that have, *Chrysochromulina tenuisquama* has only been reported from the southern part of the Atlantic Ocean (Estep et al. 1984), *C. elegans* has been reported only from the southern part of the North Atlantic and Scandinavian waters (Estep et al. 1984; Jensen 1998), and *C. throndsenii* has so far only been recorded from Scandinavian waters (Eikrem 1996; Jensen 1998).

In the Phaeocystales *Phaeocystis globosa* is recognized in the North Sea and English Channel and in temperate waters worldwide; *P. pouchetii* is common along the Norwegian coast, in the Barents Sea, and in Northern Pacific; *P. antarctica* is usual in the Antarctic; and *P. jahnii* is known from the Mediterranean Sea. All of these species have a colonial phase in their life cycle. *Phaeocystis cordata* described from the Mediterranean and *P. scrobiculata*, which has been reported from temperate and subtropic regions, are only known as flagellates (Lange et al. 1996; Medlin and Zingone 2007).

Species of the Pavlovales genera *Diacronema*, *Rebecca*, *Pavlova*, and *Exanthemachrysis* are commonly found in nearshore coastal environments (Carter 1937; Butcher 1952; Droop 1953; Van der Veer 1979), and reports from oceanic environments are scarce. *Diacronema vlkianum* has been recorded a few times from ponds and lakes in Europe, including the British Isles (Preisig 2002).

In a seasonal study of haptophyte diversity (assessed by OTU composition) in Skagerrak (Egge et al. 2015b), a strong seasonal pattern was revealed. Pavlovales representatives were only present in the summer and early spring communities and were dominated by Phaeocystales and Prymnesiales reads, together with environmental sequences that suggest a new haptophyte class. In summer and fall, reads representing coccolithophores and *E. huxleyi* in particular were frequent. Some taxa, e.g., *Phaeocystis cordata* and *Chrysochromulina simplex*, were detected all year.

Ecological Impacts of Bloom-Forming Haptophytes

Haptophytes thrive in both oceanic low-chlorophyll recycling systems and in high-biomass new-production systems, but only few species form intense blooms over large areas of the ocean. *Emiliania huxleyi* and *Gephyrocapsa oceanica* are by far the most prominent bloom formers. They can create blooms in temperate and boreal regions that cover very large areas, for instance, >200,000 km^2 in the Bering Sea (Sukhanova and Flint 1998) or about 250,000 km^2 in the North Atlantic (Holligan et al. 1993; Malin et al. 1993). Whereas cell densities of blooms in the North Sea, Western English Channel, North Atlantic, or the Bering Sea are usually below 6×10^6 cells/L (Holligan et al. 1983; Malin et al. 1993; Sukhanova and Flint 1998), higher densities have been recorded in the Black Sea (up to 30×10^6 cells/L; Mihnea 1997) and in Norwegian fjords (up to 115×10^6 cells/L, Berge 1962).

The conditions for such blooms are created in the course of seasonal succession cycles, typically after diatom blooms when waters have low amounts of macronutrients, especially silicate, prohibiting further growth of diatoms (Townsend et al. 1994; Nanninga and Tyrrell 1996). In these low-nutrient regimes that become more stratified as the season progresses, *E. huxleyi* can typically thrive and outgrow other phytoplankton. This ecological success may be attributed to key physiological traits identified in most or all *E. huxleyi* strains. Photosynthesis, for example, seems not to be inhibited by high irradiances. Cells can grow with near-maximal rates at intensities equal to or exceeding surface sunlight at 1000–1700 μmol photons m^{-2} s^{-1} (Nielsen 1995; Nanninga and Tyrrell 1996). An efficient phosphate acquisition system enables high affinity uptake of inorganic phosphate but also allows scavenging of organically bound phosphates (Riegman et al. 2000; Xu et al. 2010). *Emiliania huxleyi* tolerates nitrogen deprivation much better than diatoms (Löbl et al. 2010). The efficient metabolic recycling of organic N and the direct malate oxidation by malate-quinone oxidoreductase seem to be additional features that increase *E. huxleyi*'s competitiveness in oligotrophic environments (Rokitta et al. 2014). To overcome trace metal limitation and especially that of iron,

E. huxleyi is able to substitute Fe-containing enzymes by functionally equivalent forms that bind other metal cofactors (Read et al. 2013). Although *E. huxleyi* usually does not form blooms in Fe-limited regions (the Southern Ocean), these adaptations certainly broaden its ecological scope and explain its abundance and persistence in contemporary oceans.

Blooms of *E. huxleyi* are unique in their optical properties. As a bloom progresses, coccoliths or entire coccospheres are shed (Balch et al. 1991; Paasche 2002) and scatter the incoming light, turning surface waters turbid and milky, a phenomenon visible from ships and remote sensing satellites (Holligan et al. 1983; Balch et al. 1991). At high concentrations in surface water, the average light intensity is increased due to the scattering of light by the $CaCO_3$ crystals. With depth, however, the irradiance is strongly attenuated (Balch et al. 1991; Holligan et al. 1993; Tyrrell et al. 1999). Increased light and heat trapping in the surface layers can cause a further decrease in the depth of the euphotic zone and increase the stratification (Balch et al. 1991; Tyrrell et al. 1999).

Blooms of *E. huxleyi* can sustain considerable populations of zooplanktic herbivores and are, because of high growth rates, usually not "top-down" regulated by grazing (Nejstgaard et al. 1997). Instead, mature blooms grow into nutrient starvation and are typically lysed by specific viruses (Castberg et al. 2002). Phycodnaviruses, like animal viruses (Mackinder et al. 2009), take control of cellular machinery, replicating and inducing cell lysis and viral burst within 2–3 days (Kegel et al. 2010). This top-down regulation of E. *huxleyi* blooms enables the transition to the next stage of ecological succession (Martínez et al. 2007). *Emiliania huxleyi* exhibits a haplo-diplontic life cycle and the haploid stage is a scale-bearing, non-calcified cell that possesses flagella. The distinct morphology and striking resistance to viral attacks (Frada et al. 2008) point toward an important ecological function of life cycling: growing diploid populations sporadically produce haploid cell stages, and this "background population" of haploid individuals can function as a new founding population in the case of a virally mediated termination of the parental diploid bloom, a phenomenon termed the "Cheshire cat escape strategy" (Frada et al. 2008; Frada et al. 2012). The distinct genetics of the haploid phase and consequentially also the distinct morphology and metabolism of the haploid phase are also thought to extend the species' ability to occupy new ecological niches (Rokitta et al. 2011).

The biogeochemical impacts of such coccolithophore blooms on the global carbon cycle are well studied. As phytoplankton, coccolithophores contribute to primary production and to the export of organic matter to the deep sea. Whereas this process, termed the *organic carbon pump*, causes a net drawdown of CO_2 from the atmosphere into the ocean, the production and export of calcium carbonate has the opposite effect on air/sea CO_2 exchange, causing a net release of CO_2 to the atmosphere (Rost and Riebesell 2004). This counteracting effect on the ocean–atmosphere CO_2 flux is referred to as the *carbonate counter pump*. As coccolithophores contribute to both carbon pumps, the drawdown of CO_2 caused by organic carbon production is partly compensated by the release of CO_2 via calcification. Primary production by coccolithophores is therefore a smaller sink

for CO_2 when compared to a non-calcifying production system, such as a diatom bloom (Robertson et al. 1994). In cases of calcite overproduction, a phenomenon typical for *E. huxleyi* blooms growing into nutrient limitation can become a net source of CO_2 and effectively release CO_2 into the atmosphere (Purdie and Finch 1994). $CaCO_3$ also acts as a "ballast" mineral that increases the transfer efficiency of organic matter from surface waters to depth (Klaas and Archer 2002). It has been shown that coccoliths in fecal pellets and marine snow enhance their sedimentation rate (Buitenhuis et al. 1996).

Estimates of global calcium carbonate production ranges from 0.64 to 2 Gt C per year (Morse and Mackenzie 1990; Milliman 1993; Westbroek et al. 1993; Wollast 1994; Milliman and Droxler 1996). Global annual marine primary production are ~45–50 Gt C (Antoine and Morel 1996; Field et al. 1998; Carr et al. 2006), of which 5 ~ 10 Gt C are exported to the deep sea (Laws et al. 2000; Palmer and Totterdell 2001; Henson et al. 2011). A significant part is driven by the ballast effects derived from $CaCO_3$ created by *E. huxleyi* and *G. oceanica*, but also other heavily calcified, non-blooming coccolithophore species, such as *Calcidiscus leptoporus* or *Coccolithus pelagicus*, may contribute substantially to $CaCO_3$ vertical fluxes (Baumann et al. 2004; Ziveri et al. 2007).

Phaeocystis is a cosmopolitan mucilage-producing genus whose species may occur in high concentrations in both northern and southern hemispheres (Veldhuis et al. 1986; Moestrup and Thomsen 2003; Schoemann et al. 2005), and the species *Phaeocystis globosa*, *P. pouchetii*, and *P. antarctica* (Edvardsen and Imai 2006; Medlin and Zingone 2007) are important bloom formers. Off the British coast and along the coasts of Netherlands and Germany, *P. globosa* regularly blooms in late spring or early summer, producing mucilage in sufficient quantity to clog fishing nets. High winds cause the decomposing mucilage to foam and accumulate on beaches and shores where it is considered a nuisance for recreational beach use (Moestrup 1994). Blooms of *Phaeocystis* may cause harmful effects on animals and *P. pouchetii* may be toxic to cod larvae (Aanesen et al. 1998; Hansen et al. 2004). *Phaeocystis* blooms have influenced herring migration through the North Sea (Savage 1930).

Phaeocystis and other haptophytes are known to be prodigious producers of dimethylsulfoniopropionate (DMSP) (Keller et al. 1989), the precursor compound to dimethyl sulfoxide (DMS), a climate-active gas that induces atmospheric cloud formation and thus may affect planetary albedo. *Phaeocystis* species produce DMSP that is cleaved into acrylic acid and DMSP, but is not considered toxic to animals (Schoemann et al. 2005). It is unclear whether the observed harmful effects derive from toxin production, the toxic nature of breakdown products as blooms decays, or deoxygenation of the water during bloom decays.

The controversial CLAW hypothesis (Charlson et al. 1987; Quinn and Bates 2011) proposed that this DMS-cloud albedo system would represent a negative feedback acting to stabilize climate. Several studies on *Phaeocystis* and *E. huxleyi* in culture and in natural blooms have contributed significantly to our current understanding of DMSP production and cycling (Keller et al. 1989; Malin and Steinke 2004). Many haptophytes, both calcifying and non-calcifying species,

produce high amounts of DMSP (Holligan et al. 1983; Holligan et al. 1993; Malin et al. 1993; Malin and Steinke 2004), and this compound has typical properties of a compatible solute/osmolyte (Kirst 1996) but may also have additional physiological roles (Stefels 2000), e.g., acting as a mitigator of oxidative stress (Sunda et al. 2002). Several environmental factors (nutrients, irradiance, and temperature) alter intracellular DMSP content; while little DMSP is produced in exponential growing cultures, nutrient limitations or stress causes unbalanced growth and increased DMSP cell quotas (Stefels and van Boekel 1993; Sunda et al. 2002). Grazing or viral lysis releases DMSP to the water column (Malin et al. 1993). Despite a large marine DMSP pool, only a very small proportion is ever emitted as DMS to the atmosphere, the rest being recycled within the marine food web or transported to deeper waters (Malin and Steinke 2004). *Phaeocystis* is one of few microalgal genera found to be able to enzymatically convert DMSP into the antibacterial compound acrylic acid and the volatile compound DMS (Stefels 2000). Already Sieburth emphasized the antibiotic properties of acrylic acid produced by *Phaeocystis* to the intestinal bacterial flora of animals (Sieburth 1961).

Widely reported from coastal and inland saline waters in Britain, Denmark, the Netherlands, Israel, Norway, China, and North Africa (Holdway et al. 1978; Moestrup 1994; Edvardsen and Paasche 1998; Edvardsen and Imai 2006; Johnsen et al. 2010) as well as lakes and river basins in southern United States (Baker et al. 2007; Southard et al. 2010), *Prymnesium parvum* causes serious economic losses because of its association with extensive fish kills. It produces toxins with ichthyotoxic, cytotoxic, neurotoxic, antibacterial, and allelopathic activity (Shilo 1981; Meldahl et al. 1994; Edvardsen and Imai 2006; Graneli et al. 2012), which act on biological membranes. The ichthyotoxic effect is assumed to be caused by increased permeability in fish gills resulting in disturbed ion balance and possibly in higher susceptibility to any toxic agents in the water, including other components of the *P. parvum* toxins (Yariv and Hestrin 1961; Ulitzur and Shilo 1966). Several different compounds have been ascribed the toxic effects of *P. parvum* such as proteolipids (Ulitzur and Shilo 1970), glycolipids (Kozakai et al. 1982), hemolysins (Kozakai et al. 1982), polyethers (Igarashi et al. 1996), prymnesins −1 and −2 (e.g., Igarashi et al. 1995; Igarashi et al. 1996), and recently fatty acid amides (Bertin et al. 2012a; Bertin et al. 2012b). Toxins produced by *Prymnesium polylepis* show the same type of toxicity as *P. parvum* including toxicity to the brine shrimp *Artemia* (Yasumoto et al. 1990; Meldahl et al. 1994). In 1988 an extensive bloom of this species occurred in the Skagerrak, northern Kattegat, west coast of Sweden, and coastal waters of Southern Norway (Dahl et al. 1988; Granéli et al. 1993). Both natural fauna and flora were affected severely, and 900 metric tons of caged fish were killed (Gjøsæter et al. 2000). A number of additional haptophytes, such as members of *Chrysochromulina*, *Haptolina*, *Phaeocystis*, and *Chrysotila* (*Pleurochrysis*), have been associated with fish kills or with other toxic or allelopathic activities (Edvardsen and Paasche 1998; Edvardsen and Imai 2006). Several species of *Chrysotila* and *Jomonlithus littoralis* have been shown to be toxic to the brine shrimp *Artemia salina.* Local blooms of *Chrysotila* species have been reported with some harmful effects (Houdan et al. 2004b), and also *Chrysochromulina*

parva has been associated with fish kills (Hansen et al. 1994). A bloom (5–9 million cells L^{-1}) of *C. breviturrita* was reported to have produced lake-wide obnoxious odors in Ontario and New Hampshire, North America (Nicholls et al. 1982).

Coccolith Function and Calcification

Despite intensive research on coccolithophores, the ecophysiological function of calcification is not yet understood (Young 1994; Paasche 2002; Brownlee and Taylor 2004). It has been hypothesized that the coccosphere serves to protect against grazing and/or virus attack, but as yet no experimental proof of these hypotheses has been reported (Harris 1994; Young 1994). Coccoliths could optimize the light interception by the algal cell (Young 1994), or calcification could provide a way of dissipating absorbed light energy to avoid photodamage under nutrient limitation (Paasche 2002), but these hypotheses also remain unproven. It was suggested that cells use the coccosphere to regulate their buoyancy, because controlled sinking might provide means of escaping high irradiances or reaching depths with higher nutrient concentrations (Young 1994; Balch et al. 1996). However, calculated rates of sinking vary significantly among authors and are numerically negligible compared to the wind-driven mixing and wave turbulence. It therefore seems unlikely that a coordinated sinking in response to environmental situations is a reasonable evolutionary purpose of calcification.

There is some support from a theoretical basis for a function of calcification as a carbon-concentrating mechanism (CCM). $CaCO_3$ precipitation releases CO_2 or protons in the course of calcification according to the following reactions:

$$Ca^{2+} + 2HCO_3^- \rightarrow CaCO_3 + CO_2 + H_2O$$

$$Ca^{2+} + HCO_3^- \rightarrow CaCO_3 + CO_2 + H^+$$

Consequently, CO_2 derived from calcification can in principle be used in photosynthesis, or protons could be used in the conversion of HCO_3^- to CO_2 for the same purpose. In either case, this may provide the calcifying cell with a mechanism to access HCO_3^-, which represents the largest pool of inorganic carbon in seawater. Such functional coupling between calcification and photosynthesis was first proposed by Sikes et al. (1980) and has since then been discussed by various authors (Nimer and Merrett 1993; Anning et al. 1996; Buitenhuis et al. 1999).

Experimental data, however, suggest that calcification in coccolithophores is neither a prerequisite for efficient photosynthesis nor is it particularly effective in mitigating CO_2 limitation. The latter is indicated, for example, by the fact that photosynthesis continues unaffected when calcification ceases (Paasche 1964; Herfort et al. 2002; Trimborn et al. 2007), and non-calcifying haploid cells of *E. huxleyi* can photosynthesize as efficiently as or even more efficiently than the diploid calcifying ones (Rost and Riebesell 2004). Moreover, non-calcifying cells of *E. huxleyi* are equally capable of direct HCO_3^- utilization for photosynthesis, which

implies that HCO_3^- utilization is not tied to calcification (Trimborn et al. 2007; Rokitta and Rost 2012). Ultimately, calcification appears unsuited to prevent CO_2 limitation in *E. huxleyi*, which is indicated by observations that the rate of photosynthesis often decreases with decreasing CO_2 concentration despite a concomitant increase in calcification rate (Riebesell et al. 2000; Berry et al. 2002; Hoppe et al. 2011).

The removal of Ca^{2+} ions from the cytoplasm is a prime necessity of literally all organisms to prevent cytotoxic effects of uncontrolled Ca^{2+} signaling. Calcification in coccolithophores may thus represent a form of "irreversible removal" from the cell (Young 1994). Recent data indeed show that, in contrast to non-calcifying phytoplankton, coccolithophores can tolerate massively increased [Ca^{2+}] and maintain fitness even at concentrations 4–5fold higher than in today's oceans. Most strikingly, strains that were earlier described as "non-calcifying" started to re-calcify after ~2 weeks in high Ca^{2+} medium. Hence, the key evolutionary advantage of intracellular calcification may lie in the removal of potentially toxic Ca^{2+} ions, thus enabling cells to have a better control on the transient regulation of cytoplasmic enzyme activity (Müller et al. 2015).

Calcification and Ocean Acidification

Several future emission scenarios predict an increase from currently 400 to more than 750 µatm CO_2 for the year 2100 (IPCC scenario IS92a). As the ocean takes up CO_2, concentrations of dissolved inorganic carbon increase and the pH of seawater decreases. This ocean acidification (OA) is expected to intensify, so that pH levels will have dropped by 0.4 units relative to preindustrial values by the end of this century (Wolf-Gladrow et al. 1999). Ongoing OA will decrease saturation states for $CaCO_3$ minerals. Whereas only "true" undersaturation will cause dissolution, a lowered saturation state can already to some extent affect the biological mineralization processes, simply because $CaCO_3$ precipitation under low pH is thermodynamically less favored (Ridgwell and Zeebe 2005).

Specific differences in the sensitivity to OA do exist (Langer et al. (2006)). In *Calcidiscus leptoporus*, an optimum curve was observed with maximum calcification rates at present-day CO_2 levels, but calcification rates did not vary significantly with pH in *Coccolithus pelagicus*. In both species, photosynthetic carbon fixation rates remained constant at CO_2 levels ranging between 150 and 920 µatm. Most of our current understanding of the processes and sensitivities of calcification and photosynthesis derives from studies on *E. huxleyi* and the closely related species *G. oceanica*. Both belong to an evolutionary very young lineage of rather atypical coccolithophores in terms of structure, physiology, and ecology (Sáez et al. 2004; de Vargas et al. 2007). Different OA response patterns have also been observed between different strains of *E. huxleyi*, with strains largely showing negative or no effects on calcification at pCO_2 values expected for the end of the century (Langer et al. 2009). Overall, most studies have observed negative responses in growth, positive or no responses in biomass production, and negative or no responses in calcification under

high CO_2, leading in most of the studies to a lowered PIC:POC ratio under OA (Zondervan 2007; Hoppe et al. 2011). When assessing possible responses of this group to global change, the intraspecific variability and the diversity within coccolithophores have to be acknowledged, including the different life cycle stages (haploid and diploid) because they display different morphologies and modes of calcification or no calcification and thus may differ in their sensitivity to ocean acidification.

The intracellular mechanism of calcification by coccolithophores was for a long time not well understood (Brownlee and Taylor 2004), despite the wealth of information on the effects of environmental conditions on coccolith production (see review in Paasche 2002). Recently molecular techniques have yielded insights into the functions of calcification-related genes and their responses to environmental change (Mackinder et al. 2010; Rokitta et al. 2012; Rokitta and Rost 2012). Unlike other calcifying organisms, where calcification occurs in extracellular fluids, calcite precipitation in coccolithophores takes place in intracellular vesicles (at least in the case of heterococcoliths) and hence is under control of the cell. It is therefore surprising that calcification in *E. huxleyi* shows such a strong dependency on seawater carbonate chemistry, similar to that observed in Foraminifera and corals (Gattuso et al. 1998; Wolf-Gladrow et al. 1999; Riebesell et al. 2000).

Coccolithophores have been at the center of debate about the consequences of ocean acidification. Numerous findings from laboratory and mesocosm studies (Riebesell et al. 2000; Zondervan et al. 2002; Delille et al. 2005; Hoppe et al. 2011), suggest that calcification by *E. huxleyi* will be reduced in response to OA. In most studies, the decrease in calcification was accompanied by an increase in biomass production (Hoppe et al. 2011), which has been attributed to an intracellular reallocation of acquired carbon away from the impacted calcification toward photosynthesis (Rokitta and Rost 2012). Under OA, multiple parameters of the carbonate system change, which affect the different physiological processes in various ways. The cell-integrated changes in calcification and photosynthesis under elevated pCO_2 have typically been ascribed to the decrease in carbonate ion concentration and thus calcite saturation levels (Cyronak et al. 2015), but more recent and systematic investigations could show how exactly the particular processes are affected by the isolated parameters of the carbonate system. To elucidate the effects of the different parameters of the carbonate system, Bach and coworkers have uncoupled the carbonate chemistry in their experiments (Bach et al. 2011; Bach et al. 2013). They were able to show that growth, biomass production, and carbon acquisition are primarily controlled by CO_2 supply at low (subsaturating) levels, whereas at higher concentrations, they are adversely affected by the concomitant decrease in pH. Further (also transcriptomic) evidence suggests that calcification of scales varies with HCO_3^- supply and is impaired by low pH (Bach et al. 2013). Despite some differences between coccolithophore species and strains, these authors derived a unifying mathematical concept that robustly describes the dependence of calcification rates on carbonate chemistry speciation (Bach et al. 2015).

The precipitation of $CaCO_3$ and the consequential shift in carbonate chemistry inevitably cause acidosis in the cytoplasm of the cells. This is prevented by rapid H^+

effluxes via voltage-gated H^+ channels that are situated in the plasma membranes of many eukaryotes. The increased acidity under OA causes a less steep proton gradient, therefore impairing channel gating and leading to overall higher $[H^+]$ in the cytoplasm of cells (Suffrian et al. 2011; Taylor et al. 2011). The impairment of calcification leads to an intracellular reallocation of inorganic carbon toward the competing reaction, biomass production. This happens in such way that OA often does not significantly affect production of total carbon, i.e., biomass and calcite (Zondervan et al. 2002; Feng et al. 2008; Langer et al. 2009). This effect of carbon reallocation from calcification toward photosynthesis seems to be dependent on light intensity (Rokitta and Rost 2012). Under high light conditions, cells can mitigate and prevent the effects of OA, whereas under limiting light intensities, the reallocation effects are large. This modulation of OA effects by light intensity is accompanied by metabolic reconstellations, in which reductive, anabolic pathways, for example, may synthesize glucans and fatty acids to be upregulated over oxidative, catabolic pathways such as glycolysis and respiration (Rokitta et al. 2012). Cellular redox levels appear to be the informational "hub" that mediates the modulation of OA responses by integrating light intensity into cellular organic carbon metabolism.

In general, a reduction in the degree of calcification is assumed to put coccolithophores at an ecological disadvantage, suggesting a rather "grim future" for this phytoplankton group. This view is derived mostly from short-term acclimation studies over several generations. However, there are also new lines of evidence regarding the midterm and long-term adaptability to OA. Lohbeck et al. (2011) have grown monoclonal cultures of *E. huxleyi* under OA scenarios for ~500 generations and observed that these strains were still affected by OA, but exhibited higher calcification rates than unadapted strains when confronted with OA. This implies that evolution occurring at timescales of months may help to maintain calcification as a cellular function under global change. Data from present-day phytoplankton assemblages and sediment cores covering the last 40,000 years indicate, however, that changes in carbonate chemistry impose a massive selective pressure on the degree of calcification and induce floristic shifts from heavily calcified to less calcified species and strains with increasing CO_2 levels (Beaufort et al. 2011). In the Chilean upwelling system, a rare but distinct over calcified morphotype of *E. huxleyi* thrives under permanently low pH conditions, suggesting that this species is in general able to cope with and adapt to changing ocean acidity.

Characterization and Recognition

Cell Shape and Organization

Unicellular haptophytes exhibit a variety of cell shapes (Fig. 1). In the Coccolithophyceae, cells may be more or less spherical as in *Dicrateria* (Fig. 1e) and many coccolithophores, e.g., *E. huxleyi* and *C. pelagicus* (Figs. 1j and 7a). Saddle-shaped species are confined to the *Chrysochromulina* species (*C. campanulifer*a and

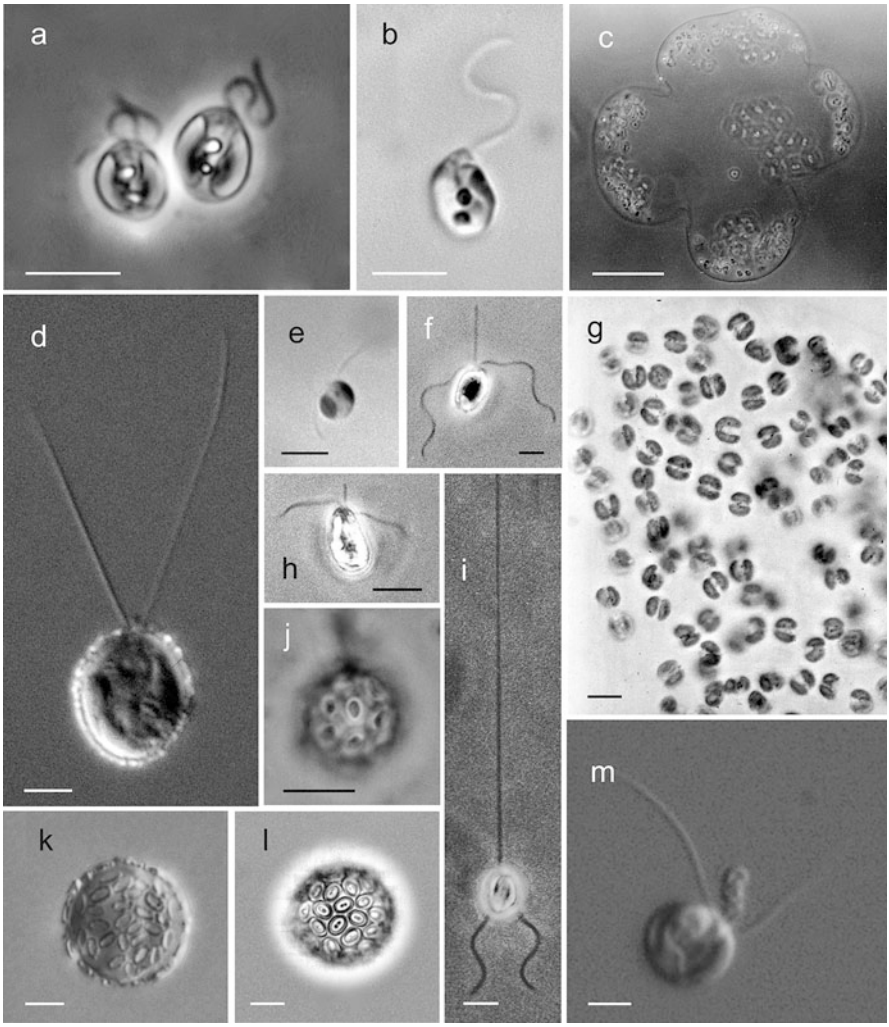

Fig. 1 Light micrographs of representatives of the Haptophyta. (**a**, **b**) Pavlovophyceae, (**a**) *Pavlova*, (**b**) *Rebecca*; (**c**–**m**) Coccolithophyceae, (**c** and **g**) *Phaeocystis pouchetii* colonies; (**d** and **k**) *Chrysotila carterae*; (**e**) *Dicrateria rotunda*; (**f**) *Prymnesium polylepis*; (**h**) *Prymnesium parvum*; (**i**) *Chrysochromulina simplex* with extended haptonema; (**j**) *Emiliania huxleyi*; (**k**) *Chrysotila carterae*; (**l**) *Coronosphaera binodata*; (**m**) *Chrysochromulina campanulifera* with coiled haptonema. Scale bars 5 μm Figs. **a**–**b**, **d**–**m**; Fig. **c**, 100 μm

C. rotalis, Fig. 1l) in which the flagella and haptonema (the appendages) are inserted ventrally. Elongate forms are found in *Prymnesium* (Fig. 1f, h), *Haptolina*, and *Chrysocampanula* and some coccolithophores such as *Calciopappus caudatus* and *Syracosphaera pirus*. Many species such as *Haptolina brevifila*, *Dicrateria rotunda* (Fig. 1e), the motile stage of *E. huxleyi*, and *Calyptrosphaera sphaeroidea* have their

appendages inserted in a polar position, sometimes in association with clusters of spine scales (coccoliths) as can be seen in *Michaelsarsia elegans*. Clusters of spine scales may be located both at the apex and antapex as in *Calciosolenia murrayi* and *Acanthoica quatrospina. Ophiaster hydroideus* has spines only at the antapex. Spines may also cover the entire cell body as in *Haptolina ericina* and *Rhabdosphaera clavigera*. In *Prymnesium*, *Isochrysis*, *Chrysoculter*, and *Chrysotila* species, the appendages are usually inserted sub-anteriorly. The appendages may arise from a depression as in *Corymbellus aureus* and the large, amoeboid cells of *Prymnesium pigrum.*

In the class Pavlovophyceae, cells may be variously shaped, but are almost always flattened with the appendages arising sub-anteriorly on the ventral side. In *Diacronema lutheri*, the insertion of the appendages is almost in the center of the ventral face (Green and Hibberd 1977; Bendif et al. 2011). Species of *Isochrysis*, *Ruttnera*, and the Pavlovophyceae have an asymmetric appearance that is accentuated by the possession of only one plastid, whereas most members of the Haptophyta appear to have two (rarely four, *Dicrateria inornata*). There are a few instances of colonial, stalked, and filamentous stages within the Coccolithophyceae. In *Phaeocystis* (Fig. 1c, g), several species form palmelloid colonial stages. *Phaeocystis* are commonly observed as gelatinous bladders that, in their younger condition, are roughly spherical and up to a few millimeters in diameter, but which later become irregular in form and may be several centimeters in their longest dimension. The cells themselves are small (approximately 3–8 μm diameter) and are arranged in a layer at the periphery. They are separated from each other and with no apparent connection between them. The exact nature of the colorless bladder is not known, but from its physical properties, it seems the surface has some of the elastic properties of a membrane and the matrix, while holding the cells in position, is apparently semiliquid, dispersing readily once the bladder is punctured (Kornmann 1955; Zingone et al. 2011). Benthic palmelloid forms are also known from cultures (Gaebler-Schwarz et al. 2010).

Motile colonies are seen in *Corymbellus aureus* in which the flagellated cells are attached to each other laterally and the colony has an annular shape (like a doughnut ring). In the motile colonies of *Prymnesium radiatus*, the cells are attached to each other at the posterior end and the colony has a ball shape with the flagella extending outward (Sym et al. 2011).

Ruttnera lamellosa and *Chrysotila stipitata* form benthic colonies made by concentric layers (*Ruttnera*) or stalks (*Chrysotila*) of gelatinous material. The motile cells of *R. lamellosa* are asymmetrical and *Isochrysis*-like, but after they have settled, they become spherical with a thick, lamellate mucilage sheath (Andersen et al. 2014). The benthic "Apistonema" stage of *Chrysotila* has cell walls composed of organic scales in a cementing substance and forms branched filaments. The motile cells bear coccoliths (Pienaar 1994). Nonmotile palmelloid cells have been reported in a number of species. Parke et al. (1955) described palmelloid cells in cultures of *Chrysochromulina* species, and nonmotile mucilage-embedded stages are known in *Ochrosphaera* (Fresnel and Probert 2005) and several species of *Pavlova* (Bendif et al. 2011).

Flagella, Transition Zone, and Flagellar Roots

In the Pavlovophyceae, the two flagella are markedly unequal, the more posteriorly inserted one is much shorter than the anterior flagellum. In *Rebecca salina*, the short flagellum is reduced to a short stump, detectable only with electron microscopy. The longer flagellum in the Pavlovophyceae usually carries a covering of fine hairs and small, dense, knob-like scales (Fig. 6a). The fine hairs do not resemble the tubular hairs (mastigonemes) of the heterokont algal groups in their structure and consist only of a fine non-tubular thread (Green 1980; Green and Hori 1994; Bendif et al. 2011). The knob scales (Fig. 6a) are often regularly arranged on the longer flagellum as in *Pavlova gyrans*, but in *Diacronema lutheri*, they are irregularly arranged and they are totally absent in *Exanthemachrysis* and *Diacronema vlkianum* (Bendif et al. 2011).

Coccolithophyceae flagella when present are more or less equal and naked. In flagellated species, two flagella are common, but *Chrysochromulina quadrikonta* has four (Kawachi and Inouye 1993).

The flagellar action may be homo- or heterodynamic. In Pavlovophyceae, the longer flagellum is directed forward with respect to the direction of swimming and beats with a sinuous S-like beat. The shorter flagellum is directed posteriorly, away from the cell body, and beats with a stiff, inflexible action. In swimming Coccolithophyceae cells, the flagellar pole may be in front with the flagella moving along the cell surface, or posterior with the flagella directed away from the cell because the smooth flagella always push the cell. The action of the flagella may be homodynamic and display an undulating motion as in *Chrysochromulina*, *Haptolina*, and many Coccolithales or be heterodynamic as in *Chrysocampanula* and many *Prymnesium*.

The axoneme consists of the usual "9 + 2" arrangement of microtubules except where reduction has taken place as in the short posterior flagellum of *Rebecca salina* in which the axoneme consists only of a ring of nine single microtubules (Green 1976). At the proximal end of the normal flagellum, there is a short transition region in which there are two transverse partitions, the more distal often appearing rather diffuse and thickened in the center. The central pair of axoneme microtubules stops at this partition. The double partition structure appears to extend throughout the phylum (Green and Hori 1994), having been recorded in *Chrysochromulina* (Eikrem and Moestrup 1998), *Haptolina* (Eikrem and Edvardsen 1999), *Prymnesium* (Manton 1964b; Green and Hori 1990), *Phaeocystis* (Parke et al. 1971), and *Dicrateria* (Green and Pienaar 1977), although in species of *Isochrysis* (Hori and Green 1991), *Hymenomonas*, and *Chrysotila* (*Pleurochrysis*) only the proximal partition is present. A helical band is located distally to it in the flagella in *Chrysotila carterae* (Beech and Wetherbee 1988) and *Hymenomonas coronata* (Roberts and Mills 1992). Tiers of tubular rings may also be present proximal to the axosome (Green and Hori 1994; Billard and Inouye 2004). In *Prymnesium*, tubular rings are present in addition to the double partition structure (Birkhead and Pienaar 1994, 1995). Some Pavlovales appear to have one partition only in the posterior flagellum (Green and Hibberd 1977). *Chrysoculter rhomboides* and *Diacronema vlkianum* are

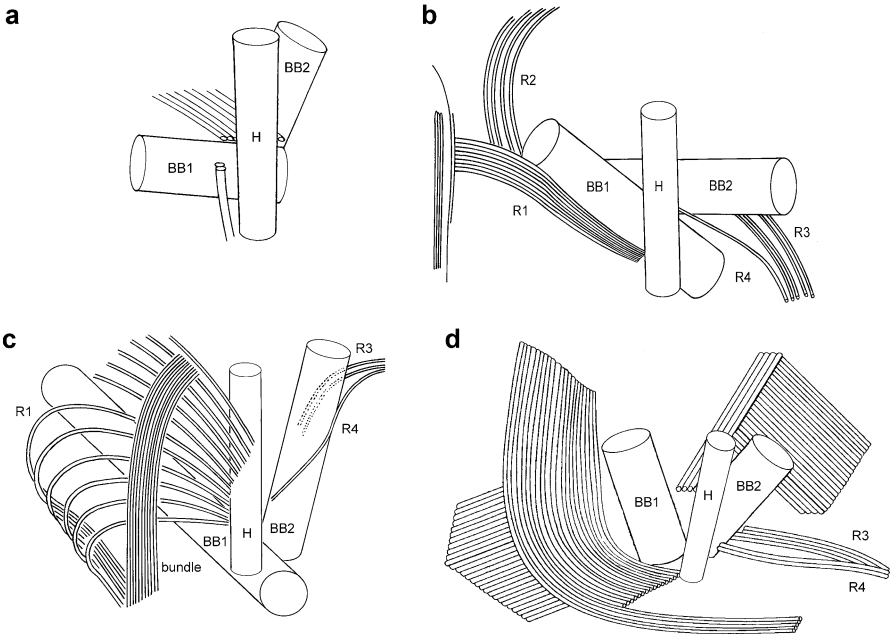

Fig. 2 Schematic three-dimensional reconstruction of the flagellar apparatus with microtubular roots of the Haptophyta: (**a**) *Diacronema*; (**b**) *Chrysochromulina scutellum*; (**c**) *Prymnesium palpebrale*; (**d**) *Chrysotila*

unusual in that the shorter posterior flagellum has a swelling on the side adjacent to the cell body (Green and Hibberd 1977).

The flagella bases and flagellar roots anchor the flagella within the cell and are components of the cell's cytoskeleton as well as being involved in cellular functions, such as mitosis. Both microtubular (Fig. 2) and fibrous flagellar roots are recorded in the Haptophyta and the microanatomy of the flagellar apparatus is believed to offer phylogenetic information because its morphology appears to evolve very slowly. Coccolithophyceae flagellar roots R1 and R2 are associated with the left flagellum and R3 and R4 with the right flagellum (see Eikrem and Moestrup 1998). R1 originates close to the base of the haptonema. The roots are numbered in a clockwise direction starting at the left flagellum with R1 (Green and Hori 1994). Over generations, the right flagellum and its basal body develop into the left flagellum. The left flagellum is termed the mature flagellum and it corresponds to the longer flagellum; the right flagellum is shorter and will transform into a mature flagellum in the next generation (Beech et al. 1988).

Inouye and Pienaar showed that the coccolithophores, *Umbilicosphaera foliosa*, and a species of *Chrysotila* (*Pleurochrysis*) have a complex root system with some components consisting of as many as two hundred microtubules (Inouye and Pienaar 1984; Inouye and Pienaar 1985). Such roots have been termed compound roots and consist of a sheet of microtubules and a closely packed bundle of numerous

microtubules. The bundles are termed crystalline roots (CR1, CR2) and are associated with the roots (R1, R2) of the basal body of the left flagellum (Fig. 2d). Some species have crystalline roots in both R1 (termed CR1) and R2 (termed CR2), whereas others have only one of them (Billard and Inouye 2004). Crystalline roots (Fig. 2c) are also found in *Isochrysis* (Hori and Green 1991) and *Prymnesium* (Birkhead and Pienaar 1994; Birkhead and Pienaar 1995).

Syracosphaera pulchra (Inouye and Pienaar 1988), *Algirosphaera robusta* (Probert et al. 2007), and the saddle-shaped species of *Chrysochromulina* seem to lack crystalline roots, and the R1 of saddle-shaped *Chrysochromulina* species (Fig. 2b) often consist of less than ten microtubules (Moestrup and Thomsen 1986; Eikrem and Moestrup 1998; Jensen and Moestrup 1999). In non-saddle-shaped Prymnesiaceae species, they may number more than 20 and form a broad sheet of microtubules.

The cytoplasmic tongue (Beech and Wetherbee 1988) is a complex formed by some microtubules of the R1 sheet and the fibrous root originating on the left basal body. It is delineated by an extension of the peripheral endoplasmic reticulum and extends deep into the cell in a narrow space of cytoplasm (Billard and Inouye 2004) in several *Chrysotila* species (Gayral and Fresnel 1983; Beech et al. 1988; Fresnel and Billard 1991) and *Prymnesium palpebrale* (Birkhead and Pienaar 1995). In *Prymnesium nemamethecum*, it is present, but reduced (Birkhead and Pienaar 1994).

R2 may be compound, but only a few microtubules constitute the sheet of R2, and it originates between the basal bodies close to the left basal body. Possible homologies between the complex and simple systems have been suggested (Inouye and Pienaar 1984; Moestrup and Thomsen 1986; Green and Hori 1994). Roots R3 and R4 are never compound and consist of only a few microtubules. R3 originates from the right side of the right basal body and R4 from the left. Accessory and connecting fibers link the flagellar bases and the haptonema base. They may appear striated or nonstriated in electron micrographs of thin sections (Green and Hori 1994; Pienaar 1994). The fibrous root associated with the cytoplasmic tongue is the most prominent.

The flagellar roots found in the Pavlovophyceae are different. Two microtubular roots, R1 and R2, with only a few microtubules are accompanying the basal body of the short flagellum. A conspicuous fibrous root is associated with the basal body of the long flagellum extending deep into the cell close to the nucleus. Accessory and connecting fibers are present (Green and Hori 1994).

Haptonema

In its most extreme form, the haptonema is very long, often many times the diameter of the cell body in length as in *Chrysochromulina rotalis* (Fig. 1i). In *C. strobilus*, the extended haptonema may be up to 100 μm in length, the cell diameter being only approximately 8 μm. The reduced haptonema of *Isochrysis* and *Chrysotila* is very short (1–2 μm) and barely detectable with light microscopy. In *Dicrateria rotundata*, reduction is more extreme such that the haptonema is represented by at most a small

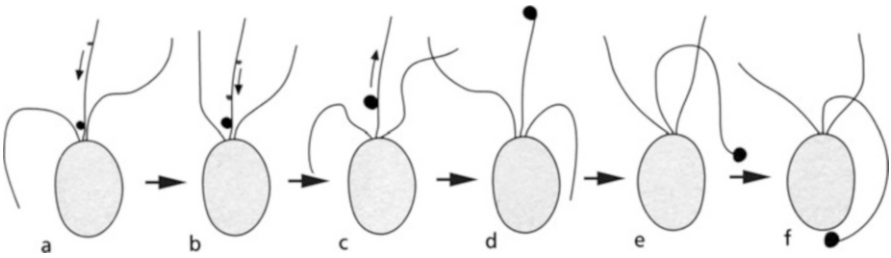

Fig. 3 Schematic interpretation of nutrient particle uptake studies in *Haptolina hirta* by Inouye and Kawachi (1994) from Graham and Wilcox (2000): (**a**–**b**), food particles captured by the distal part of the haptonema and transported along the haptonema surface to aggregate in a larger particle on the proximal part; (**c**–**d**) food particle aggregates move to the haptonema tip; (**e**–**f**) haptonema manipulating the food aggregate to be deposited on the posterior cell surface where it will be engulfed

elevation between the flagella. Between these extremes may be seen a variety of haptonema lengths. In some taxa, the haptonema coils (*Haptolina ericina*, *Chrysochromulina campanulifera*), whereas in others (*Prymnesium parvum*, *Phaeocystis pouchetii*), the haptonema flexes, but without any organized pattern of movement.

The haptonema may function as a feeding organelle (Inouye and Kawachi 1994; Kawachi and Inouye 1995), and the process is demonstrated in Fig. 3. In swimming cells of *Haptolina hirta* with the haptonema directed forwardly and the flagella alongside the cell, prey particles adhere to the haptonema. They are transported to a point ca 2 μm from the base where an aggregate of prey is formed. The aggregate is moved to the tip of the haptonema and the haptonema bends to deliver it to the surface of the rear end of the cell where it is phagocytized into a food vacuole.

In both long and short haptonema-bearing species, the cell may attach to the substrate (slide, cover glass) either at the tip or, in the case of a long haptonema, by any point along its length. Attached haptonema may show gliding or sliding movements in a sinuous manner, whereas unattached, extended haptonema may demonstrate bending or flicking movements. Coiling often occurs at contact with an obstacle. The most spectacular movements, however, are seen in the coiling and uncoiling of long haptonema of *Chrysochromulina* species. Coiling is a very rapid process and may take only 1/60–1/100th of a second, whereas the uncoiling process is much slower and may take between 2 and 10 s. Coiling is usually initiated from the haptonema tip, and the direction and orientation of coiling and number and diameter of gyres is predetermined (Parke et al. 1971; Leadbeater 1971a; Inouye and Kawachi 1994). Coiling is believed to be the result of an influx of Ca + from the medium in which the cells live and into the lumen of the haptonema (Gregson et al. 1993; Inouye and Kawachi 1994).

The fine structure of the haptonema (Fig. 4) is quite unlike that of the flagella. The plasmalemma of the free part typically encloses a fenestrated cylinder of endoplasmic reticulum (ER) within which there is a ring of 6 or 7 single microtubules.

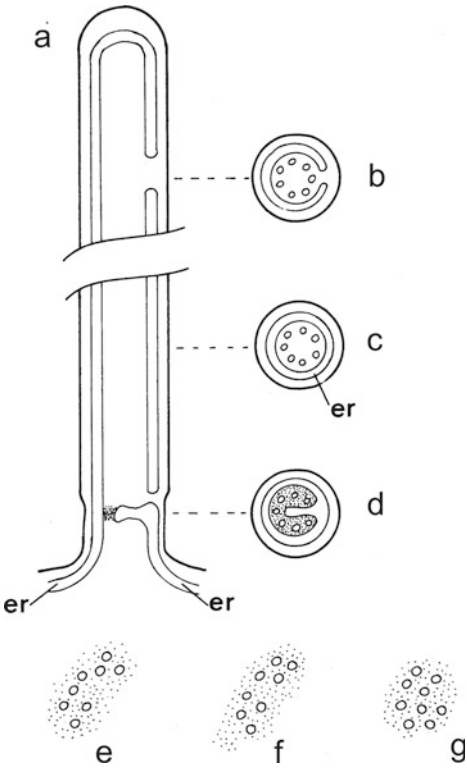

Fig. 4 Schematic view of a haptonema: (**a**) longitudinal section with endoplasmic reticulum, microtubuli not shown; (**b**–**d**) transverse section at indicated positions showing endoplasmatic reticulum and microtubuli; (**e**–**g**) microtubuli within the cell. Abbreviation: *er*, endoplasmic reticulum

The plasmalemma of the haptonema is confluent with that of the cell body, and the ER is continuous with the peripheral ER of the cell. Toward the proximal end of the haptonema, the ring of microtubules becomes reoriented into an arc facing one of the flagella, with the ER cisterna lying on the outer curved side of the arc. Immediately beneath this level, the ER once again forms a complete cylinder, but with a flat-ended, fingerlike component projecting inward; in transverse section, the projection appears to be capped by the arc of microtubules. On entering the cell, additional microtubules appear and further rearrangements of the microtubules take place to form two superposed arcs of 4 microtubules each, followed in some cases by the addition of a ninth microtubule (Manton 1964b; Moestrup and Thomsen 1986; Billard and Inouye 2004).

Reduced haptonema are known in many Coccolithophyceae species, such as the short bulbous haptonema of many *Chrysotila* species (Manton and Peterfi 1969; Billard and Inouye 2004). In *Isochrysis* and *Ruttnera*, the haptonema is reduced to a small protrusion containing ER profiles and only three microtubules, increasing to four within the cell. In *Emiliania huxleyi* and *Dicrateria inornata*, there is no trace of a haptonema (Klaveness 1972; Green and Pienaar 1977).

In the Pavlovophyceae, the free part of the haptonema is short and the number of microtubules reduced (only one to four microtubules), although the number

increases to seven or eight inside the cell (Green and Hibberd 1977; Gayral and Fresnel 1979; Inouye and Kawachi 1994). The ER is strongly fenestrated and may be reduced to a small vesicle on one side of the organelle (Green 1980).

Haptonemal roots have been described in a few species of the Pavlovophyceae where they appear as fibrous structures originating at the proximal end of the haptonema microtubules (Green and Hori 1994). Haptophyte haptonema microtubules may also be attached to one of the kinetids by a fibrous connection (Manton 1964a; Moestrup and Thomsen 1986; Green and Hori 1994).

Plastid, Nucleus, Golgi Apparatus, Pyrenoids, and Stigma

Haptophyta cells normally possess 1–2 plastids containing three thylakoid lamellae and there is no girdle lamella (Fig. 5). Pyrenoids may be immersed within the plastid and penetrated by one or a few pairs of thylakoids (Fig. 5c), but in some genera, they may bulge from the inner face of the plastid. The plastid and pyrenoid are surrounded by endoplasmic reticulum confluent with the nuclear envelope (Fig. 5b, c), the nucleus itself usually lying close to the plastid (Pienaar 1994). Coccolithophyceae cells usually lack a stigma, but an autofluorescent substance has been associated with the flagella in several species (Kawai and Inouye 1989).

A stigma or "eyespot" consisting of a single layer of lipid globules occurs in many Pavlovophyceae (Fig. 5d), although its position is variable. It is absent in *Diacronema ennorea* and *Rebecca helicata*. In some, it lies on the inner face of the

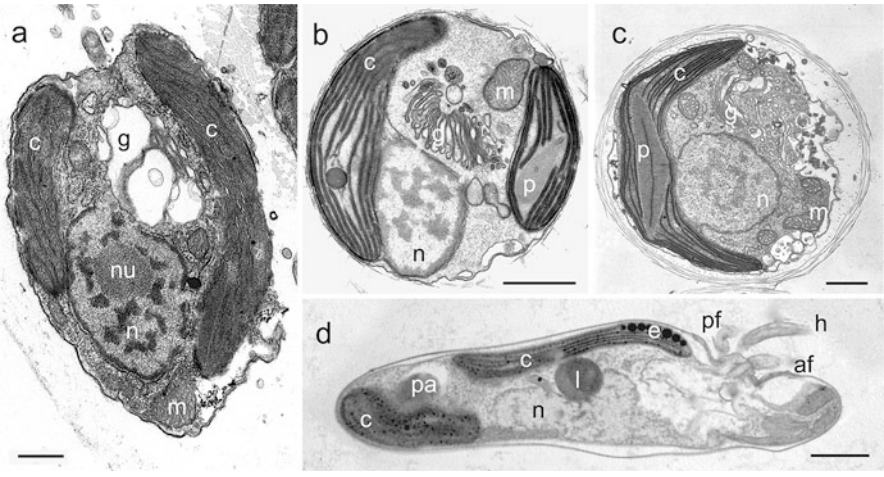

Fig. 5 Ultrastructure, TEM sections. (**a**) *Phaeocystis antarctica*, (**b**) *Chrysochromulina throndsenii*, (**c**) *Calyptrosphaera sphaeroidea*, (**d**) *Diacronema noctivaga*. Abbreviations: *c*, chloroplast; *n*, nucleus; *nu*, nucleolus; *pf*, posterior flagellum; *af*, anterior flagellum; *h*, haptonema; *p*, pyrenoid; *l*, lipid droplet; *m*, mitochondrion. Scale bars 5 μm (Image of *Phaeocystis* by courtesy of Adriana Zingone, *Calyptrosphaera* by Dag Klaveness and *Diacronema* by Madhi Bendif)

plastid close to the anterior flagellum, but in *Diacronema lutheri* and *D. vlkianum*, it is found on the outer face of the plastid lying beneath the shorter flagellum (Green 1980; Van Lenning et al. 2003; Bendif et al. 2011).

The mitochondrion has tubular cristae and is probably single and highly reticulated (Beech and Wetherbee 1984). The Golgi apparatus consists of a single dictyosome (Fig. 5b) and lies between the nucleus and the kinetids. In sections, the cisternae are arranged in a fan formation with the edges of the cisternae closer and less dilated on the side of the stack nearer the kinetids. The central parts of several adjacent cisternae may be inflated in a manner that seems to be unique to members of the Coccolithophyceae (Manton 1967; Hibberd 1980; Pienaar 1994) and may be concerned with carbohydrate polymerization during scale formation (Romanovicz 1981).

Storage Metabolites, Lipids, and Sterols

The primary storage metabolite of most members of the Haptophyta is assumed to be the water-soluble 1–3 glucan chrysolaminarin, as demonstrated for *Phaeocystis globosa* motile cells (Janse et al. 1996) and *Emiliania huxleyi* (Vårum et al. 1986). In the Pavlovales, another 1–3 glucan, the solid paramylon, commonly found in the euglenoids, has been identified by X-ray analysis (Kreger and Van der Veer 1970). Lipid bodies are also commonly present in the Haptophyta. Lipids and sterols found in the Haptophyta have been reviewed by Conte et al. (1994) and Marlowe et al. (1984). Many Isochrysidales species are unusual as they produce long-chain polyunsaturated C_{36} fatty acids and C_{37}–C_{39} sterols and diverse other neutral lipid compounds that can be collectively referred to as "polyunsaturated long-chained (C_{37}–C_{39}) alkenones, alkenoates, and alkenes" (PULCAs) (Eltgroth et al. 2005). The relative composition of the latter compounds, their degree of unsaturation, and their ^{13}C and ^{2}H signatures are often well correlated with environmental parameters such as temperature, salinity, and also CO_2 concentration (Marlowe et al. 1984; Pagani 2002; Van der Meer et al. 2007). Additionally, they are comparably resistant to digenesis in sediments (see Rontani et al. (2013) for a recent review), which makes PULCAs a tool widely used by geologists for paleo-reconstructions of temperature, salinity, and CO_2 (Conte et al. 1998; Pagani 2002; Beltran et al. 2007; Liu et al. 2008). These genera also have particularly high concentrations of the sterol 24-methylcholesta-5,22E-dien-3-ol, which occurs as well in some other coccolithophores but has not been recorded in the Prymnesiales taxa examined and only occurs in low concentrations in the Pavlovophyceae. Other sterols occurring in significant concentrations, though not universally distributed throughout the class, include cholest-5en-3-ol (cholesterol), 24-methylcholest-5-en-3-ol, 24-ethycholesta-5,22E-dien-3-ol, and 24-ethylcholest-5-en-3-ol. Well-known PULCA producers include the Isochrysidales species *Emiliania huxleyi*, *Gephyrocapsa oceanica*, and *Isochrysis galbana* (Conte et al. 1998); PULCA production has also been observed in the benthic lacustrine *Ruttnera* (Sun et al. 2007). Biochemically, these compounds derive from specialized cellular lipid

synthetic pathways, possibly similar to polyketide synthesis, as can be interpreted on the basis of genomic evidence (Read et al. 2013) and gene expression patterns (Rokitta et al. 2011). PULCAs are typically deposited in cytoplasmic liposomes and may function as sinks of cellular reductive energy and carbon; this latter function may especially be important in situations when growth is arrested, under nutrient starvation (Eltgroth et al. 2005). In experimental mesocosm blooms, cells of *E. huxleyi* accumulated up to 6 pg. PULCA cell^{-1} during exponential phase growth, a significant portion of the cellular biomass (Benthien et al. 2007). In addition, PULCAs appear also to serve as energy stores as they can be degraded in the dark (Eltgroth et al. 2005).

Pigments

Haptophytes have high pigment diversity. Chl *a* and the accessory pigments divinyl protochlorophyllide (MgDVP), Chl c_2, diadinoxanthin, diatoxanthin, and β,β-carotene comprise the common haptophyte pigments (Van Lenning et al. 2004). The haptophytes can then be divided into eight pigment types based on the content of nine chl *c*-type pigments (DV-Chl c_{PAV}, MV-Chl c_{PAV}, DV-Chl c_3, MV-Chl c_3, MgDVP, Chl c_2, Chl c_1, Chl c_2-MGDG$_{Ehux}$, Chl c_2-MGDG$_{Cpoly}$) and five fucoxanthin derivatives (Unk-Fx, 4kFx, Bfx, HFx, 4kHFx) (Van Lenning et al. 2003; Van Lenning et al. 2004; Zapata et al. 2004). Among the coccolithophores, the pigment profiles follow large phylogenetic groups and/or ecological preferences (Van Lenning et al. 2004). The pigment profiles of the class Pavlovophyceae agrees with SSU rDNA phylogenies and some ultrastructural features (Van Lenning et al. 2003). The pigment types within the non-calcifying order Prymnesiales do, however, not appear to correlate with phylogenetic groups (Zapata et al. 2001; Edvardsen et al. 2011).

The fucoxanthin derivative 19-hexanoyloxyfucoxanthin (HFx) was suggested as a pigment marker to determine the contribution of haptophytes to phytoplankton assemblages (Everitt et al. 1990), but was later found to be absent in the coastal families Isochrysidaceae, Pleurochrysidaceae, and Hymenomonadaceae and to be present in some dinoflagellates with plastids of haptophyte origin such as species of *Karenia* and *Karlodinium* (Berger et al. 1977), as well as in the ochrophytes *Dictyocha speculum* (Daugbjerg and Henriksen 2001) and *Pseudochattonella farcimen* (Edvardsen et al. 2007). The chemotaxonomic approach should be based on the combined use of chlorophylls and carotenoids to define pigment types (Seoane et al. 2009) and validated by microscopy or molecular species identification.

Scales

The unmineralized scales of the Coccolithophyceae (Fig. 6d–q) are composed of microfibrils (see Leadbeater 1994 and references therein) usually arranged in two layers where the proximal face (facing the cell membrane) has a radial pattern of

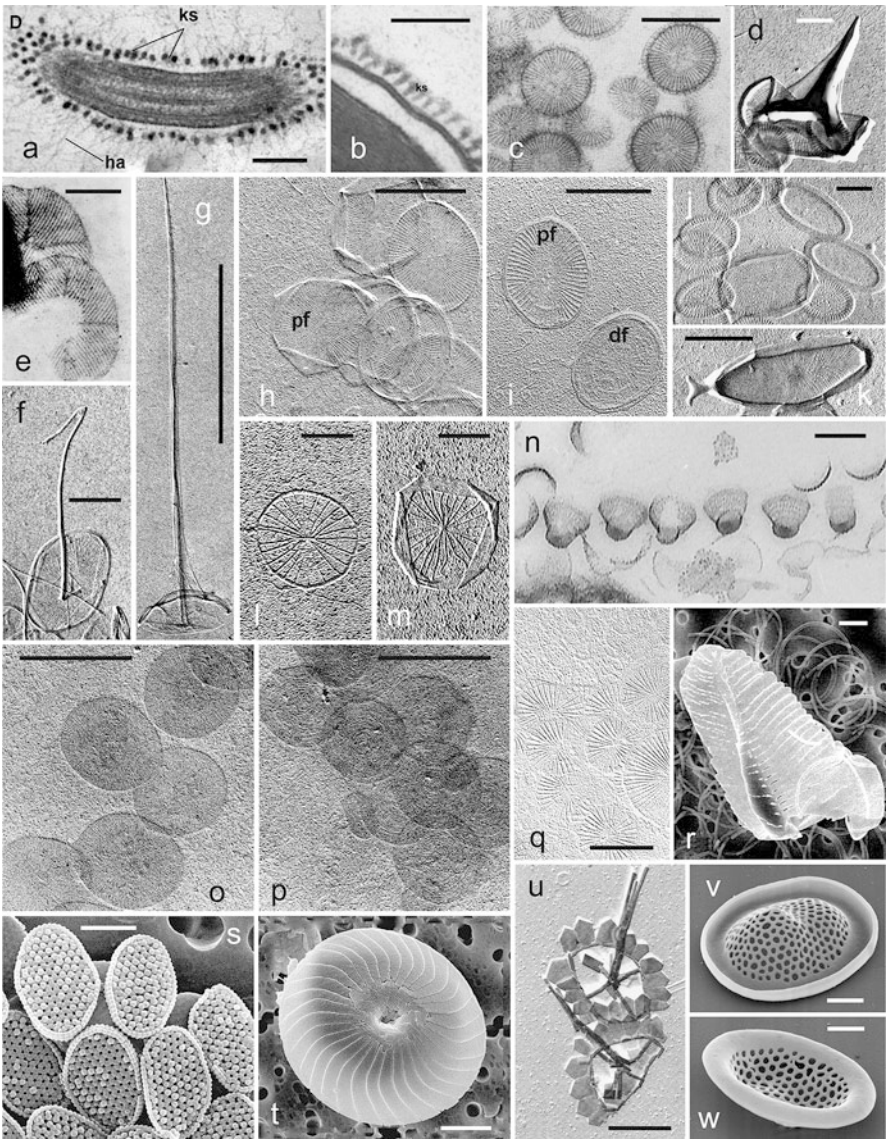

Fig. 6 Scales and coccoliths in Haptophyta. (**a**–**b**) Pavlovophyceae: (**a**) *Pavlova pinguis*, knob scales on flagella; (**b**) cell surface with knob scales in *Rebecca salina*. (**s**, **t**) *Calcidiscus leptoporus*: (**s**) holococcoliths, crystallolith (*Crystallolithus rigidus* stage), (**t**)

microfibrils, often arranged into quadrants (Fig. 6e, h), whereas the distal face is more variable with spiral and interwoven patterns that are common and modifications often form spines, cylinders, or cup-shaped structures (Fig. 6d, g, n). The distal face may have marginal thickenings as in the plate scale of *Chrysochromulina campanulifera* or more substantial rims that can be inflexed as in *Prymnesium polylepis* (Fig. 6j) or upright as in outer layer scales of *Chrysochromulina throndsenii* and *Dicrateria rotunda* (Fig. 6m). The scales may be arranged in one or more layers and with scales bearing spines (*Haptolina hirta*) (Fig. 6f, g), cups (*C. campanulifera*) (Fig. 6o), or cylinders (*C. microcylindra*) constituting the outer layer when present. Scale form and ornamentation are important taxonomic characters at the species level. In *Prymnesium neolepis*, both organic scales and silicified scales (Fig. 6v, w) are present (Yoshida et al. 2006).

Scales occur in a variety of structures from apparently simple plates, such as those found in *Isochrysis* (Green and Pienaar 1977), *Chrysotila*, and the motile stage of *Emiliania huxleyi* (Fig. 6e), to scales formed into spines that can be elaborated as in the alternate stage of *Prymnesium polylepis* (Fig. 6d) and sometimes of considerable length as in *Haptolina ericina* (9–15 μm long). Spines are often formed by hypertrophy of the distal face of the scale, either wholly or in part, such as the long spines of *H. ericina* (Manton and Leedale 1961) or *Chrysochromulina mantoniae* (Leadbeater 1972). Some spines are closed as in *Haptolina* (Fig. 6f, g) whereas others such as those covering *H. ericina* and *Chrysocampanula spinifera* are open-ended tubes (Manton and Leedale 1961; Pienaar and Norris 1979). Lateral development of the scales is shown in the authentic stage of *Prymnesium polylepis* in which there are a variety of oval plate scales, some of which have fishtail extensions at one end (Fig. 6j, k).

The scales are usually distributed over the entire cell surface, and where there is more than one type of scale, these may be in discrete layers. In *C. campanulifera*, the cuplike scales form a distal layer overlying the plate scales (Manton and Leadbeater 1974), and in *Phaeocystis globosa* (Fig. 6c) and *Dicrateria rotunda* (Fig. 6l, m), the scales with erect rims overlie the scales without such rims. However, the scales are not always evenly distributed and examples of this may be seen in the spine scales of *Chrysochromulina mantoniae*, which occur in clusters at the poles of the ovoid cells, or the very small scales found only on the haptonema in *Isochrysis* species (Green and Pienaar 1977) and in *Prymnesium nemamethecum* (Pienaar and Birkhead 1994).

The cells in the filamentous "Apistonema" stage of Chrysotila have several layers of tightly packed scales (Leadbeater 1971b; Pienaar 1994).

Pavlovophycean scales are small spherical or clavate dense bodies (6 a, b) known as "knob scales," produced in the Golgi body and found particularly on the longer flagellum, although in some species they may also be found also on the cell body (Fig. 6b) as in *Pavlova gyrans* and occasionally on the haptonema, for example, in *Diacronema lutheri*. Such scales are usually smaller and sparser than those of the flagellum. The latter are often arranged in regular rows longitudinally, each row being slightly displaced relative to those adjacent. In a few species, however, the flagellar knob scales are disposed randomly on the flagellum. Most members of the Pavlovophyceae lack a distinct cell covering, but nonmotile cells may be invested with layers of mucilage (Green 1980; Leadbeater 1994; Bendif et al. 2011).

Scale Composition and Formation

Unmineralized Coccolithophyceae scales consist largely of complexed carbohydrates and some protein (Allen and Northcote 1975; Klaveness and Paasche 1979; Romanovicz 1981; Leadbeater 1994). The structural aspects of scale formation were first reviewed by Hibberd (1980) and Romanovicz (1981). The Golgi body is the site of scale formation. Scales are released to the cell surface by fusion of the plasmalemma with the cisternal membrane. Scales are often composed of four distinct components where the proximal radial microfibrils are to a large extent composed of sulfated polysaccharides, whereas the distal spiral microfibrils contain cellulose and protein. A glycoprotein covers the spiral microfibrils and there is also an amorphous layer composed of acidic polysaccharides. The radial fibrils are laid down before the spiral fibrils and then the amorphous matrix is added. In the Pavlovophyceae microfibrillar, scales are unknown (Leadbeater 1994).

Coccoliths

The coccolithophores possess external calcified ($CaCO_3$ as calcite) scales termed coccoliths (Figs. 6s–v and 7a–i). There are many living and fossil forms exhibiting an astounding variety in morphology and an extensive literature exists on the subject (see, e.g., Tappan (1980), Kleijne (1993), and Jordan et al. (2004)). The characteristics of these structures are briefly outlined here. Coccoliths have been classified into two main types, heterococcoliths and holococcoliths, based on coccolith ultrastructure and morphology, and there are a number of terms in use to describe both the overall form of the coccolith and its crystal structure (Jordan et al. 1995; Young et al. 1997). Nannoliths are a third group that differs from both holo- and heterococcoliths in structure and architecture (Jordan et al. 1995; Billard and Inouye 2004). Coccospheres are made up of multiple coccoliths and may be multilayered and monomorphic as in *Emiliania huxleyi* (Fig. 7a), have two layers of

morphologically different coccoliths (dithecate) as in most *Syracosphaera* species, or have two types of coccoliths within one layer (dimorphic and monothecate) (Fig. 7b).

Heterococcoliths are elaborate interlocking structures composed of multiple strongly modified calcite crystals (Figs. 6u, v and 7a–g). The crystallographic orientation of subvertical "V-units" and sub-radial "R-units" (Young et al. 1992) is key to understanding heterococcolith ultrastructure and phylogenetic relationships (especially when dealing with their fossil record). There are several types of heterococcoliths, such as placoliths (Figs. 6u and 7a, d, f), caneoliths (Fig. 7b), cribriliths, lopadoliths (Fig. 7c), helicoliths (Fig. 7g, h), and pappoliths (Fig. 6v). Pentaliths (Fig. 7e) and ceratoliths (Fig. 6s) are considered nannoliths.

Holococcoliths are non-interlocking structures composed of rhombohedral crystallites of uniform size (ca. 0.1 μm in diameter) that cover the cell surface. Each holococcolith is made up of numerous identical calcite elements in the form of minute rhombohedral or hexagonal prisms (Figs. 6t and 7h, i). A variety of holococcolith types exist including crystalloliths (composed of rhombohedra arranged evenly on an organic baseplate in *Crystallolithus hyalinus* stage of *Coccolithus pelagicus*), calyptroliths (cap-shaped coccoliths of hexagonal crystals in *Calyptrosphaera*), and zygoliths (elliptical rings with crossbars and a distal knob) in *Helladosphaera cornifera*.

Coccolith Formation

Detailed observations of coccolith formation are possible in ultrathin sections of fixed cells in transmission electron microscopy, and complimentary information is provided by biochemical studies. The mechanisms of intracellular formation of heterococcoliths have been most extensively studied in *Emiliania huxleyi* (Wilbur and Watabe 1963; Klaveness 1976; Van Der Wal et al. 1983; Van Emburg et al. 1986; Figs. 9 and 10) and *Chrysotila* (Manton and Leedale 1969; Outka and Williams 1971; Van Der Wal et al. 1983; Marsh et al. 2002), with additional information available from a few taxa such as *Coccolithus braarudii* (Manton and Leedale 1969), *Umbilicosphaera sibogae* (Inouye and Pienaar 1984), *Syracosphaera pulchra* (Inouye and Pienaar 1988), and *Algirosphaera robusta* (Probert et al. 2007). By comparison, little information is available concerning holococcolith formation.

The heterococcoliths (Fig. 8b, c) of *E. huxleyi* are synthesized intracellularly in a system of vacuoles derived from the Golgi body, consisting of a coccolith vesicle (cv) enclosing the growing coccolith and a reticular body (rb) with anastomosing tubes (Fig. 8a). Inside the coccolith vesicle, coccolith production occurs through two discrete processes, controlled nucleation of crystals and their subsequent growth (Young et al. 1999). Crystal nucleation of a "proto-coccolith rim" occurs around the rim of the baseplate scale. These crystals subsequently grow in various directions to form complex crystal units. Crystal growth is regulated by a coccolith-associated

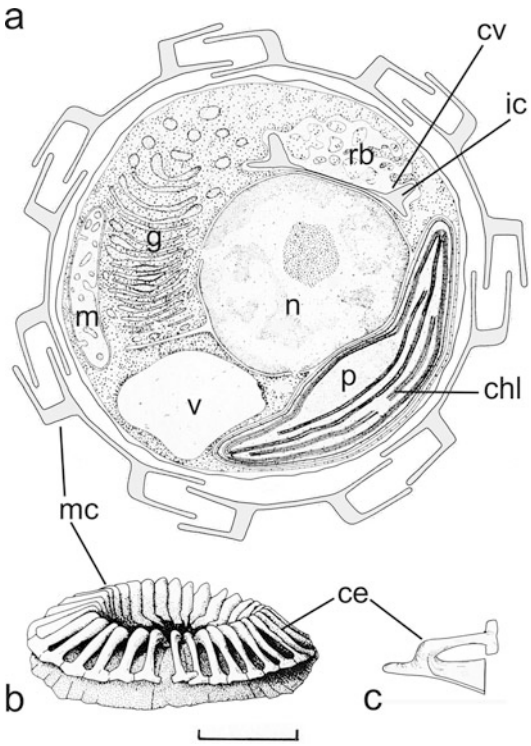

Fig. 8 Schematic drawing *Emiliania huxleyi*: (**a**) transverse section of whole cell showing the chloroplast (*chl*), coccolith vesicle (*cv*), Golgi body (*g*), immature coccolith (*ic*), mature coccolith (*mc*), mitochondrion (*m*), nucleus (*n*), pyrenoid (*p*), reticulate body (*rb*), vacuole (*v*), (**b**) single mature coccolith showing elements arranged in an oval ring, (**c**) calcite element (*ce*) of a coccolith. polysaccharide (CAP) that has been located in the cv-rb system at four different sites: the outline of the membranes, fine threads inside the lumen, the baseplate, and a thin film surrounding the $CaCO_3$ crystals. The CAP is a highly complex soluble acidic polysaccharide containing at least 13 different monosaccharide residues, including uronic acids, mono- and dimethylated sugars, and sulfate esters (Fichtinger-Schepman et al. 1981). It has been shown that this CAP can inhibit crystal growth (Borman et al. 1982) and influence crystal morphology by site-specific attachment to crystallographic steps (Henriksen et al. 2004). It is therefore thought that this polysaccharide has a regulatory function in the inhibition, termination, and therefore modeling of crystal growth. The regulation of coccolith shape is also thought to be dependent on the morphology of the membrane of the coccolith vacuole. Using various inhibitors, Langer et al. (2010) experimentally demonstrated that cytoskeletal microtubules and actin filaments play a role in coccolith morphogenesis in *E. huxleyi*, presumably by determining the shape of the coccolith vesicle. After it is completed, the coccolith is transported to the cell membrane and exuded to the extracellular coccolith cover. In the motile scale-bearing form of *E. huxleyi*, the scales are formed in the Golgi apparatus, but do not calcify, although a cv-rb system is present (Klaveness 1972).

In contrast to *E. huxleyi*, *Chrysotila carterae* scales and coccoliths are produced in the trans (maturing) part of the Golgi apparatus. Granular elements termed

coccolithosomes are formed in cisternae at the cis side of the Golgi. They appear to be transported to vesicles containing calcifying scales where they disintegrate as the formation of a $CaCO_3$-associated matrix proceeds. Coccolithosomes contain high concentrations of calcium and polysaccharide (Van Der Wal et al. 1983). Three types of polysaccharide have been identified in *C. carterae* (PS1, PS2, PS3; (Marsh et al. 2002)). PS1 and PS2 bind calcium and form coccolithosomes, with PS2 probably playing an important role in the nucleation of the proto-coccolith ring, as shown by the fact that mutant *C. carterae* cells deficient in this polysaccharide show very little calcification (Marsh and Dickinson 1997). During coccolith growth, PS3 is located between the crystals and the vesicle, and it is believed to be involved in shape regulation, because *C. carterae* cells not expressing PS3 produce a proto-coccolith ring that does not develop further (Marsh et al. 2002).

Comparison of observations of heterococcolith formation in other taxa reveals a similar overall pattern with calcification occurring in Golgi-derived vesicles and commencing with nucleation of a proto-coccolith ring of simple crystals around the rim of a precursor baseplate scale, followed by growth of these crystals in various directions to form complex crystal units. However, significant diversity is also evident, with, for example, coccolithosomes only being observed in *Chrysotila*, the reticular body being unique to *E. huxleyi* and *Gephyrocapsa*, and the peripheral endoplasmic reticulum playing a role in coccolithogenesis in *Algirosphaera robusta*.

Very few holococcolithophore cultures have been maintained and only three species have been studied in TEM sections; *Coccolithus braarudi* (as *Crystallolithus braarudi)* was studied by Manton and Leedale (1963, 1969) and by Rowson et al. (1986). *Calyptrosphaera sphaeroidea* was studied by Klaveness (1973) and Sym and Kawachi (2000) studied *Calyptrosphaera radiata*. As with heterococcoliths, holococcoliths are underlain by an organic baseplate scale and develop in Golgi vesicles. Individual rhombohedral calcite crystals have been observed within Golgi cisternae in *C. radiata* (Sym and Kawachi 2000), but despite numerous observations, fully formed holococcoliths have not been observed inside cells. It has therefore been inferred that the assemblage of crystals to form holococcoliths occurs outside the cell membrane, after exocytosis of the baseplate scale. This poses obvious problems for understanding how calcification is regulated. A potential explanation is provided by observations that a delicate hyaline "skin" envelopes the coccosphere of holococcolithophores, meaning that even if holococcoliths are assembled outside the cell membrane, this is likely to occur in a regulated environment. Alternatively, it is possible that holococcoliths are assembled just below the cell membrane but that it is a rapid process immediately preceding exocytosis and so has not been captured in TEM preparations.

Life Cycles

Organisms with heteromorphic phases in their life histories are common in the Haptophyta (Fig. 9a–c). An alternation of a haploid stage with a diploid stage has been documented in all orders and many families within the Coccolithophyceae. So

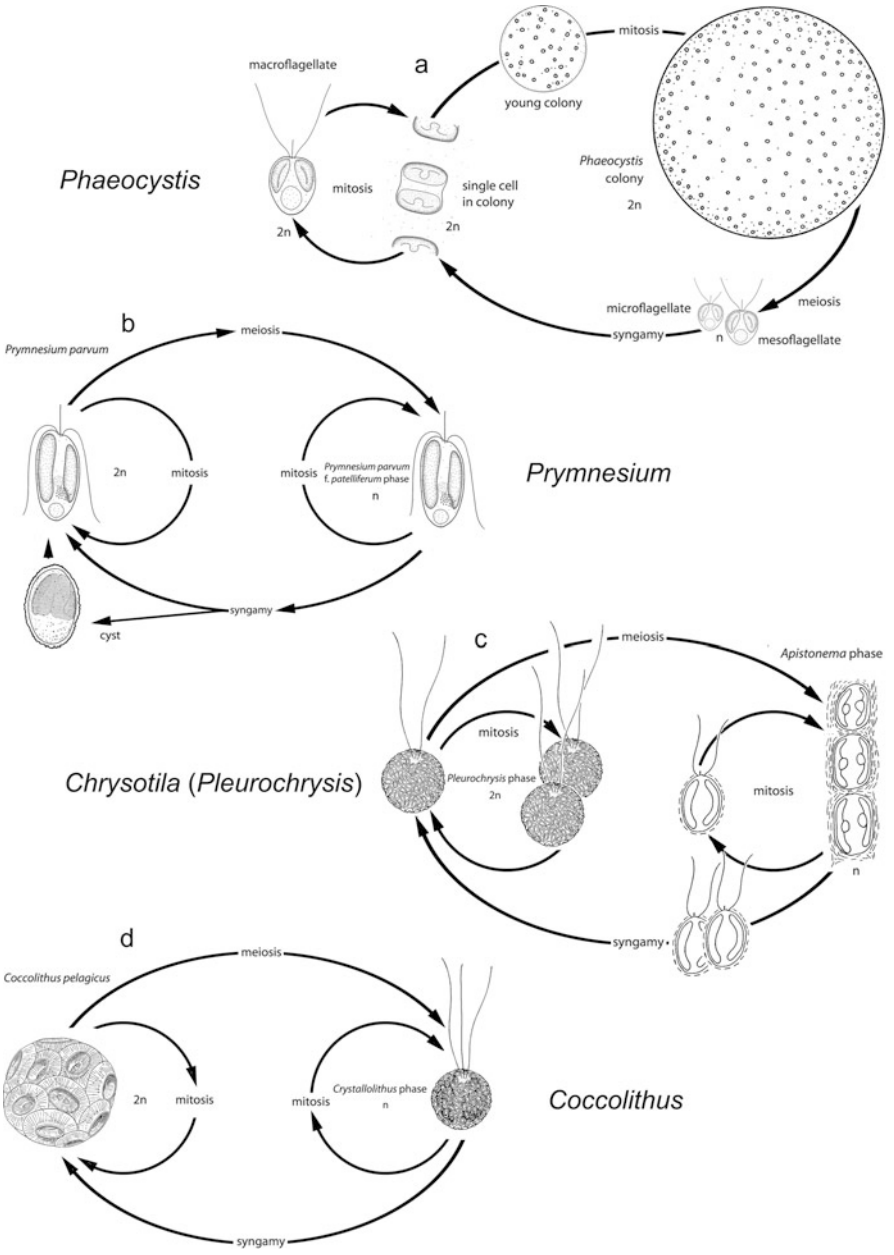

Fig. 9 Schematic life cycles in Coccolithophyceae: (**a**) *Phaeocystis globosa*, (**b**) *Prymnesium parvum*, (**c**) *Chrysotila carterae*, (**d**) *Coccolithus pelagicus*

far alternation of generations has not been demonstrated in members of the Pavlovophyceae, although transitions between motile and nonmotile forms occur in many species (Billard 1994; Bendif et al. 2011).

Alternation between a nonmotile planktonic palmelloid phase (Figs. 1c, g and 9a) and motile swarmers occurs in *Phaeocystis pouchetii*, *P. antarctica*, *P. jahnii*, and *P. globosa.* In *P. globosa*, four different cell types have been distinguished; two of them are haploid: the microflagellate and the slightly larger mesoflagellate. The largest flagellate type, the macroflagellate, and the palmelloid phases are diploid. The function of these cells and their order of appearance in the life cycle are still unknown, but the short-lived macroflagellate is believed to develop into a colony. Micro- and mesoflagellates (meiosis) are produced within the colony and are eventually released and multiply vegetatively. The life cycle is completed by syngamy between a micro- and mesoflagellate that develops into a macroflagellate that forms a new colony (Peperzak et al. (2000) and references therein). A nonmotile zygote linking the haploid unicellular stages and the diploid colonial stages has been documented in *P. antarctica* (Gaebler-Schwarz et al. 2010). The zygote can divide vegetatively as a benthic palmelloid stage and not revert to the colonial stage at least in culture conditions. The characteristic α-chitin containing pentagonal stars (Chrétiennot-Dinet et al. 1997) are produced by the mesoflagellate in *P. globosa* (Peperzak et al. 2000). These star-shaped structures are also produced by *P. antarctica*, *P. pouchetii*, and *P. cordata* but have not been observed in *P. jahnii.* In *P. scrobiculata*, a nine-ray star has been reported. *Phaeocystis scrobiculata* and *P. cordata* are believed to occur as flagellates only. *Phaeocystis* flagellates may be covered by minute scales (Fig. 6d) and the ornamentation of the scales may vary slightly between species (Rousseau et al. 2007). A plausible life cycle for *Phaeocystis* is illustrated in Fig. 9a.

In *Prymnesium*, two distinct cell types with differing scale morphology and cell size may occur within their haplodiploid life cycle as is seen in *Prymnesium polylepis* (Edvardsen and Vaulot 1996; Edvardsen and Medlin 1998) (Fig. 6d, j, k) and *P. parvum* (Larsen and Medlin 1997; Larsen and Edvardsen 1998). Their life cycle may also contain nonmotile cells (Parke et al. 1955) and even a silicified cyst in the case of *P. parvum* (Pienaar 1980) (Fig. 9b).

Life cycles of coccolithophores provide an excellent documentation of the alternation between haploid and diploid generations. Each generation is characterized by a specific cell covering and is capable of vegetative multiplication and dispersal. Diploid generations bear heterococcoliths, whereas haploid generations, depending on the family/genera they represent, are either covered by holococcoliths (Coccolithaceae, Helicosphaeraceae, Figs. 7i and 9d) or, nannoliths (Ceratolithaceae, Figs. 6s and 7e), or are a non-calcifying benthic stage (Pleurochrysidaceae, Hymenomonadaceae, Fig. 9c), or a non-calcifying motile stage (Noëlhaerhabdaceae) (Billard and Inouye 2004).

Parke and Adams (1960) showed that the heterococcolithophore *Coccolithus pelagicus* ssp. *braarudii* (Geisen et al. 2002) phase alternated with a motile

holococcolithophore (*Crystallolithus braarudii*) phase. The haploid and diploid state of the holococcolith and heteroccoccolith stage, respectively, has been more recently demonstrated by flow cytometric DNA analysis (Houdan et al. 2004a). Reports of combination cells with the heterococcolithophore placed inside the gametangium (zygote stage) bearing holococcoliths are increasing in occurrence since their first reports in the early 1900s (Kamptner 1941; Thomsen et al. 1991; Kleijne 1993; Cros et al. 2000).

Alternation of a nonmotile stage ("Apistonema stage") with one or more motile forms (Fig. 9c) has been observed in *Chrysotila* (Leadbeater 1970; Gayral and Fresnel 1983) and *Ochrosphaera* Schussnig (Schwarz 1932; Lefort 1975). In *Chrysotila pseudoroscoffensis*, the diploid coccolith-bearing phase produces motile spores without coccoliths after meiosis. These give rise to a haploid benthic filamentous phase that eventually releases isogametes with flagella and a haptonema. Fusion takes place and a zygote is formed that releases diploid, coccolith-bearing motile cells within 24 h. In *Ochrosphaera neapolitana* meiosis, isogamete formation and syngamy were reported already by Schwarz (1932).

In *Ruttnera* species, the benthic, nonmotile, mucilage ensheathed cells form the dominant stage; the nonmotile cell may divide within the mucilage sheath to form a variable number of offspring cells (usually 8 or 16) that are released as swarmers. They settle quickly and secrete a new mucilage sheath after which they divide vegetatively (Green and Parke 1975).

A complex life cycle involving naked, scale-bearing, and coccolith-bearing stages was described in *Emiliania huxleyi* by Klaveness (1972). Flow cytometric analysis has shown that its life cycle includes a diploid and a haploid phase (Green et al. 1996) where the motile scale-covered flagellate is haploid and the coccolithophore may be diploid; however, haploid coccolithophores were reported by Medlin et al. (1996). This is a type of life cycle (Fig. 9d) that is considered typical of the Noëlhaerhabdaceae (Billard and Inouye 2004).

So far alternation of generations has not been demonstrated in members of the Pavlovophyceae, although transitions between motile and nonmotile forms occur in many species (Billard 1994; Bendif et al. 2011).

There are few reports of cysts in the Haptophyta. Cysts of *Prymnesium* were described by Carter (1937) and have been investigated by Pienaar (1980) who has shown that the walls of *Prymnesium parvum* cysts are composed of layers of scales with siliceous material on the distal surfaces. There is a simple sub-anterior pore. Cysts have also been reported in *Isochrysis galbana* (Parke 1949).

Differences in gene expression between the haploid flagellate and the diploid coccolith-bearing stage have been demonstrated (Von Dassow et al. 2009; Rokitta et al. 2011), but the ecological role of the different life cycle stages, their occurrence, and distribution are poorly understood. It has been shown that the colonial diploid stage of *Phaeocystis* may be resistant to viral attacks, whereas single cells are more susceptible to viral infection (Jacobsen et al. 2007). In *Emiliania huxleyi*, the haploid flagellate has been reported to escape viral infection (Frada et al. 2008).

Maintenance and Cultivation

Some haptophytes are easily cultivated, but many are more demanding to isolate and keep in culture. Of those in culture, most are euryhaline with wide nutritional tolerance. *Isochrysis* and *Pavlova* are easily cultivated and extensively used as feed in the aquaculture industry. *Prymnesium parvum* is extremely euryhaline and eurytherm and thrives in eutrophic waters (Edvardsen and Paasche 1998) and is also easily cultivated. About half of the described Prymnesiales species in all genera have at some point been cultured and most *Phaeocystis* species are presently kept in culture. Of the coccolithophore species, approximately half of those currently accepted are in culture, but most culture-based studies on coccolithophore physiology, genetics, and biochemistry use the cosmopolitan *Emiliania huxleyi*. Most cultured coccolithophores are from coastal waters of the families Pleurochrysidaceae, Hymenomonadaceae, Noëlaerhabdaceae, and Coccolithaceae. Few oceanic oligotrophic species have been cultured likely because they are sensitive to high nutrient concentrations (Probert and Houdan (2004) and references therein). The few oceanic picoplanktonic haptophyte cultures partly reflect our lack of information on nutritional requirements and physiology of haptophytes in oligotrophic oceanic waters but also the logistical problems of isolating rare and small species in remote places.

Many isolates were made of single cells by micropipette, either from the original water sample or from an enriched culture (10:1 or 20:1). Motile haptophytes, such as *Chrysochromulina*, tend to swim toward the light and can be concentrated at the surface prior to isolation. It is advisable to have a selection of media and dilutions available. The serial-dilution method can yield small and abundant haptophytes, such as *Dicrateria* and *Chrysochromulina* (Edvardsen et al. 2000). These and other isolation techniques are described in Andersen and Kawachi (2005).

Many marine media (f/2, IMR1/2, ErdSchriber, for a review, see Andersen (2005) are based on natural seawater with added nutrients, vitamins, and trace elements and have proved useful in the maintenance of many haptophytes. IMR1/2 and f/2 have the advantage that no soil extract is used in the enrichment, thus eliminating a variable component. Artificial media, such as ASP- and S-media (Provasoli et al. 1957) and their modifications made by Paasche (1964) have been useful in the culture of some coccolithophores. Paasche's medium is broadly similar to ASP2 but includes a number of minor elements (Br, Sr, Al, Rb, Li, I) and the only vitamins are B_{12}, thiamine, and biotin. A thorough review on culturing coccolithophores was published by Probert and Houdan (2004). Light intensity and quality, day length, temperature, mixing, mode of sterilization of media, and growth containers are other factors that must be taken into consideration for the cultivation of haptophytes, similar to other sensitive microalgae (Probert and Houdan 2004; Andersen 2005).

Axenic cultures of haptophytes have been obtained (Guillard 2005), although not all species readily lend themselves to bacteria-free culturing; presumably the bacteria are providing, or making available, micronutrients or organic compounds not accessible to the algae in the standard media used. Several haptophytes have been shown

to be mixotrophic and can feed on bacteria (Jones et al. 1994) or algae (Tillmann 1998). The method generally used to remove bacteria is treatment with a range of concentrations of antibiotics (penicillin, streptomycin, gentamicin, etc.) followed by subculturing into fresh, antibiotic-free medium.

Some haptophytes produce nonmotile cells surrounded by masses of mucilage, and these may be difficult to obtain bacteria-free, seemingly because bacteria are embedded in the mucilage and are protected from the antibiotics. Green and Course (1983) found that *Chrysotila lamellosa* could be obtained apparently bacteria-free by first inducing the formation of motile swarmers, which do not carry a mucilage investment, and exposing these to antibiotics before subculturing them into new medium.

Several haptophyte species are cultivated as feed for both experimental and commercial shellfish farming, particularly for oysters (Jeffrey et al. 1994; Moestrup 1994). *Isochrysis galbana* has proved to be particularly valuable and has been in use since its isolation into culture by Parke (Flagellate "I" in Bruce et al. (1940)) more than 70 years ago. *Tisochrysis lutea* (as *Isochrysis* affinis *galbana* or T-Iso, a culture isolated from the sea off Tahiti) is also widely used as feedstock in bivalve aquaculture (Jeffrey et al. 1994; Brown et al. 1997; Bougaran et al. 2003). The pavlovophytes *Diacronema lutheri* (as *Monochrysis lutheri*, then *Pavlova lutheri*) and *Pavlova gyrans* are also being extensively used as feed in the aquaculture of bivalves, crustaceans, and fish (Green 1975; Meireles et al. 2003; Ponis et al. 2006). Haptophytes are rich in fatty acids, a large proportion of which may be of the valuable, long-chain polyunsaturated omega-3 fatty acids EPA (eicosapentaenoic acid, C20:5n-3) and DHA (docosahexaenoic acid, C22:6n-3) (Meireles et al. 2003; Guschina and Harwood 2006). Algae are the only producers of EPA and DHA in marine food webs, and cultivation of microalgae, including haptophytes, as supplement in fish feed is rapidly increasing.

Evolutionary History

Fossil Record

Fossil coccoliths and other fossil remains of calcifying nanoplankton (calcareous nannofossils) first appear ca. 225 Ma. Older reports are disputed and represent forms that are not ancestral to the latest Triassic and Early Jurassic coccoliths (Bown 1998).

Pioneering studies of calcareous nannofossils date back to the nineteenth century (Ehrenberg 1836; Huxley 1858; Siesser 1994). Species-level taxonomy is based on nannofossil morphology (Perch-Nielsen 1985a; Perch-Nielsen 1985b; Bown 1998; Jordan et al. 2004). Not all extant coccolithophores are well represented in the fossil record. Selective dissolution of rare and fragile taxa arguably impedes the reconstruction of "true" species richness through time (Young et al. 2005). The fossil record is largely composed of dissolution-resistant heterococcoliths, recording the diploid life stage of coccolithophores and rarely the haploid holococcoliths (Dunkley Jones et al. (2008)). Bown et al. (2004) compiled an overview of calcareous nannofossil morphospecies richness and evolutionary rates over the last 225 Ma.

Mesozoic Era

The earliest known coccoliths, of Late Triassic (Norian and Rhaetian) age, are very small (~2 μm) and possess very simple "murolith" morphologies. The Triassic/Jurassic boundary is characterized by significant extinctions, and only one species (*Crucirhabdus primulus*) survived (Bown 1998). Following this event, calcareous nanoplankton abundance and diversity steadily increased during the Jurassic and Cretaceous periods, with relatively low background extinction and speciation. Maximum morphospecies diversity was reached during the Late Cretaceous (Campanian-Maastrichtian), with large coccoliths and nannofossils with sophisticated architecture (Perch-Nielsen 1985a; Bown et al. 2004). Provincialism in calcareous nannofossil assemblages, between low (tethyan realm) and high (boreal and austral realms) paleolatitudes, is well documented during the Cretaceous (Roth and Bowdler 1981).

The Cretaceous-Paleogene boundary (K-T boundary; 65.5 Ma) is marked by a catastrophic event in which 93% of all species or 83% of all genera went extinct leaving only 10 survivors (Perch-Nielsen et al. 1982; Bown et al. 2004; Bown 2005). Survivor species included both common, opportunistic taxa as well as those typically rare in Late Cretaceous assemblages.

Cenozoic Era

After the K-T event, calcareous nanoplankton was characterized by the dominance of few survivor species and the appearance of small-sized (~2 μm) Cenozoic newcomers. Paleocene species diversity rapidly increased, with new coccolith morphologies and novel nannolith groups (*Sphenolithus*, *Fasciculithus*, *Heliolithus*, *Discoaster*) that differed significantly from the Mesozoic architectures (Perch-Nielsen 1985a; Bown et al. 2004). The Paleocene-Eocene Thermal Maximum (PETM; ca. 55 Ma) represents a relatively short-lived but rapid climatic perturbation of global warming, elevated atmospheric CO_2, and lowered ocean pH that drove significant evolutionary turnover affecting both fragile and robust taxa across broad ecological preferences (Gibbs et al. 2006).

The transition from the Eocene "greenhouse" into the Oligocene "icehouse" (ca. 34 Ma) was characterized by a rapid decline in diversity and global prominence (Aubry 1992; Hannisdal et al. 2012) and a macroevolutionary decrease in coccolith size (Aubry 1992; Henderiks and Pagani 2008). Nannofossil diversity recovered and increased again in the Middle and Early Late Miocene but decreased sharply during the remainder of the Miocene into the Pliocene and Pleistocene, marked by the loss of discoasters, sphenoliths, and large coccolith morphospecies (*Coccolithus miopelagicus*, *Reticulofenestra pseudoumbilicus*, *Calcidiscus macintyrei*). The latter part of the Neogene is characterized by the dominance of small placoliths and rapid evolution within the *Reticulofenestra*, which gave rise to the modern genera *Gephyrocapsa* and *Emiliania* (Thierstein et al. 1977; Takayama 1993; Bollmann et al. 1998; Okada 2000). Modern coccolithophores are extremely small in comparison to most of their Mesozoic and Cenozoic ancestors (Henderiks et al. 2004; Aubry 2007).

Nannofossil Evolution and Climate Change

In the short term, biocalcification releases CO_2 to the environment. On geological timescales, the burial of calcium carbonate into deep-sea sediments represents a long-term removal ("sink") of carbon from the surface oceans and the atmosphere. Calcareous nannofossils have been a major component of pelagic carbonates since the Early Jurassic, ca. 180 Ma (Bramlette 1958; Mattioli and Pittet 2002). The widespread Late Cretaceous chalk deposits (the white cliffs of Dover) are prime examples of calcifying nanoplankton as rock-forming organisms. Quantitative estimates of calcareous nannofossils and their corresponding calcite mass, as determined by morphometry (Young and Ziveri 2000) and polarized light microscopy (Beaufort 2005; Beaufort et al. 2014), provide important insights into the process of deep-sea carbonate burial and its climatic feedbacks, from the Jurassic to Recent times (Bornemann et al. 2003; Ziveri et al. 2007). Advances in the geochemical analysis of nannofossils (Stoll and Ziveri 2004; Rickaby et al. 2007), automated microscopy techniques (Beaufort 2005), and the quantification of fossil coccosphere and cell geometries (Henderiks 2008; Gibbs et al. 2013) have expanded investigations of ancient coccolithophore productivity, calcification, and their phenotypic evolution.

It remains a challenge to understand the mechanisms and rates of climatic adaptation by coccolithophores, on both ecological and evolutionary timescales. Scenarios for the future ecological success of coccolithophores are largely informed by short-term experiments on few extant species and field studies. Extrapolation of current physiological knowledge to studies of nanoplankton evolution should be treated with caution because of the very different temporal scales involved. Nevertheless, a range of hypotheses exist linking nanoplankton evolution and ecological prominence to climate variability and ocean chemistry in the past (Aubry 1992; Bown et al. 2004; Erba 2006; Aubry 2007; Henderiks and Rickaby 2007; Henderiks and Pagani 2008).

Not all modern coccolithophore lineages are represented in the fossil record, but the evolution of some morphospecies (*Coccolithus pelagicus*, *Helicosphaera carteri*, and *Braarudosphaera bigelowii*) can be traced back to the Paleocene or even the Cretaceous. Detailed coccolith morphometric analyses can address the evolutionary significance of phenotypic variation in coccolithophores (Knappertsbusch 2000; Reitan et al. 2012).

The first sedimentary evidence of alkenones in Cretaceous black shales, ca. 120 Ma (Farrimond et al. 1986; Brassell and Dumitrescu 2004) post-dates the molecular divergence between the Isochrysidales and other coccolithophore clades (Fig. 10), ca. 195 Ma (Medlin et al. 2008). This supports the notion that the Isochrysidales clade is distinct from all other clades and that modern *Gephyrocapsa* and *Emiliania* may have some unique strategies in adapting to current climatic change (Henderiks and Rickaby 2007).

Molecular Clock Reconstructions

A haptophyte molecular clock with selected extant genera is presented in Fig. 10 and calibrated with the fossil coccolith record. Clocks that average the rate of evolution across all lineages (Takezaki et al. 1995; Medlin and Zingone 2007) and that allowed

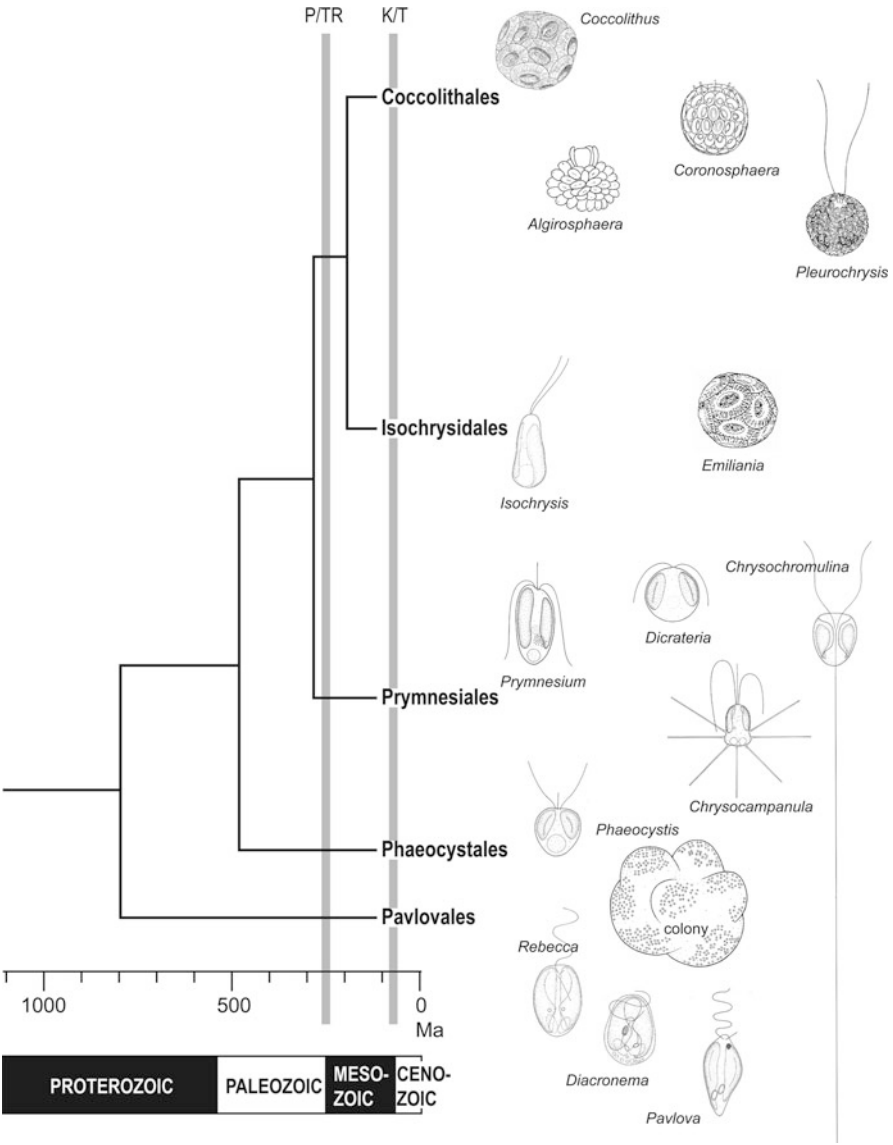

Fig. 10 Haptophyte molecular clock, with selected extant genera, illustrated to represent five orders. Coccolithophyceae, Coccolithales: *Coccolithus*; *Algirosphaera*; *Coronosphaera*; *Chrysotila*. Isochrysidales: *Isochrysis*; *Emiliania*. Prymnesiales: *Prymnesium*; *Dicrateria*; *Chrysochromulina*; *Chrysocampanula*. Phaeocystales: *Phaeocystis*, Pavlovophyceae. Pavlovales: *Rebecca*, *Diacronema*, *Pavlova*. Timescale million years ago (Ma), geologic eras indicated

the evolution to vary across the lineages (Sanderson 2006; Medlin et al. 2007) have been made and calibrated using characters and divergence points, such as the character-based constraint of 195 Ma for the emergence of all coccolithophores

and the divergence-based constraints of 64 Ma for the divergence of *Coccolithus* from *Cruciplacolithus* and 50 Ma for the divergence of Helicosphaeraceae from Pontosphaeraceae. The molecular clock extrapolates to dates of origin for some of the undated nodes. Another molecular clock has been made using the SSU and LSU rRNA genes (de Vargas et al. 2007). Divergence dates in that study are slightly older than those found by Medlin and coworkers who used a relaxed molecular clock.

The Haptophyta as a group diverged from other eukaryotes deep in the Proterozoic, >1200 Ma, in the crown group radiation (Medlin et al. 1997). Their true sister group has never been confirmed, and various trees place them in different positions in the crown group radiation. The long time period between the origin of haptophytes and the initial divergence (~800 Ma) of the two classes, Pavlovophyceae and Coccolithophyceae (Fig. 10), indicates that many of the early evolutionary branches in this group are extinct or that they have not yet been sampled (Edvardsen et al. 2000). A new group of picoplankton (Cuvelier et al. 2010) breaks up this long branch substantiating the hypothesis that the latter reason was the cause of this long branch. The order Phaeocystales diverged from all other Coccolithophyceae at ~480 Ma and then the Prymnesiales diverged from the Coccolithales plus Isochrysidales at ~280 Ma, making this a Late Paleozoic-Early Mesozoic event that may be associated with Permian-Triassic boundary (250 Ma). Modern diversifications in these lineages occurred some time after the lineage origin so many taxa were presumably lost during this time.

Within the order Phaeocystales, the divergence of the warm water *Phaeocystis* species from the cold water species occurs at 30 Ma when the Drake Passage opened to isolate the Antarctic Continental waters and dispersal to the Arctic occurred across the equator during a cooling trend at 15 Ma, and then the two polar populations were separated by a warming trend that then isolated the two polar species (Medlin and Zingone 2007).

Molecular diversification occurred earlier within the Prymnesiales than within the Coccolithales plus Isochrysidales where most of these latter divergences occurred fairly late in the haptophyte timetree (Fig. 10). The diversification within the Coccolithales plus Isochrysidales occurred predominantly after the Mesozoic-Cenozoic boundary (66 Ma), as predicted by the fossil record. Mesozoic coccolithophores have been intensively studied, and at the Mesozoic-Cenozoic boundary, an abrupt extinction is documented in the fossil record with ~90% of end-Cretaceous species disappearing (MacLeod et al. 1997; Bown 2005). After that, there is a major radiation in the Early Cenozoic with new clades rapidly diversifying and forming the origins of the modern coccolithophore biota (Bown et al. 2004).

One significant insight learned from the haptophyte molecular tree is that the Mesozoic-Cenozoic boundary extinction does not seem to have affected the Prymnesiales, Phaeocystales, or Pavlovales to the same degree as the Coccolithales, which is assessed by comparing the depth of clade diversification. In non-calcifying groups, there are 25 clades/lineages that cross the Mesozoic-Cenozoic boundary (Medlin et al. 2007) as compared to 11 coccolithophore clades. This type of branching pattern is suggestive of a major extinction (Medlin et al. 2008). This interpretation of tree branching pattern has been confirmed in other groups

(Vergroeben et al. 2014). One possible explanation for this difference in their survival may be the mode of nutrition in the haptophyte lineages. Those that are mixotrophic (Jones et al. 1994) or who could produce resting stages did not go extinct, whereas those that were obligate phototrophs without resting stages did. There appears to be a selective extinction of the order Coccolithales at the Mesozoic-Cenozoic boundary where calcified organisms were affected by ocean chemistry, and the uncalcified lineages likely switched to mixotrophy to take advantage of the poor light conditions at this extinction event. Modern coccolithophores represent terminal points of a number of evolutionary lines, some extending back to the Triassic and before. These lines have developed to some extent in parallel with each other and with those represented by the Prymnesiales, Phaeocystales, and the Pavlovophyceae.

Taxonomy

A haptophyte taxonomy (Table 1) has been constructed from Silva et al. (2007), de Vargas et al. (2007), and Edvardsen et al. (2011). Two classes are included in the phylum Haptophyta, Pavlovophyceae, and Coccolithophyceae (Prymnesiophyceae) and are separated by features of cell shape, flagellar insertion, and type and location

Table 1 The major taxonomic groups within the Haptophyta, their main characteristics, and examples of the genera of living algae included in them[a]

Phylum Haptophyta	Cells with haptonema
Class: Pavlovophyceae	Cells with knob scales
Order: Pavlovales	Motile cells with two unequal flagella, the longer with an investment of small knob scales and fine hairs and the shorter sometimes vestigial. Haptonema present but reduced (e.g., *Diacronema*, *Pavlova*)
Class: Coccolithophyceae (Prymnesiophyceae)	Cells with organic scales, with or without coccoliths
Order: Isochrysidales	Motile cells with two equal or subequal flagella, haptonema reduced or absent (e.g., *Ruttnera*, *Emiliania*, *Isochrysis*)
Order: Coccolithales	Cells coccolith bearing many genera with a polymorphic life cycle. Haptonemata recorded in several genera (e.g., *Acanthoica*, *Braarudosphaera*, *Calyptrosphaera*, *Chrysotila*, *Coccolithus*, *Corisphaera*, *Crenalithus*, *Cyclolithella*, *Discosphaera*, *Helicosphaera*, *Laminolithus*, *Rhabdosphaera*, *Syracosphaera*, *Umbellosphaera*, *Umbilicosphaera*)
Order: Prymnesiales	Motile cells with two (rarely four) equal or subequal flagella and usually an obvious haptonema which may be very long and coiling (e.g., *Chrysochromulina*, *Haptolina*, *Prymnesium*)
Order: Phaeocystales	Motile cells with two flagella and short haptonema. Flagellate alternating with colonial stage (*Phaeocystis*)

[a]Based on Parke and Adams (1960), Parke and Dixon (1976), Edvardsen et al. (2000), de Vargas et al. (2007), Silva et al. (2007), and Edvardsen et al. (2011) (note that these are not formal taxonomic descriptions)

of scales (Edvardsen et al. 2000). Pavlovophyceae has one order, the Pavlovales, and the class Coccolithophyceae (Prymnesiophyceae) may be divided into four orders: the Phaeocystales, Prymnesiales, Isochrysidales, and Coccolithales. Of these, the Phaeocystales with the genus *Phaeocystis* is the most basal and clearly defined in SSU rDNA phylogenetic trees. The Prymnesiales consists of two well-supported molecular clades, which have been separated at the family level (Prymnesiaceae and Chrysochromulinaceae) based on the shape of cells (saddle shaped or rounded, respectively) and the length and nature of the haptonema (Edvardsen et al. 2011). The coccolithophores have traditionally been classified on the basis of coccolith morphology, and the Coccolithales is the order within the Haptophyta that includes the highest number of described genera and species and is almost certainly a heterogeneous assemblage. de Vargas et al. (2007) erected the subclass Calcihaptophycidae and recognized the orders Isochrysidales, Syracosphaerales, Zygodiscales, and Coccolithales (see also Jordan et al. 2004). Molecular data show Isochrysidales to be the sister of Coccolithales. The Isochrysidales includes two families, the Noëlhaerhabdaceae with the coccolith-bearing genera *Emiliania*, *Gephyrocapsa*, and *Reticulofenestra* and the Isochrysidaeae with the non coccolith-bearing genera *Isochrysis*, *Chrysotila*, and *Tisochrysis* (Bendif et al. 2013).

Centrohelida and Other Heliozoan-Like Protists

26

Rebecca J. Gast

Abstract

The Centrohelida has arisen through the dissolution of the Heliozoa and the gradual removal of morphologically similar, but ultrastructurally and genetically distinct taxa from the group. The taxonomy of these other heliozoan-like protists is still largely in flux, as are the groups within the Centrohelida. Centrohelida and heliozoan-like protists are heterotrophic, free-living species that are found in most aquatic benthic environments where they feed on bacteria and other protists, including algae. Morphologically the cells are conspicuous, generally round in shape with eye-catching raylike axopodia. They can be found in habitats that represent a wide range of temperatures and salinities, including extreme environments. Most are free floating, but some attach to substrates by a stalk. Interest in the heliozoan-like protists ("sun animalcules") is largely in regard to cell biology. Their size (some can be 500 μm in diameter) and axopodial structure have made them useful subjects for biochemical and ultrastructural studies of microtubules.

Introduction

General Characteristics and Occurrence

The phagotrophic spherical amoebae with microtubule-supported axopodia once called "sun animalcules" used to be grouped together into a formal class called Heliozoa. The cells range from 10 to 500 μm in size, either naked or coated with organic or siliceous scales, and radiating long axopodia (Fig. 1). Centrohelida and other heliozoan-like protists have been isolated from fresh and marine water; from polar, temperate, and subtropical regions; as well as from some extreme environments. They are generally found just above the sediment-water interface, but can be isolated from the pelagic environment as well.

Literature and History of Knowledge

The body of literature on heliozoan-like protists includes works from the end of the nineteenth century and the beginning of the twentieth century devoted to light microscopy and systematics and more recently papers focusing on ultrastructure (electron microscopy), life cycles and cell physiology (including motility and feeding processes), molecular systematics, and biogeochemistry. Articles that comprise the basis of this work include Penard's monograph (Penard 1904); the descriptions of Valkanov (1940), Rainer (1968), and Tregouboff (1953); studies by Febvre-Chevalier (Febvre-Chevalier 1982; Febvre-Chevalier and Febvre 1984); and work by Mikrjukov, Patterson, and Cavalier-Smith (Mikrjukov 1998, 2000a, b; Mikrjukov and Patterson 2001; Cavalier-Smith and von der Heyden 2007).

Haeckel first described spherical protists with raylike pseudopodia as heliozoan in 1866 Haeckel 1866), and the name was eventually applied to many organisms with similar morphologies. Penard (1904) proposed the first classification of the group based largely upon morphological observations of their skeleton, resulting in the separation of the Heliozoa from the radiolarians. The Heliozoa included the groups Centrohelida, Actinophryida, Clathrulinidae, Dimorphida (or Heliomonadida), and Gymnosphaerida. *Sticholonche*, belonging to the Taxopodida, was also placed within the Heliozoa. Light and electron microscopy studies were next used to propose more comprehensive systematics (Hartmann 1913; Kühn 1926; Valkanov 1940; Rainer 1968; Febvre-Chevalier and Febvre 1984; Smith and Patterson 1986). Most recently, molecular phylogenetic methods have been used to help understand the evolutionary relationships between groups and species (Nikolaev et al. 2004; Cavalier-Smith and von der Heyden 2007; Bass et al. 2009; Yabuki et al. 2012). It is now generally recognized that the class Heliozoa was established based upon convergent morphological characteristics, and it has been dissolved in recent taxonomic revisions (Mikrjukov 1998, Mikrjukov and Patterson 2001; Adl et al. 2005, 2012). Currently many of the heliozoan-like protists are placed within the Centrohelida (see section "Centrohelida and Heliozoan-Like Taxonomy" below).

Practical Importance

The Centrohelida and heliozoan-like protists have been useful for investigating aspects of cell biology. Studies of fibrillar proteins and microtubules involved in cell shape and movement (Cachon et al. 1977; Cachon and Cachon 1984; Febvre-Chevalier and Febvre 1980), the role of the cell membrane in detection and response to stimuli and control of contraction (Febvre-Chevalier et al. 1983, 1986), and the influence of the environment on the cell (Febvre-Chevalier 1981) were conducted using *Sticholonche* and *Actinocoryne*. Morphogenesis (Tilney and Byers 1969; Roth and Shigenaka 1970; Edds 1975), feeding (Suzaki et al. 1980; Patterson and Hausmann 1981; Hausmann and Patterson 1982; Linnenbach et al. 1983), and the biochemistry of tubulin and associated proteins within the axoneme (Little et al. 1983) were all studied using isolates of *Actinosphaerium*. $Ca2^{+}$-dependent axopodial contraction (Arikawa et al. 2006; Kakuta and Suzaki 2008) and feeding behavior (Pierce and Coats 1999; Sakaguchi et al. 1998) have been studied using *Actinophrys sol*.

Habitats and Ecology

Centrohelida and other heliozoan-like protists are widely distributed in aquatic environments, and while they have been isolated primarily from freshwater, they have also been observed in brackish or marine water in the euphotic zone. Primarily sub-benthic or benthic, they can be sampled with plankton net tows and can be abundant when conditions are favorable. The only exclusively pelagic marine form is *Sticholonche zanclea*. Freshwater centrohelid-like organisms have been collected from diverse sources of relatively still water, including lakes, regions of rivers, stagnant water, artificial ponds, marshes, and temporary pools (Penard 1904; Rainer 1968). Marine and brackish species are found in the coastal zone, again in waters that are not energetic, like harbors, coves, and brackish channels. Most species are free living and float or roll in the water, but *Sticholonche* is unique and moves by using an axopodial rowing motion (Cachon and Cachon 1978). Some species may secrete a long proteinaceous peduncle or stalk that temporarily attaches them to surfaces in the environment (e.g., *Clathrulina*, *Wagnerella*, *Actinocoryne*).

Centrohelida and heliozoan-like cells seem to prefer oxygenated water with plenty of organic matter to support the growth of other protists that serve as prey organisms. They also appear to be able to tolerate a wide range of temperatures and salinities. For example, *Cienkowskya mereschkovskyi* was found by Villeneuve (1937) in salt-marsh channels near Sete, France, that experience highly variable salinities, and

Fig. 1 (continued) (**e**) *Polyplacocystis pallida*, (**f**) *Actinophrys sol* (cell body is approximately 43 μm in diameter), (**g**) *Actinosphaerium eichornii*, (**h**) *Actinosphaeridium* sp., (**i**) *Hedriocystis pellucida*, and (**j**) *Clathrulina elegans* (the shell is 35 μm and the stalk 112 μm) (All images are courtesy of Ferry Siemensma. Additional images of amoeboid protists may be viewed at Microworld (http://www.arcella.nl))

Febvre-Chevalier reported collecting it in Villefranche in water of salinities between $37^0/_{00}$ and $38^0/_{00}$ (Febvre-Chevalier 1990). *Cienkowskya* also illustrates the wide temperature range that some isolates can tolerate; it has been isolated from the White Sea (mean temperature of 2 °C), from Villefranche (temperatures between 13 °C and 27 °C), and from salt-marshes near Sete (temperatures up to 30 °C).

pH also likely plays a role in the distribution of these species with different habitats varying from pH 4.6–8.5, (Rainer 1968). *Actinophrys sol* and *A. eichorni* tolerate very wide ranges in pH (4.6–8.5), while species like *Raphidiophrys elegans* and *Acanthocystis echinata* are observed at more limited ranges (between 6.0 and 8.2 for the former and 4.5–5.4 for the latter). *Polyplacocystis symmetrica*, *Raphidophrys intermedia*, *R. ovalis*, *R. echinata*, *Clathrulina elegans*, and *Pompholyxophrys punicea* were isolated from acidic bogs (pH 4.3–5.1) in Russia (Leonov 2010). Recently, the acidic limits of pH tolerance have been lowered further with reports of *Actinophrys* species in Spain's Rio Tinto (pH approximately 2.0; Amaral Zettler et al. 2000) and of *Actinophrys sol* in lower Lusatia, Germany, at pH 2.3 and 2.6 (Packroff 2000).

Centrohelida and heliozoan-like protists feed by phagocytosis of bacteria, other protists (including algae), and larvae of invertebrates. They are generally considered passive predators that capture prey as it comes along. Despite the occurrence of free-floating forms, their ecological niche is considered to be the benthic environment where they inhabit the superficial layer of detritus and interstitial spaces. Swimming prey is thought to impact and stick to the mucous coat of the axopodia, stimulating contraction and movement of the prey toward the cell where a food vacuole is formed (Febvre-Chevalier and Febvre 1980; Patterson and Hausmann 1981; Suzaki et al. 1980).

Characterization and Recognition

General Appearance and Ultrastructure

Centrohelida and heliozoan-like protists are spherical, 10–500 μm in diameter, with long slender axopodia and short pseudopods, or branched filopods (Fig. 1). The genera *Heliomorpha*, *Tetradimorpha*, and *Acinetactis* have one or more flagella in addition to axopodia. In general, Centrohelida lack a central capsule and are either naked or covered with a mucoid cell coat. Some members of the heliozoan-like protists belonging to the Clathrulinidae have latticed organic capsules. The mucous coat, ranging in thickness from 0.05 to 5 μm depending upon the species and physiology, is secreted at the cell surface. Most cell surfaces also contain external skeletal spicules, scales, or small spheres. These can be composed of silica or organic material, and the morphology of the spheres, spicules (spatula, needles, tubes, cups, funnels, clubs), and scales (elliptic, lens shaped) is a key element of species identification and systematics.

Various kinds of extrusomes (organelles involved in prey capture) are scattered in the axopodial and cortical cytoplasm. Their contents are ejected after excitation by an outside stimulus by rupture of the cell membrane. The different types of extrusomes that have been described include dense and mottled granules (Actinophryidae), mucocysts, and kinetocysts (Centrohelida and Clathrulinidae) (Febvre-Chevalier 1985; Mikrjukov 1998; Davidson 1976).

Vegetative cells can be either mono- or multinucleated, and some genera alternate between spherical free-living and stalked sessile forms (members of the Gymnosphaerida and Clathrulinidae). Some stalks are inert, while others are cytoplasmic and may be capable of contraction (*Actinocoryne* and *Wagnerella*). The formation of resting cysts when growth conditions become unfavorable has been observed. Some heliozoan-like protists have also been reported to contain symbiotic algae (*Hedraiophrys* Febvre-Chevalier 1973a), or to retain functional chloroplasts from their algal food (*Acanthocystis*, *Raphidiocystis*, and *Chlamydaster*; Patterson and Dürrschmidt 1987).

A key feature of heliozoan-like protists is the axopodia, although this is now considered to be a trait acquired independently in the different lineages rather than an indication of shared evolutionary history. These are long, thin projections supported by arrays of microtubules called axonemes. Axopodia are able to contract rapidly, at a velocity of 50–300 lengths of the cell per second (Davidson 1975; Febvre-Chevalier and Febvre 1980). Filopods, long supple projections of the cell body, and pseudopods, temporary extensions of the cell surface, lack microtubular structure. All three structures are involved in feeding.

The axopodia are made up of bundles of microtubules (Little et al. 1983) connected to one another by cross-bridges resulting in distinct patterns (see Dustin 1978). There are five basic patterns that are generally recognized. There are the slightly irregular hexagons and equilateral triangles found in the Centrohelida (Fig. 2, panel 1b and 2b, e.g., *Heterophrys*, *Raphidiophrys*, *Acanthocystis*; Tilney 1971; Bardele 1975). Two interlocking coils in a spiral pattern are present in the Actinophryidae (Tilney and Porter 1965; Roth et al. 1970; Ockleford and Tucker 1973). Irregular adjacent hexagons that form a "parquet" pattern are present in the Gymnosphaerida (Febvre-Chevalier 1973a, 1975, 1982). A square microtubule arrangement is found in the Heliomonadida (Fig. 2, panel 3b; Brugerolle and Mignot 1983, 1984), while the Clathrulinidae exhibit an irregular pattern (Fig. 2, panel 4b; Bardele 1972).

Microtubules are generated by microtubule-organizing centers or microtubule-nucleating centers (MTOC or MNC: Pickett-Heaps 1969). These are located in the center of the cell or on the outer nuclear membrane (Actinophryidae and Clathrulinidae). The central MTOC, called a centroplast, may possess a central disc sandwiched between two dense caps about 0.1–1.5 μm in diameter (Centrohelida; Fig. 2, panel 1a, 2a). In other instances it may lack this inner differentiation and is then sometimes called an axoplast (Anderson 1988; Febvre-Chevalier 1973b; Gymnosphaerida and Heliomonadida; Fig. 2, panel 3a, 4a).

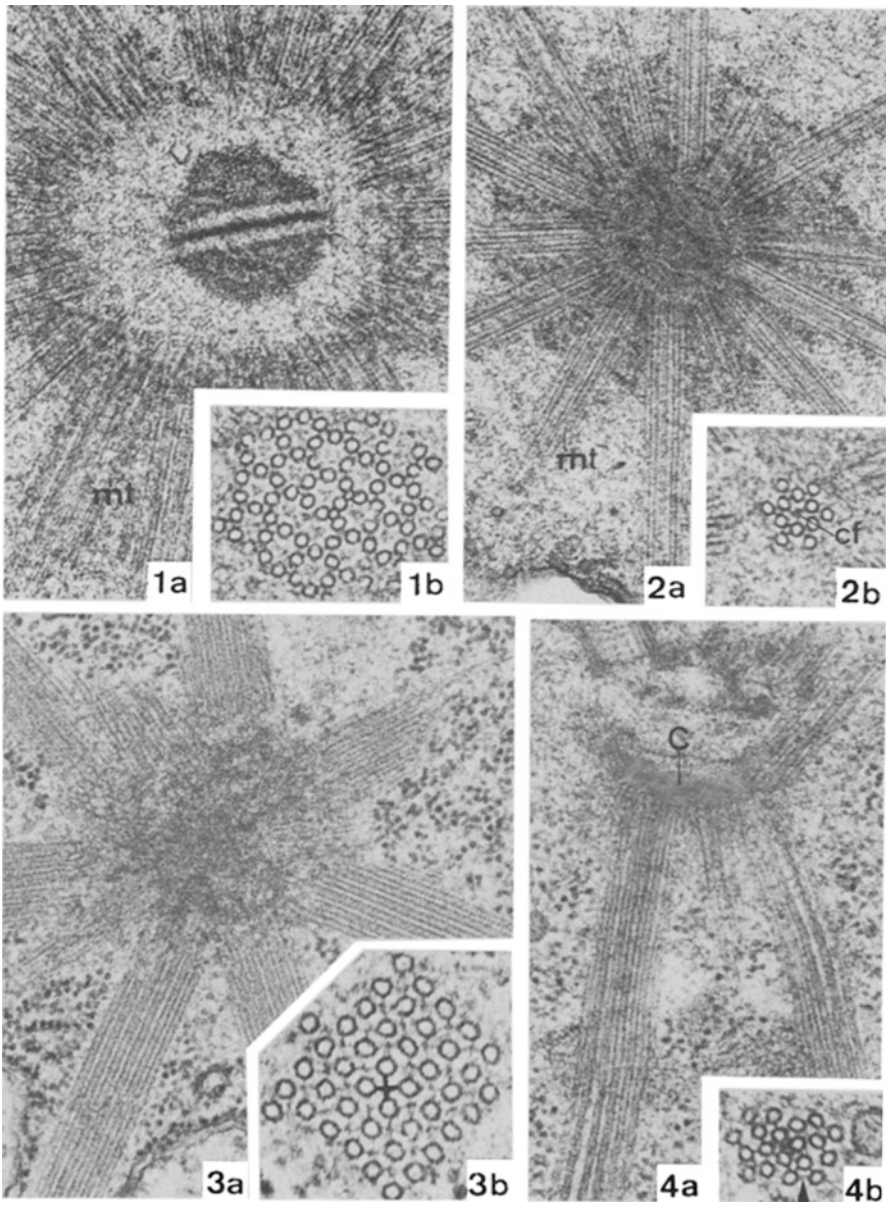

Fig. 2 Transmission electron micrographs of *Raphidiophrys elegans*, *Acanthocystis turfacea*, *Dimorpha mutans*, and *Tetradimorpha radiata*. Panel **1a** The centroplast of *Raphidiophrys elegans* has a tripartite central disc with an electron dense equatorial plate. Axopodial MTs arise from a shell around the centroplast. ×60,000. **1b** Axopodial MTs are triangles grouped in x-shapes, resulting in hexagonal or irregular hexagon patterns. ×90,000. Panel **2a** In the centroplast of *Acanthocystis turfacea*, the dense plate at the equator of the central disc is less obvious, and the axopodial MTs originate directly from the dense material around the disc. ×60,000. **2b** Axopodial MTs are

Life Cycle

Reproduction is usually asexual, with binary cell division most commonly observed. Division can give rise to equal- or unequal-sized offspring cells, with the smaller cell in the unequal division called a bud. Multiple fission, where multiplication of nuclei is followed by rapid synchronous division, can result in a large number of offspring cells produced at the same time. Division in stalked, sessile species takes place in the head, or in the base after withdrawal of both stalk and head (Zuelzer 1909; Febvre-Chevalier 1982). The offspring cells become free and fall onto the substratum where they undergo morphogenesis to give rise to a stalked cell.

Sexual reproduction occurs through autogamy in the cysts of *Actinophrys* and *Actinosphaerium* (Mignot 1979; Bělař 1923). First, the parent cell encysts and forms the gamontocyst, followed by progamic fission, resulting in two gamonts. Each gamont goes through meiotic division, after which one offspring nucleus degenerates. The remaining two cells differentiate into male and female gametes, and they fuse to form a zygote.

Centrohelida and Heliozoan-Like Taxonomy

The revised taxonomy of the Centrohelida and other heliozoan-like protists presented here is based upon Adl et al. (2005, 2012). The taxonomy of these protists is actively under revision, and other versions can be found in Cavalier-Smith and von der Heyden 2007; Mikrjukov et al. 2000; Mikrjukov 2000a, b; Mikrjukov and Patterson 2001; Yabuki et al. 2012; and on the web at *Microworld, world of amoeboid organisms* Siemensma, F. J. 2015 http://www.arcella.nl.

Eukaryota; Centrohelida (Kühn 1926)

Members of the Centrohelida have axonemes arising from a centroplast that has a tripartite disc flanked by two regions of electron-dense material. Axonemes have

Fig. 2 (continued) arranged in a single hexagon containing a central filament (cf) which is linked to the six neighboring MTs. ×90,000. Panel **3a** The centroplast of *Dimorpha mutans* is composed of microfibrillar material from which the axopodial axonemes arise. ×54,000. **3b** Axopodial MTs are arranged in a "quincunx" pattern that makes a squared packed array. ×150,000. Panel **4a** In *Tetradimorpha radiata* the lens-shaped centroplast (C) is composed of unstructured dense material, with the axopodial MTs arising from its periphery. ×93,000. **4b** The MTs are arranged irregularly with some having more than four links and others having triangular figures (*arrow*). ×102,000 (Used with kind permission from Springer Science+Business Media: Origins of Life, *The cell characters of two Helioflagellates related to the Centrohelidian lineage: Dimorpha and Tetradimorpha*, volume 13, 1984, 305–314, Guy Brugerolle and Jean-Pierre Mignot, Figs. 1, 2, 3, 4; original (first) copyright by D. Reidel Publishing Company)

hexagonal and triangular patterns of microtubules, and the mitochondrial cristae are lamellate (flat) in shape. The kinetocysts are complex ball-and-cone-shaped structures. Some members have mucous stalks, and cell body coverings include naked, mucous, organic spicules, and siliceous rods, platelike scales, and spicules (tubelike, trumpetlike, and spine-like).

Heterophryidae (Poche 1913). Members of this group are naked or with a mucous coat. Some have tangential or radial organic spicules (revised in Mikrjukov 1996a).

Genera *Sphaerastrum*, *Heterophrys*, *Oxnerella*, *Chlamydaster.*

Acanthocystidae (Claus 1874). The surface of these protists is composed of two to three types of siliceous scales. The basal layer is usually composed of oval scales, the outer layer is composed of funnel-like structures or radial spicules (may have branched tips and/or flat, centrally attached basal disc).

Genera *Acanthocystis*, *Choanocystis*, *Pseudoraphidiocystis*, *Echinocystis*, *Pseudoraphidiphrys*, *Pterocystis.*

Raphidiophyridae (Mikrjukov 1996b). This group of centrohelid protists has siliceous scales or spicules (trumpetlike, tubelike, or funnel-like) (revised in Mikrjukov 1996b).

Genera *Parasphaerastrum*, *Polyplacocystis*, *Raphidiophrys*, *Raphidiocystis.*

Rhizaria; Cercozoa; Granofilosea; Clathrulinidae (Claus 1874; Desmothoracida Hertwig and Lesser 1874)

The most distinctive characteristic of this group is the presence of a perforated or latticed capsule. Some have a non-cytoplasmic stalk, while others do not. There is a single, central nucleus, and the mitochondrial cristae are tubular. Axopodia tend to be long and are sometimes branched or forked, with the axonemes terminating on the nuclear envelope. The axonemes have unorganized microtubular arrays. Extrusomes are present, but resemble ones of cercomonads more than those of centrohelids. Reproduction occurs by binary fission, with one of the daughter cells forming a uni- or biflagellated cell that transforms into an amoeba after settling. The stalk and capsule are then secreted. Most isolates are freshwater organisms.

Genera *Clathrulina*, *Cienkowskya*, *Hedriocystis*, *Penardiophrys.*

Incertae sedis Clathrulinidae *Servetia* – A marine genus with a naked spherical head and hollow, non-cytoplasmic stalk with a broad base.

SAR; Stramenopiles; Actinophryidae (Claus 1874; Emend Hartmann 1926)

Members of the actinophryid group are round bodied with stiff axopodia that taper from the base out to the tip. Microtubule organization within the axopodia is a striking double hexagonal spiral array, and the MTOCs are present on electron-dense material at the surface of the nucleus or near a nucleus. Cells have either a single

central nucleus or multiple nuclei located centrally in the cell, and mitochondrial cristae are tubular. The extrusomes are of two types – large and osmiophilic and small and granular. The cell surface is naked and cysts with multiple walls can form. Binary fission is the primary mode of reproduction, but autogamy within the cyst occurs through the formation and fusion of amoeboid gametes. Actinophryids are the heliozoan-type most commonly recovered from freshwater, but are also found in marine and soil environments. The flagellated genus *Ciliophrys* (Cienkowsky 1876) was originally included among the actinophryids, but is now considered a member of the pedinellids.

Genera *Actinophrys*, *Actinosphaerium.*

Retaria; Acantharia; Taxopodida

The single member of this pelagic marine group is *Sticholonche zanclea* Hertwig, 1877. It is about 200 μm in size and has a bilateral symmetry rather than the radial symmetry seen in other members of the heliozoan-like protists. Its oar-shaped axopodia are arranged in 50–60 rows that terminate on the surface of the large central nucleus. Axopodia are used for buoyancy and movement. The microtubules are arranged in irregular hexagonal arrays. There has been debate regarding the taxonomic placement of *Sticholonche*, but molecular evidence indicates this organism is related to the Polycystinea and Acantharea (Nikolaev et al. 2004).

Incertae Sedis Rhizaria; Gymnosphaerida (Poche 1913; Emend Mikrjukov 2000b)

Most of the gymnosphaerid protists are found in marine environments. Cells can be uni- or multinucleate, and the nuclei can be present in the amoeboid base of the cytoplasmic stalk. The cell body with radiating axopodia is present at the top of the stalk, and the surface of the cell may be naked or covered by mucous or siliceous spicules. Mitochondria have tubular cristae. The life cycles appear to be complex and are not fully resolved. The original description of *Hedraiophrys hovassei* reported the presence of algal and bacterial symbionts (Febvre-Chevalier 1973a).

Genera *Hedraiophrys*, *Actinocoryne*, *Gymnosphaera.*

Incertae Sedis Eukaryota; Heliomonadida (Formerly Dimorphida); Heliomorphidae/Acinetactidae/Tetradimorphidae (Helioflagellates or Heliomonads; Siemensma 1991)

Axopodial microtubules arise from MTOCs near the flagellar bases. The cells are mononuclear and have tubular mitochondrial cristae, and kinetocysts are present.

Members of the genus *Heliomorpha (Dimorpha)* and *Acinetactis* have two flagella, while members of the genus *Tetradimorpha* have four. Molecular studies suggest placement of these organisms as relatives of the Cercozoa, and *Acinetactis* was added to this group by Bass et al. (2009).

Genera *Heliomorpha (Dimorpha)*, *Tetradimorpha*, *Acinetactis.*

"Other" Heliozoan-Type Genera

Wagnerella incertae sedis Rhizaria – This marine genus has a noncontractile cytoplasmic stalk with an enlarged base and a spherical head. The axoplast is located centrally within the head, and the head is covered by mucilaginous material and siliceous spicules. Amoeboid cells are produced during reproduction, from both the head and from the base.

Actinolophus incertae sedis Rhizaria – A marine genus with a noncontractile cytoplasmic stalk and a pyriform head that is covered by a gelatinous layer. The single nucleus is located eccentrically within the head, and the axoplast is pear shaped.

Actinosphaeridium incertae sedis Granofilosea – A space is present between the mucous layer and the cell body of this organism, and the stalk ends at the mucous coat rather than on the cell body. The species was previously called *Nuclearia caulescens*.

Lithocolla incertae sedis Eukaryota – Found in both marine and freshwater, this organism is covered in a dense coating of sand grains. Movement is accomplished by rodlike filopods, and the nucleus is located centrally. The sand coat has made ultrastructure studies difficult, and its taxonomic position remains largely uncertain.

Maintenance and Cultivation

Benthic cells are collected by direct sampling of the sediment surface at the water-sediment interface. *Sticholonche zanclea* and other pelagic forms can be collected using a plankton net (mesh size of 40 μm). The organisms can be cultivated from collected sediments using serial dilution into a culture medium (e.g., SES medium for freshwater or Plymouth Erdschreiber medium for marine, Catalogue of the UK National Culture Collection). They can be enriched from water samples by adding Cerophyll or a grain of rice or barley to the collected sample. Algae, such as *Chlorogonium elongatum* (freshwater) or *Dunaliella* (marine; Davidson 1975), can be added as a food source, but enrichments generally support the growth of bacteria and small flagellated protists that serve as prey. Although enrichment cultures are usually successful in initially recovering heliozoan-like cells, it can be difficult to maintain them for long periods and to isolate the organisms into clonal culture. Some species may be available from culture collections like the Culture Collection of Algae and Protozoa, but this is rare.

Evolutionary History

Over the past 15 years, it has become accepted that the heliozoan-like protists are a polyphyletic group based upon both morphological (Smith and Patterson 1986; Mikrjukov 1998, 1999, 2000a, b; Mikrjukov et al. 2000) and largely 18S rDNA-based molecular studies (e.g., Nikolaev et al. 2004; Cavalier-Smith and von der Heyden 2007; Cavalier-Smith and Chao 2003). The centrohelids are proposed to share a molecular evolutionary history with the haptophytes and cryptomonads and more broadly with the stramenopile/alveolate/Rhizaria (SAR; Cavalier-Smith and von der Heyden 2007; Burki et al. 2009). The Heliomorphids (Dimorphids) and Clathrulinids (Desmothracids) are considered to share an evolutionary history with the Cercozoa, and actinophryids are proposed to share common ancestry with the Stramenopiles (Fig. 3; Nikolaev et al. 2004; Bass et al. 2009). Due to a lack of molecular data, the history of the gymnosphaerids remains unresolved, with their placement limited to incertae sedis within the Rhizaria.

Jakobida

27

Alastair G. B. Simpson

Abstract

Jakobida is a small group (<20 described species) that is related to Heterolobosea and Euglenozoa. Jakobids are free-living heterotrophs with two flagella. They primarily eat prokaryotes that are captured by suspension feeding, using a current produced by the posterior flagellum (which has a dorsal vane), and an "excavate"-type feeding groove. Most are marine or freshwater aerobes, although the Stygiellidae (*Stygiella*, *Velundella*) are marine and brackish water anaerobes. Most jakobids are free-swimming cells, some of which temporarily attach to surfaces, while Histionidae (e.g., *Histiona*, *Reclinomonas*) are freshwater sessile forms that sit within conical or wineglass-shaped organic loricas. Jakobids have rarely been identified as major components of microbial ecosystems, except in some anoxic marine waters. They are of special evolutionary importance, however, because their mitochondrial genomes retain more ancestral bacterial-like features than those of other eukaryotes. The mitochondrial genomes of aerobic jakobids encode more genes than those of any other eukaryote group; around 100 genes in total, including up to 69 protein-coding genes, ~10 of which occur in no other mitochondrial genome examined to date. In particular, they encode (subunits of) a bacterial-type RNA polymerase, while the mitochondrial RNA polymerase in other eukaryotes is a nucleus-encoded single-subunit enzyme with viral affinities. This retention by jakobids of the inferred-to-be-original mitochondrial RNA polymerase is an important datum for inferring the evolutionary history of eukaryotic cells, including the mitochondrial symbiosis. Malawimonads are a small group of heterotrophic flagellates that superficially resemble jakobids, but are of uncertain evolutionary position within eukaryotes and thus also of particular evolutionary importance.

Introduction

General Characteristics

Jakobids (Jakobida) are small free-living heterotrophic flagellates. All well-studied species have two flagella. Jakobids are one group of the "typical excavates," which signifies that they have a conspicuous feeding groove supported by a particular set of

cytoskeletal elements that originate in association with the basal body of the posterior flagellum (Simpson 2003). As in other typical excavates, the posterior flagellum bears vanes and beats within the groove to generate the feeding current. There are <20 formally described jakobids, including *incertae sedis* species. Species of *Jakoba*, *Moramonas*, *Andalucia*, *Stygiella*, and *Velundella* are free swimming (as are some undescribed forms), while the Histionidae ("histionids") are sessile and usually reside within a lorica.

Jakobids are of interest primarily because of their ancestral-like mitochondrial genomes. Jakobid mitochondrial genomes are uniquely gene rich, as first demonstrated by Lang et al.'s (1997) seminal study of *Reclinomonas americana*. In addition to a large total number of genes (up to 100), jakobid mitochondrial genomes typically contain about nine genes that have not been found in the mitochondrial genomes of any other eukaryote (Burger et al. 2013; Gray et al. 2004). Most remarkably, this includes genes encoding subunits of a bacterial-type RNA polymerase, whereas other eukaryotes use a completely different "phage-type" RNA polymerase in their mitochondria.

Occurrence

Jakobids have been observed or detected in many habitats, including water column and sediments from both freshwater and saline/marine habitats (e.g., Behnke et al. 2006; Flavin and Nerad 1993; Pascher 1942, 1943; Patterson 1990). They have also been isolated from soil and observed in hypersaline samples (e.g., Lara et al. 2006, 2007; Ruinen 1938; Strassert et al. 2016). Jakobids do not appear to be particularly abundant in most habitats. One exception is seen in anoxic marine waters, where sequences from the presumably anaerobic taxon Stygiellidae can be abundant in environmental SSU rDNA/rRNA surveys or even dominant (Stock et al. 2009; Weber et al. 2014). Some accounts describe histionids as rare (Nicholls 1984).

Literature and History of Knowledge

Jakobids have been recognized as a group for a little over two decades, yet organisms now classified as jakobids were first described more than 100 years ago. Voigt (1901) described the loricate species now known as *Histiona velifera* and in 1902 introduced the genus name *Histiona* itself (Voigt 1902), while Penard (1921) and Pascher (1943) described additional *Histiona* species. These early accounts were based primarily on light microscopy of living cells. In the systematics of the time, *Histiona* was generally appended to other groups of loricate flagellates, namely, bicosoecids or chrysophyceans, or to the prymnesiophytes/haptophytes (e.g., Bourrelly 1968; Pascher 1942, 1943).

Petersen and Hansen (1961) and Nicholls (1984) subsequently combined detailed light microscopy studies with transmission electron microscopy (TEM) of whole

mounts of *Histiona* spp. This showed better the organization of the lorica and the flagella – the "posterior" flagellum had been overlooked in most previous studies. Further observations of *Histiona aroides* by Mylnikov (1984, 1989) included some ultrathin-section TEM data. These data led to skepticism about the previous systematic assignments for *Histiona* (e.g., Petersen and Hansen 1961), but did not connect *Histiona* positively to any other group.

Ruinen (1938) had described a free-swimming flagellate as *Cryptobia libera*. True *Cryptobia* species are parasites or commensals and are now recognized to be kinetoplastids (see ▶ Kinetoplastea). Patterson (1990) rediscovered this organism in marine samples. Light microscopy and TEM observations showed that it lacked the diagnostic features of kinetoplastids and did not closely resemble any other well-studied group. Patterson (1990) therefore proposed a new genus, *Jakoba*, and new family, Jakobidae, and renamed the species *Jakoba libera*. The genus name was chosen in honor of Ruinen – "Jakoba" was her given name.

Soon afterward Flavin and Nerad (1993) described a new loricate flagellate, *Reclinomonas americana*, using TEM and scanning electron microscopy (SEM). They realized that *Reclinomonas* was similar to both *Histiona* and *Jakoba*. They nonetheless placed *Reclinomonas* and *Histiona* in a separate new family, Histionidae. O'Kelly (1993) then compared *Reclinomonas*, *Histiona*, and *Jakoba* in detail and referred to them collectively as the "jakobids." O'Kelly (1993) also discussed an "undescribed jakobid" that was later formally described as *Malawimonas jakobiformis* (O'Kelly and Nerad 1999). Malawimonads, it turns out, are not specifically related to jakobids, despite their similar appearance by light microscopy (see Coda).

Bernard et al. (2000) described a new species from oxygen-poor intertidal sediments under the name *Jakoba incarcerata*. TEM studies demonstrated a strong similarity with other jakobids (Bernard et al. 2000; Simpson and Patterson 2001), but subsequent molecular phylogenies did not group *Jakoba incarcerata* with *Jakoba libera* (Edgcomb et al. 2001; Simpson et al. 2002). Lara et al. (2006) then reported a new soil flagellate that was specifically related to *Jakoba incarcerata* in small subunit ribosomal DNA (SSU rDNA) phylogenies. A new genus, *Andalucia*, was introduced, with the soil species described as *Andalucia godoyi* and with *Jakoba incarcerata* renamed *Andalucia incarcerata* (Lara et al. 2006). Recently, an extensive cultivation effort focused on anaerobic jakobids was reported by Pánek et al. (2015), who also proposed splitting *Andalucia* into multiple genera. *Jakoba*/*Andalucia incarcerata* was transferred to the new genus *Stygiella*, as *Stygiella incarcerata*, along with three new species, *Stygiella adherens*, *Stygiella agilis*, and *Stygiella cryptica.* Two further new species of anaerobic jakobids were assigned to a second new genus, *Velundella*, as *Velundella nauta* and *Velundella trypanoides* (Pánek et al. 2015). *Stygiella* and *Velundella* are closely related (Pánek et al. 2015).

The genera *Stenocodon* and *Stomatochone* were introduced by Pascher (1942) for several small, sessile flagellates. *Stenocodon epiplankton*, currently considered the only species in its genus, is a *Histiona*-like loricate organism (Pascher 1942; Flavin and Nerad 1993). The several nominal species of *Stomatochone* are similar to *Stenocodon*, except that they have no lorica, and most reportedly have a single

flagellum (Pascher 1942). There are no molecular or TEM data for *Stenocodon* or *Stomatochone*, and both are considered Histionidae *incertae sedis*. As a matter of purely historical interest, one of Pascher's *Stomatochone* species, *Stomatochone excavata*, was originally described in the late nineteenth century (as *Oikomonas excavata;* see Pascher 1942). This species might be the first-described jakobid, if it is indeed correctly assigned.

Two other jakobids are currently under study and are referred to in the literature as *Seculamonas ecuadoriensis* and *Jakoba bahamensis* or *J. bahamiensis* (e.g., Burger et al. 2003, 2013; Gray et al. 2004; Marx et al. 2003; Rodriguez-Ezpeleta et al. 2007; Shutt and Gray 2006a, b). As of yet, there are no published morphological data or a formal description of either species. Very recently, however, a new soil isolate that is specifically related to *Seculamonas ecuadoriensis* was formally described as *Moramonas marocensis* (Strassert et al. 2016). It is possible that *Moramonas* will be a suitable generic vehicle for the *Seculamonas ecuadoriensis* organism, if and when it is formally described.

Much of the work on jakobids over the last two decades has been in the fields of biochemistry, molecular biology, and evolutionary genomics. The mitochondrial genome of *Reclinomonas americana* strain ATCC 50394 was published in 1997 (Lang et al. 1997; see also Burger et al. 1996; Lang et al. 1996). Mitochondrial genome sequences have since been completed for three other strains of *Reclinomonas americana* and for *Histiona aroides*, *Jakoba libera*, *Jakoba bahamensis*, *Seculamonas ecuadoriensis*, and *Andalucia godoyi* (Burger et al. 2013; see also Gray 1999; Gray et al. 1998, 1999, 2004; Lang et al. 1999a, b). In addition, extensive mitochondrial genome sequence data, including most or all of the coding regions, was recently reported for *Moramonas marocensis* (Strassert et al. 2016). The uniquely bacterial-like nature of jakobid mitochondrial genomes makes them important for understanding the evolution and full capabilities of mitochondria. This has inspired several studies of mitochondrial genes, proteins and RNAs in jakobids, including the positive identification of a mitochondrial gene of previously unknown function (Burger et al. 2003), characterization of respiratory complex organization (Marx et al. 2003), examination of the catalytic properties of the RNA component of mitochondrial RNase P (Seif et al. 2006), identification and/or characterization of additional (nearly) "jakobid-specific" mitochondrial genes (Jacob et al. 2004; Keiler et al. 2000; Tong et al. 2011), and studies of mitochondrial tRNA processing (Leigh and Lang 2004). Recently it was established that at least some jakobids belong to the selection of protists with nuclear genes that encode a bacterial-like FtsZ plus MinC-E protein system, which is inferred to form part of the ancestral mitochondrial division mechanism in eukaryotes (Leger et al. 2015). In fact, mitochondrial localization of the Min proteins was demonstrated using heterologous expression of *Stygiella incarcerata* proteins in yeast (in parallel with studies of *Dictyostelium* sequences).

Examination of nuclear genes from jakobids began primarily for phylogenetic purposes (Archibald et al. 2002; Cavalier-Smith 2000; Edgcomb et al. 2001; Simpson and Roger 2004; Simpson et al. 2002, 2006). *Jakoba libera*, *Reclinomonas americana*, *Histiona aroides*, *Andalucia godoyi*, *Stygiella incarcerata*, *Jakoba bahamensis*, and *Seculamonas ecuadoriensis* have all been the subjects of expressed

sequence tag (EST) projects or more extensive transcriptomic surveys (e.g., Hampl et al. 2009; Leger et al. 2016; O'Brien et al. 2007; Lang, personal communication), while whole genome sequencing projects are underway for *Andalucia godoyi* and *Reclinomonas americana* (Lang, personal communication; see Burger et al. 2013). Some phylogenetic studies focusing on jakobids have relied heavily on these resources (e.g., Hampl et al. 2009; Rodríguez-Ezpeleta et al. 2007; Simpson et al. 2008). These databases have also been used for gene discovery, for example, for finding nucleus-encoded mitochondrial or hydrogenosomal proteins (Shutt and Gray 2006a, b; Tong et al. 2011; Leger et al. 2015, 2016), for intron confirmation (Russell et al. 2005), and to establish that jakobids have "TTAGGG" telomeres like those of vertebrates (actually inferred to be the ancestral type for eukaryotes; Fulnečkova et al. 2013).

Cultures identified as *Jakoba libera* have been used to examine several aspects of predation by nanoflagellates. These include comparative studies of feeding and growth kinetics with different species of predators and/or prey (Christaki et al. 2005; Eccleston-Parry and Leadbeater 1994; Mohapatra and Fukami 2004a, 2005), production of hydrolytic enzymes during predation (Mohapatra and Fukami 2004b), chemosensory attraction of predators to different bacterial prey (Mohapatra and Fukami 2007), and the influence of different predators on the composition of experimental prokaryote communities (Vázquez-Domínguez et al. 2005).

Practical Importance

At present jakobids are studied primarily because of their evolutionary importance rather than any direct impacts on humans. They are all free living, and there are no indications of pathogenicity or toxicity. There is no known commercial exploitation of jakobids.

Habitats and Ecology

Free-swimming jakobids have been reported from diverse habitats, including marine water column, marine sediments, freshwater, and soil (Lara et al. 2007; Patterson 1990; Patterson et al. 1993; Vørs et al. 1995; Strassert et al. 2016). The morphospecies *Jakoba libera* was first observed in hypersaline samples, apparently including saturated brine (Ruinen 1938). All described species of *Stygiella* and *Velundella* were isolated from anoxic marine or saline material (Bernard et al. 2000; Pánek et al. 2015; Simpson et al. 2008), and related SSU rDNA/rRNA sequences have been detected from different oxygen-poor, sulfide-rich water samples, including some associated with deep hypersaline anoxic basins (Alexander et al. 2009; Behnke et al. 2006; Luo et al. 2005; Pánek et al. 2015; Stock et al. 2009, 2012; Weber et al. 2014). By contrast, histionids seem to be restricted to freshwater. They attach to surfaces, including larger algae, or are neustonic (Penard 1921; Petersen and Hansen 1961).

As with other "typical excavates," jakobids are suspension feeders. The beating of the posterior flagellum creates a current through the feeding groove. Individual suspended particles are phagocytosed within the groove, usually at its posterior end. Jakobids are generally considered to be bacterivores (e.g., O'Kelly 1997; Patterson et al. 1993), although *Jakoba libera* can also consume the extremely small (1 μm) eukaryote *Ostreococcus tauri* (Christaki et al. 2005). Unsurprisingly, very different growth rates have been recorded for *Jakoba libera* when fed different prey species (Mohapatra and Fukami 2004a, 2005).

Jakobids are fairly slow swimmers (e.g., Eccleston-Parry and Leadbeater 1994) and generate a modest feeding current if tethered. This suggests that their clearance rate (the volume from which prey is extracted per unit time) may be low compared with many suspension-feeding flagellates. Single-bacterium growth experiments on *Jakoba libera* yielded clearance rates of <5 nl cell^{-1} h^{-1}, at the low end of those reported for nanoflagellates (Eccleston-Parry and Leadbeater 1994; Mohapatra and Fukami 2004a, 2005). In one trial *Jakoba libera* had by far the lowest volume-specific clearance rate (clearance rate/predator cell volume) of six flagellates tested under common conditions (Eccleston-Parry and Leadbeater 1994). It is possible that jakobids are adapted to relatively high concentrations of prokaryotes, such as those associated with surfaces in sediments and on detritus particles. The loricate histionids are normally attached to surfaces, while *Jakoba libera*, *Stygiella incarcerata*, and *Velundella nauta* often attach temporarily to surfaces by the distal portion of the anterior flagellum (Bernard et al. 2000; Patterson 1990; Pánek et al. 2015). Meanwhile, cells of *Stygiella adherens* and *Stygiella cryptica* adhere with either flagellum, while those of *Stygiella agilis* and *Velundella trypanoides* reportedly adhere by the cell body (Pánek et al. 2015). These attachment strategies may also improve clearance, relative to feeding while swimming (see Cristensen-Dalsgaard and Fenchel 2003).

Characterization and Recognition

General Appearance

Free-swimming jakobids are usually <12 μm long (though *Velundella trypanoides* can reach 15 μm; Pánek et al. 2015) and roughly pyriform in shape (Figs. 1a, b and 2a–f). The "ventral" side of the cell is formed into a broad groove. The right margin of the groove is more conspicuous than the left margin, which becomes reduced about halfway down the cell (Fig. 1b). The two flagella insert near the anterior end of the cell and are generally 1–2 times the length of the cell body (Figs. 1 and 2). Cultures of stygiellids often contain swimming forms with reduced grooves and sometimes different flagellum lengths (Bernard et al. 2000: Pánek et al. 2015). For example, cultures of *Stygiella incarcerata* contain both grooved cells and cells with reduced or absent grooves, with many of the latter having a markedly lengthened anterior flagellum (Fig. 2c, d). The posterior flagellum, also called flagellum 1, is directed posteriorly and usually beats within the groove (Figs. 1 and 2c). The anterior

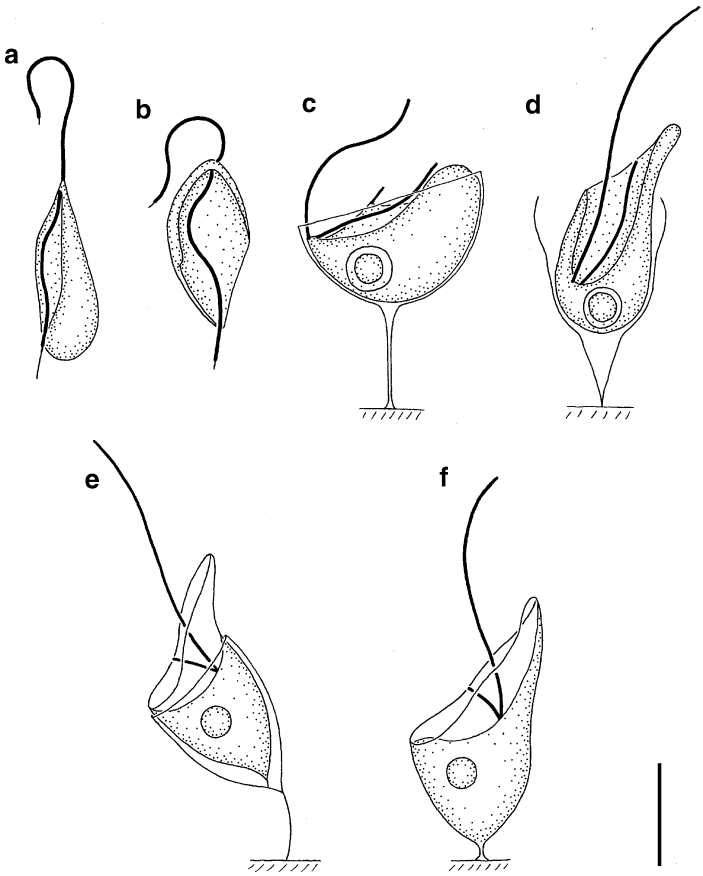

Fig. 1 Appearance of representative jakobids, viewed by light microscopy. (**a**) *Jakoba libera* (Jakobidae), lateral view; (**b**) *Stygiella incarcerata* (Stygiellidae), ventral view; (**c**) *Reclinomonas americana* (Histionidae), lateral view; (**d**) *Histiona aroides* (Histionidae); (**e**) *Stenocodon epiplankton* (Histionidae *incertae sedis*); (**f**) *Stomatochone infundibuliformis* (Histionidae *incertae sedis*). Scale bar represents 5 μm for all images (Drawings by AGBS, after drawings and images in Patterson (1990), Micro*scope (http://starcentral.mbl.edu/microscope), Simpson and Patterson (2001), O'Kelly (1997), Nicholls (1984) and Pascher (1942))

flagellum (or flagellum 2) emerges anteriorly or laterally and sometimes curves to be directed posteriorly (Figs. 1 and 2). In *Jakoba libera* and *Stygiella incarcerata*, the anterior flagellum can assume a shepherd's crook shape, and the curved portion adheres temporarily to the substrate (Figs. 1a, b and 2a, c). Most species locomote by swimming with a spiraling motion.

Loricate jakobids (i.e., almost all Histionidae) are typically around 10–15 μm. To facilitate comparisons, the site of flagellar insertion can be taken to define the anterior end. The lorica is delicate and is organic rather than mineralized. *Reclinomonas* resembles a free-swimming jakobid that is reclining, groove-side

uppermost, within a close-fitting wineglass-shaped lorica (Flavin and Nerad 1993; O'Kelly 1997; see Fig. 1c). The "stem" of the wineglass, or pedicel, attaches the organism to the substrate. *Histiona* cells have rounded anterior ends and normally reside anterior-end-downwards within the lorica (Figs. 1d and 2g). The groove margins, especially the right margin, are very broad. This gives the posterior portion of the cell a sail-like appearance (it is sometimes referred to as the "velum"), and it usually projects from the lorica (Figs. 1d and 2g). The lorica is more conical than in *Reclinomonas* and includes a shelflike structure upon which the cell itself lies (Petersen and Hansen 1962). In both taxa the anterior flagellum usually curves over to be directed posteriorly (Fig. 1c, d). The posterior flagellum lies within the groove and is difficult to see by light microscopy. In both *Reclinomonas* and *Histiona*, the left margin of the groove detaches about halfway down the cell,

forming a projection called the epipodium (Flavin and Nerad 1993; Penard 1921; O'Kelly 1997; see Fig. 1c). The epipodium can be mistaken for a short flagellum by light microscopy, but is actually supported by microtubules from the left "R1" flagellar root (see below). Some accounts suggest that the epipodium attaches the cell to its lorica (Flavin and Nerad 1993; Penard 1921), but this is disputed by O'Kelly (1997). Cells of *Stenocodon* and *Stomatochone* (both Histionidae *incertae sedis*) are more conical, and one of their two flagella is very short (Fig. 1e, f) or absent altogether (three nominal species of *Stomatochone*; Pascher 1942). *Stenocodon* has a conical lorica, while *Stomatochone* is similar to *Stenocodon* but lacks the lorica and attaches to surfaces by a pointed part of the cell (Pascher 1942).

Ultrastructure

The nucleus has a central nucleolus and is positioned in the anterior part of the cell, closely associated with the flagellar basal bodies (Fig. 3a). The mitochondria and single dictyosomal Golgi body are also located anteriorly. There is a single mitochondrion in most cases (Flavin and Nerad 1993; Lara et al. 2006; O'Kelly 1993; but see Strassert et al. 2016). The mitochondrial cristae are tubular/ampuliform in *Reclinomonas*, *Histiona*, *Moramonas*, and *Andalucia* (Lara et al. 2006; Mylnikov 1989; O'Kelly 1993, 1997; Strassert et al. 2016; see Fig. 3b), but flattened in *Jakoba libera* and absent in *Stygiella* and *Velundella* (Pánek et al. 2015; Patterson 1990; Simpson and Patterson 2001). The endoplasmic reticulum is observed throughout the cell, while food vacuoles are mostly in the posterior two-thirds (Fig. 3a). A microbody has been documented in *Andalucia* and *Moramonas* (Lara et al. 2006; Strassert et al. 2016). *Jakoba libera* and histionids possess small, round extrusomes that lie under the dorsal cell membrane (Mylnikov 1989; O'Kelly 1993, 1997). Their positioning suggests a defensive function. The lorica of *Reclinomonas americana* is decorated with fine scales that resemble carpentry nails (Flavin and Nerad 1993; O'Kelly 1997). These are produced within the endomembrane system prior to cell division, and zoospores contain a vesicle that holds numerous scales (O'Kelly 1997; see below).

The anterior flagellum (F2) is unremarkable, but the posterior flagellum (F1) of trophic cells has a vane on its "dorsal" side (i.e., the side closest to the cell body – Fig. 3d–f). The vane is not normally seen by light microscopy, but can be observed in fixed, stained material (Petersen and Hansen 1962). It is as broad as the axoneme in *Jakoba libera* and *Andalucia godoyi* (Lara et al. 2006; Patterson 1990), but 2–4 times as broad in other well-studied species (Flavin and Nerad 1993; Mylnikov 1989; Simpson and Patterson 2001; see Fig. 1d). The vane is supported by a fine paraxonemal leaf of an unknown protein composition, which can appear striated in grazing sections (Lara et al. 2006; Mylnikov 1989; Simpson and Patterson 2001). Presumably the vane plays a role in generating the feeding current (or maintaining the current close to the cell surface) or in the mechanics of food capture. The vane is absent in *Reclinomonas* zoospores (O'Kelly 1997), consistent with a role in feeding rather than locomotion.

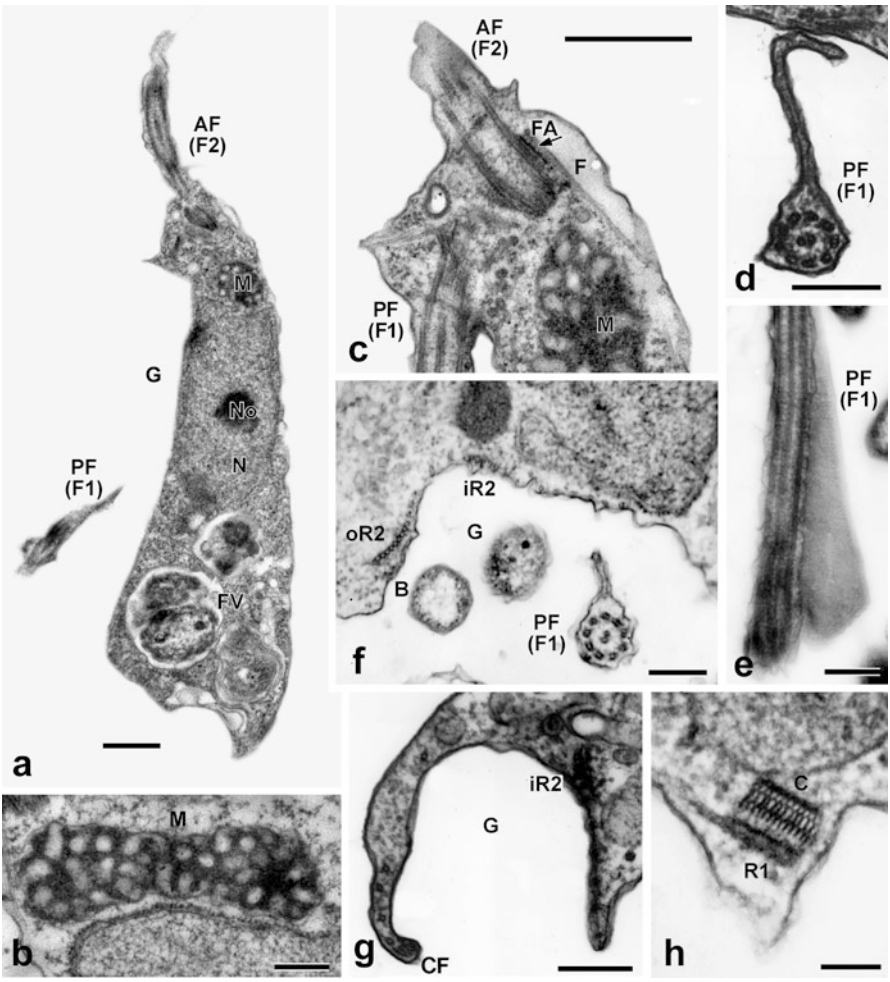

Fig. 3 Transmission electron micrographs of *Andalucia godoyi* (**a**–**c**) and *Stygiella incarcerata* (**d**–**h**): (**a**) Whole cell in longitudinal section; (**b**) mitochondrion, with tubular cristae; (**c**) flagellar apparatus, showing the dorsal fan originating close to the basal body of the anterior flagellum (flagellum 2); (**d**) transverse section of the posterior flagellum (flagellum 1) showing the single broad "dorsal" vane; (**e**) longitudinal section of the posterior flagellum and vane; (**f**) transverse section through the groove, showing the outer portion of the R2 (right) root (labeled "*oR2*") supporting the right wall of the groove together with the B fiber (here shown shortly before its end), while the inner portion of the R2 root (labeled "*iR2*") and, especially, microtubules derived from the R1 (left) root, support much of the floor of the groove. Note the dorsal position of the flagellar vane relative to the axoneme of the posterior flagellum; (**g**) the groove near the posterior end of the cell. Note the thin right wall of the groove, supported by the composite fiber (*CF*), and microtubules derived from R2; (**h**) transverse section of the C fiber, attached to the dorsal side of the R1 (left) root, at the anterior end of the groove. The R1 microtubules are sectioned obliquely here and cannot be distinguished individually. *AF(F2)* anterior flagellum/flagellum 2, *B* B fiber, *C* C fiber, *CF* composite fiber, *F* dorsal fan, *FA* fan-associated sheet, *FV* food vacuole, *G* groove, *iR2* inner portion of the R2 root (right root), *M* mitochondrion, *N* nucleus, *No* nucleolus, *oR2* outer

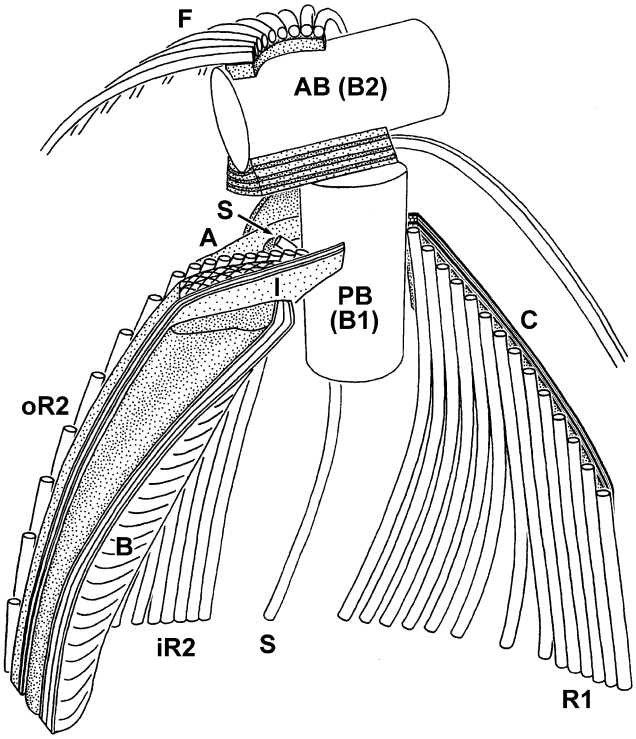

Fig. 4 Reconstruction of the proximal flagellar apparatus of *Stygiella incarcerata*, seen from the ventral side. *A* A fiber, *AB(B2)* anterior basal body/basal body 2, *B* B fiber, *C* C fiber, *F* dorsal fan, *I* I fiber, *iR2* inner portion of the R2 (right) root, *R1* left "R1" microtubular root, *PB(B1)* posterior basal body/basal body 1, *R2* right "R2" microtubular root, *S* singlet microtubular root (Modified from Simpson and Patterson (2001), reproduced with permission)

The flagellar apparatus is depicted in Fig. 4. The basal bodies lie at a wide angle to one another (see also Fig. 3c). There are two main flagellar microtubular roots: the left root "R1" and the right root or "R2" (see Yubuki et al. 2013 for corrected universal numbering for the flagellar microtubular roots of "typical excavates"). These originate in association with the posterior basal body (basal body 1). There is also a single microtubule – the "singlet root" – that originates close to basal body 1, near the dorsal side of the R2 (right) root. The proximal portion of the R2 root associates with three non-microtubular fibers, "A," "B," and "I" (O'Kelly 1997;

Fig. 3 (continued) portion of the R2 root (right root), *PF(F1)* posterior flagellum/flagellum 1, *R1* left 'R1' root. Scale bars in **a** and **c** represent 500 nm. Bars in **b** and **d**–**g** represent 250 nm. Scale bar in h represents 100 nm (**a** and **c** Images by E. Lara, reproduced from Lara et al. (2006), with permission. **b** image by E. Lara. **d**–**h** Images by AGBS, reproduced from Simpson and Patterson (2001), with permission)

Patterson 1990). The "A" fiber lies on the dorsal side of the R2 root, the "I" fiber on the ventral side, and the "B" fiber is initially aligned at an angle to the ventral side of the R2 root (Fig. 3f). The non-microtubular "C" fiber is attached to the dorsal side of the R1 (left) root and has a conspicuous multilayered appearance (Fig. 3h). It supports the origins of individual microtubules that are gradually added to the left side of R1 (see Fig. 4).

The main role of the cytoskeleton associated with basal body 1 is supporting the feeding groove. Shortly after its origin, the R2 (right) root divides into an inner portion with 4–8 microtubules (Lara et al. 2006; O'Kelly 1997; Simpson and Patterson 2001) and an outer portion with the remainder. The outer portion and the associated B fiber support the right margin of the groove (Fig. 3f). Microtubules from the R1 (left) root support the left margin. Most of the groove floor is supported by microtubules that diverge from the R1 root, while the rightmost portion only is supported by the singlet root, the inner portion of the R2 root, and a few individual microtubules that emerge between the two portions of the R2 root (Figs. 3f and 4). Progressing down the groove, the "I" fiber and "B" fiber gradually disappear, while the left margin abruptly reduces, and the microtubules supporting the left margin terminate. In histionids, the left margin edge detaches and continues to be supported by R1 microtubules and the C fiber for some distance, forming the epipodium (see above, and O'Kelly 1997; Mylnikov and Mylnikov 2014). Further down, many of the microtubules supporting the right margin terminate. The remaining microtubules are supplemented by a (partly) striated "composite fiber," which supports the right margin of the groove to the posterior end of the cell (Simpson and Patterson 2001; Fig. 3g). The groove wall at this point can become very tall and extremely thin, especially in histionids (Flavin and Nerad 1993), resulting in the sail-like appearance ("velum") seen in light microscopy (see above). The histionid velum margin is supported by more microtubules than the posterior right margin of free-swimming jakobids, and the composite fiber is more extensive as well (Mylnikov and Mylnikov 2014).

The anterior basal body (basal body 2) is associated with a fan of individual microtubules that spread out to support the dorsal side of the cell (Fig. 3c). There is a small plaque or sheet of dense material sandwiched between the originating microtubules and the basal body ("FA" in Fig. 3c; Lara et al. 2006; O'Kelly 1997). There are probably no true microtubular roots associated with basal body 2 in jakobids. A two-microtubule "root" was originally reported in *Stygiella incarcerata* (Simpson and Patterson 2001), but is not seen in the related *Andalucia godoyi*, and likely represents two individual microtubules (Lara et al. 2006).

Life Cycle

Jakobids reproduce by binary fission. Two new basal bodies form prior to mitosis and serve as the organizing centers for the mitotic spindle, which forms externally to the nucleus (O'Kelly 1993). O'Kelly (1993) reported that the nuclear envelope breaks down after spindle formation, but that the nucleolus persists through at

least the early stages of mitosis. Following cytokinesis in *Reclinomonas*, one daughter cell inherits the parental lorica while the other swims away as a zoospore, settles elsewhere, and constructs a new lorica (O'Kelly 1997). Similar swimming cells have been reported in other histionids (Mylnikov 1984; Penard 1921). There are no reports of sexuality in jakobids.

Some species form cysts with relatively delicate, unmineralized cyst walls. The soil-isolated species *Andalucia godoyi* and *Moramonas marocensis* both have spherical cysts (Lara et al. 2006; Strassert et al. 2016; Fig. 2f inset). The cysts of histionids generally remain within the lorica and have a small button-like projection (Mylnikov 1984; O'Kelly 1997; Petersen and Hansen 1961). The presence of cysts in *Jakoba libera* is uncertain (see O'Kelly 1997). The cysts of jakobids retain some vestiges of the flagellar apparatus, i.e., basal bodies and parts of the flagellar microtubular root system (O'Kelly 1997; Strassert et al. 2016).

Mitochondrial Genomes

The mitochondrion was originally an independent bacterium, specifically an alpha-proteobacterium, that was incorporated as an endosymbiont in some common ancestor of all extant eukaryotes. The mitochondrial genome is the reduced and highly modified remnant of this bacterium's genome (see Gray et al. 1999). Of all mitochondrial genomes studied to date, those of jakobids most closely resemble the ancestral mitochondrial genome, that is, they have lost the fewest bacterial features.

The exemplar jakobid *Reclinomonas americana* strain ATCC 50394 has a circular-mapping mitochondrial genome that is ~90% coding and contains nearly 100 genes, including 67 identified protein-coding genes and large ORFs (Fig. 5; Burger et al. 2013; Lang et al. 1997). This is about five times as many protein-coding genes as in animal mitochondria, for example. The several other jakobid mitochondrial genomes sequenced subsequently are generally very similar to that of *Reclinomonas americana* ATCC 50394. The biggest exceptions are in *Jakoba libera*, in which the mitochondrial genome is linear and has slightly fewer (89) putative genes (Burger et al. 2013; Gray et al. 2004), and *Moramonas marocensis*, whose mtDNA apparently includes a very large amount of noncoding sequence and is of unknown configuration (Strassert et al. 2016). Notably, the mitochondrial genome of *Andalucia godoyi* proved to have even more coding potential than *Reclinomonas*, with 100 genes, 69 of which are protein-coding genes or ORFs (Burger et al. 2013). These include *rpl35* (encoding a ribosomal protein) and *cox15* (encoding a cytochrome oxidase assembly protein), neither of which is mitochondrion encoded in any other eukaryote examined to date. Interestingly, the *Andalucia cox15* is not closely related to the nucleus-encoded *cox15* sequences from other eukaryotes and those from the great majority of alpha-proteobacteria (He et al. 2016). It most likely represents a recent gene transfer into the *Andalucia* mitochondrion from a prokaryotic source (and not an ancestral feature of the eukaryotic mitochondrial genome that has been uniquely retained in *Andalucia*).

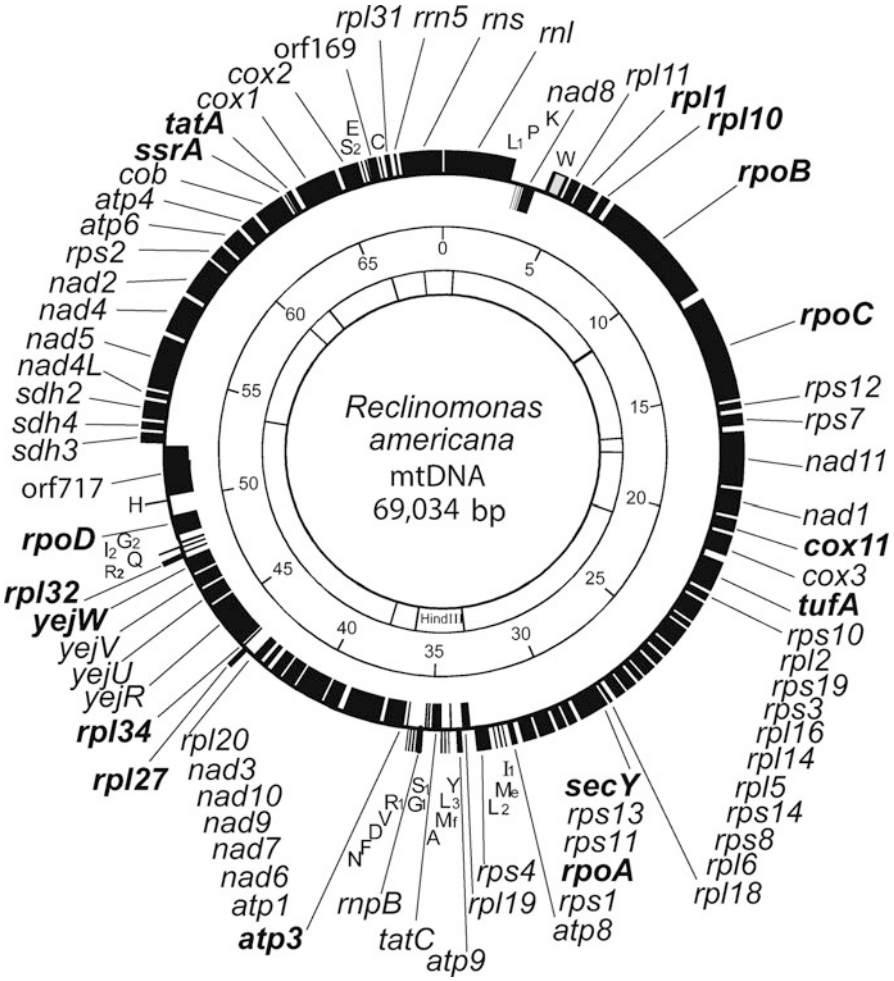

Fig. 5 Map of the mitochondrial genome of *Reclinomonas americana* (strain ATCC 50394). tRNA genes are denoted by individual capital letters according to the corresponding amino acid. Genes that appear to be unique to jakobid mitochondria, or nearly so, are denoted in bold – among these are *rpoA-D*, which encode subunits of a bacterial-type $\alpha_2\beta\beta'\sigma$ RNA polymerase; *tufA*, which encodes a translation elongation factor (also found in *Hartmannella* mtDNA – see Burger et al. 2013); *secY*, which encodes a SecY-type transporter; and *ssrA*, which encodes a transfer-messenger RNA (tmRNA) molecule (also found in oomycete mtDNA – see Burger et al. 2013) (Modified and updated from an original kindly provided by B. Franz Lang (Université de Montréal; Organelle Genome Megasequencing Program))

There are about nine protein-coding genes that are present in most or all jakobid mitochondrial genomes but are absent from all other sequenced mitochondrial genomes (Fig. 5; Burger et al. 2013). Products encoded by "jakobid-specific" genes include several ribosomal proteins, and a protein transporter of the bacterial

SecY type that is probably involved in the insertion of mitochondrion-encoded integral inner membrane proteins, though the latter is not encoded on *Andalucia godoyi* mtDNA (Burger et al. 2013; Tong et al. 2011). Most jakobid mitochondrial genomes also encode a transfer-messenger RNA (tmRNA), involved in clearing stalled ribosomes, otherwise only known from unpublished oomycete mitochondrial genome data (Burger et al. 2013; Jacob et al. 2004; Keiler et al. 2000). Most dramatically however, jakobid mitochondrial genomes encode subunits of a bacterial-type $\alpha_2\beta\beta'\sigma$ RNA polymerase. Genes for four subunits are present in *Reclinomonas americana* and most other jakobids, while *Jakoba libera* mtDNA encodes only two subunits (Burger et al. 2013; Gray et al. 2004; Lang et al. 1999a; Strassert et al. 2016). This seems to be a unique retention of a bacterial-like feature, since the mitochondrial RNA polymerases of other eukaryotes are nucleus-encoded single-subunit enzymes with no affinity to bacterial-type RNA polymerases. These have a completely distinct, though still obscure, evolutionary origin, but are ultimately related to the RNA polymerases of T7/T3 bacteriophage (Cermakian et al. 1996; Shutt and Gray 2006a).

Jakobid mitochondrial genomes also include several features that are found in only a few other eukaryotes. This includes the genes for the 5S rRNA and the RNA component of RNase P (*rrn5*, *rnpB*) and genes for some proteins required for maturation of electron transport chain components (Gray et al. 2004; Lang et al. 1996, 1997, 1999a). Like some other gene-rich mitochondrial genomes, gene order in jakobid mitochondrial genomes preserves vestiges of proteobacterial operons (Gray 1999; Lang et al. 1999a). It is especially noticeable in jakobids because of the larger number of genes. For example, *secY*, which is unique to jakobids, is positioned adjacent to the remaining ribosomal protein genes from the proteobacterial *spc* operon, and the gene order is the same as in proteobacteria (Burger et al. 2013; Lang et al. 1999a). Similarly, the RNA polymerase subunit gene *rpoA* is located "correctly" within a reduced proteobacterial "alpha" operon in all jakobids (Burger et al. 2013; Lang et al. 1999a, b). Finally, all jakobid mitochondrial genomes, except that of *Jakoba libera*, retain conserved Shine-Dalgarno-like sequences upstream of coding regions (Burger et al. 2013; Lang et al. 1997; Strassert et al. 2016).

The Nuclear Genome

As of early 2016, there are nuclear genome sequencing and annotation projects underway for at least two jakobids: *Andalucia godoyi* and *Reclinomonas americana* (Lang, personal communication; see Burger et al. 2013), but these have yet to be fully published. It appears that nuclear genes in *Jakoba*, *Reclinomonas*, and *Moramonas* (all members of Histionina) usually do include spliceosomal introns (e.g., Edgcomb et al. 2001; Archibald et al. 2002; Russell et al. 2005; Strassert, personal communication). By contrast, introns are lacking from most (but not all) of the protein-coding gene sequences reported from *Andalucia*, *Stygiella*, and *Velundella* species (Edgcomb et al. 2001; Leger et al. 2015; Simpson et al. 2008),

hinting that Andalucina as a group (see below) might have relatively intron-poor genomes. Curiously, the alpha tubulin genes from Andalucina are not closely related to those of other jakobids and instead show a strong phylogenetic affinity with alpha tubulin genes from Obazoa (e.g., opisthokonts), fornicates (e.g., diplomonads), and parabasalids (Edgcomb et al. 2001; Pánek et al. 2015; Simpson et al. 2008). This is most likely due to eukaryote-to-eukaryote gene transfer (Simpson et al. 2008) or perhaps an ancient paralogy and differential paralog retention (Eliáš, personal communication).

Systematics

The formal taxon for all jakobids is Jakobida Cavalier-Smith 1993, emended by Adl et al. (2005). Described jakobids are divided into two subtaxa: Histionina Cavalier-Smith 2013 and Andalucina Cavalier-Smith 2013. The original morphological diagnoses of these taxa do not distinguish them because the diagnosis for Andalucina is inaccurate; however, each corresponds to a well-supported clade in molecular phylogenies (see below and Pánek et al. 2015). Histionina includes Jakobidae Patterson 1990, Moramonadidae Strassert et al. 2016, and Histionidae Flavin and Nerad 1993. Jakobidae and Moramonadidae each only contains a single genus (*Jakoba* and *Moramonas*, respectively), while Histionidae includes *Histiona* and *Reclinomonas*, with *Stomatochone* and *Stenocodon* currently considered as Histionidae *incertae sedis* (Adl et al. 2005, 2012; Patterson et al. 2002). *Jakoba bahamensis*/*Jakoba bahamiensis* and *Seculamonas ecuadoriensis* are *nomina nuda* that refer to organisms that branch within Histionina, with the latter assignable specifically to Moramonadidae (Strassert et al. 2016). Andalucina is subdivided into Andaluciidae Cavalier-Smith 2013 (which includes only *Andalucia*) and Stygiellidae Pánek et al. 2015, which contains the recently introduced genera *Stygiella* and *Velundella*. A list of species (including well-studied *nomina nuda*) is given in Table 1.

Maintenance and Cultivation

Many jakobids, especially free-living forms, have been observed, encountered, and isolated from crude cultures, rather than directly from environmental samples (e.g., Bernard et al. 2000; Patterson et al. 1993). One jakobid was encountered as a contaminant in an algal culture (O'Kelly 1993). Histionids may be collected as epibionts on larger algae (Bourrelly 1953; Penard 1921).

Many of the described species are maintained in monoprotistan culture. Jakobids have been isolated by serial dilution (Flavin and Nerad 1993; Lara et al. 2006; pers. obs) or even simple serial transfer (pers. obs). Existing cultures are not axenic – they include prey bacteria. Most cultures have been isolated and maintained in standard liquid media of appropriate salinity and mineral composition (e.g., Page's amoeba saline or "WCL" for freshwater and soil organisms; f/2, sterile seawater or diluted

Table 1 Described and studied species of jakobids, and availability of various data

[g]Limited TEM data published

sterile seawater for marine/brackish organisms), supplemented with an organic carbon source to promote bacterial growth, for example, dilute tryptone soy broth (0.3%), dilute LB media (0.3%), or a sterile barley grain (Lara et al. 2006; Patterson 1990). In some cases live prey bacteria (e.g., *Klebsiella* or *Enterobacter*) have been added instead of the carbon source or in addition to it (Burger et al. 2013; Flavin and Nerad 1993). *Reclinomonas americana* grows in ATCC 802 medium (i.e., Sonneborn's *Paramecium* medium), a simple cereal grass infusion (Flavin and Nerad 1993). *Stygiella incarcerata*, which is anaerobic, but not strictly so, grows well on fairly rich media that promotes dense bacterial growth and thus reduces free oxygen, e.g., 50% seawater supplemented with 3% LB (Simpson et al. 2008). However, this species also grows in seawater variants of ATCC 802 medium (ATCC 1525 medium) and in 50% seawater supplemented with a barley grain or with 802 media (Bernard et al. 2000; Pánek et al. 2015; Simpson et al. 2008). Other *Stygiella* and *Velundella* species were also originally cultivated on ATCC 1525 medium (Pánek et al. 2015). *Jakoba libera* has been grown on several different bacteria during experimental ecology studies (Eccleston-Parry and Leadbeater 1994; Mohapatra and Fukami 2004a). Most cultured jakobids grow well at 20–25 °C (e.g., Burger et al. 2013; Mohapatra and Fukami 2004a; pers. obs). Strains of the marine/brackish species *Stygiella incarcerata* and *Velundella trypanoides* will grow at salinities 1.5 times that of seawater (56 ppt), but show poor-to-no growth at double marine salinity (Pánek et al. 2015). At least one *Jakoba c.f. libera* strain grows well at 100 ppt salinity (i.e., almost three times marine salinity; pers. obs.).

Evolutionary History

Overall Phylogenetic Position

Jakobids have been considered as eukaryotes of particular evolutionary importance for more than two decades. O'Kelly (1993) noted that jakobid flagellates were morphologically similar to some "amitochondriate" flagellates, especially retortamonads. Retortamonads, in turn, were usually considered to be related to diplomonads. At the time certain amitochondriate flagellates, including retortamonads and diplomonads, were widely thought to be the earliest-branching extant eukaryotes (Cavalier-Smith 1987; Patterson and Sogin 1992). O'Kelly (1993) proposed that jakobids represented a series of the earliest branches among the mitochondrion-bearing eukaryotes, in other words, that all amitochondriate eukaryotes were descended from jakobid or jakobid-like ancestors. The idea of jakobids being a paraphyletic group that was especially deeply branching among mitochondriate eukaryotes was later refuted by molecular phylogenetics (see below). Nonetheless, this concept was a primary motivation for Lang and colleagues to sequence mitochondrial genomes from jakobids, leading to the discovery that these genomes were uniquely bacterial-like (Gray et al. 2004; Lang et al. 1997 – see "Characteristics", above).

Early phylogenies based on one or two nuclear genes did not strongly resolve the position of jakobids within eukaryotes (Archibald et al. 2002; Cavalier-Smith 2000; Edgcomb et al. 2001; Simpson et al. 2002), although some studies hinted at a relationship with Euglenozoa and/or Heterolobosea (Archibald et al. 2002; Cavalier-Smith 2004; Edgcomb et al. 2001). Later molecular phylogenies based on multiple (4-140) nucleus-encoded proteins demonstrated with increasing conviction that jakobids are closely related to Euglenozoa and Heterolobosea, collectively known as Discicristata (Hampl et al. 2009; Rodríguez-Ezpeleta et al. 2007; Simpson and Roger 2004; Simpson et al. 2006, 2008). This clade containing Jakobida, Euglenozoa, and Heterolobosea is now referred to as Discoba (Hampl et al. 2009). Phylogenomic analyses indicate that the recently discovered heterotrophic flagellate *Tsukubamonas* also belongs to Discoba, but is probably more closely related to Euglenozoa and Heterolobosea than to Jakobida (Kamikawa et al. 2014).

Phylogenetic Relationships Within Jakobida

The phylogenetic relationships among jakobids, as currently understood, are summarized in Fig. 6a. Until recently, the principal problem was establishing the relationship between the first-described jakobids (the clade now known as Histionina) and the group now known as Andalucina. Analyses of morphological data supported the monophyly of all jakobids (Simpson 2003; Lara et al. 2006); however, phylogenetic trees of SSU rDNA sequences or tubulin genes never place Andalucina in a clade with other jakobids (e.g., Berney et al. 2004; Cavalier-Smith 2004; Edgcomb et al. 2001; Lara et al. 2006; Pánek et al. 2015; Simpson et al. 2002; Strassert et al. 2016), and phylogenies based on 6–7 nucleus-encoded proteins have given extremely weak support for a jakobid clade, at best (Pánek et al. 2015; Simpson et al. 2008). Nonetheless, phylogenomic analyses based on datasets of >100 proteins, or mitochondrion-encoded proteins, recover a jakobid clade with strong statistical support, with Andalucina as the sister group to other jakobids (Burger et al. 2013; Hampl et al. 2009; Kamikawa et al. 2014). Jakobid monophyly, and the deep branching of Andalucina (represented by *Andalucia*), is also recovered in analyses of genes of probable mitochondrial origin in eukaryotes (Derelle et al. 2015).

The relationships within Andalucina are currently inferred from recent analyses of SSU rDNA, which demonstrate the monophyly of Stygiellidae to the exclusion of Andalucidae (i.e., *Andalucia*) and the reciprocal monophyly of *Stygiella* and *Velundella* (Pánek et al. 2015; Fig. 6a). The relationships within Histionina are inferred from an assortment of partial, overlapping datasets. Morphological analyses and phylogenetic/phylogenomic analyses of nucleus-encoded proteins, as well as mitochondrial proteins, all support the monophyly of *Histiona* and *Reclinomonas*, suggesting strongly that Histionidae is indeed monophyletic (Burger et al. 2013; Hampl et al. 2009; Lara et al. 2006; Rodríguez-Ezpeleta et al. 2007; Pánek et al. 2015; Simpson 2003; Strassert et al. 2016). The relationships between Histionidae, Moramonadidae, *Jakoba libera*, and *Jakoba bahamensis* remain

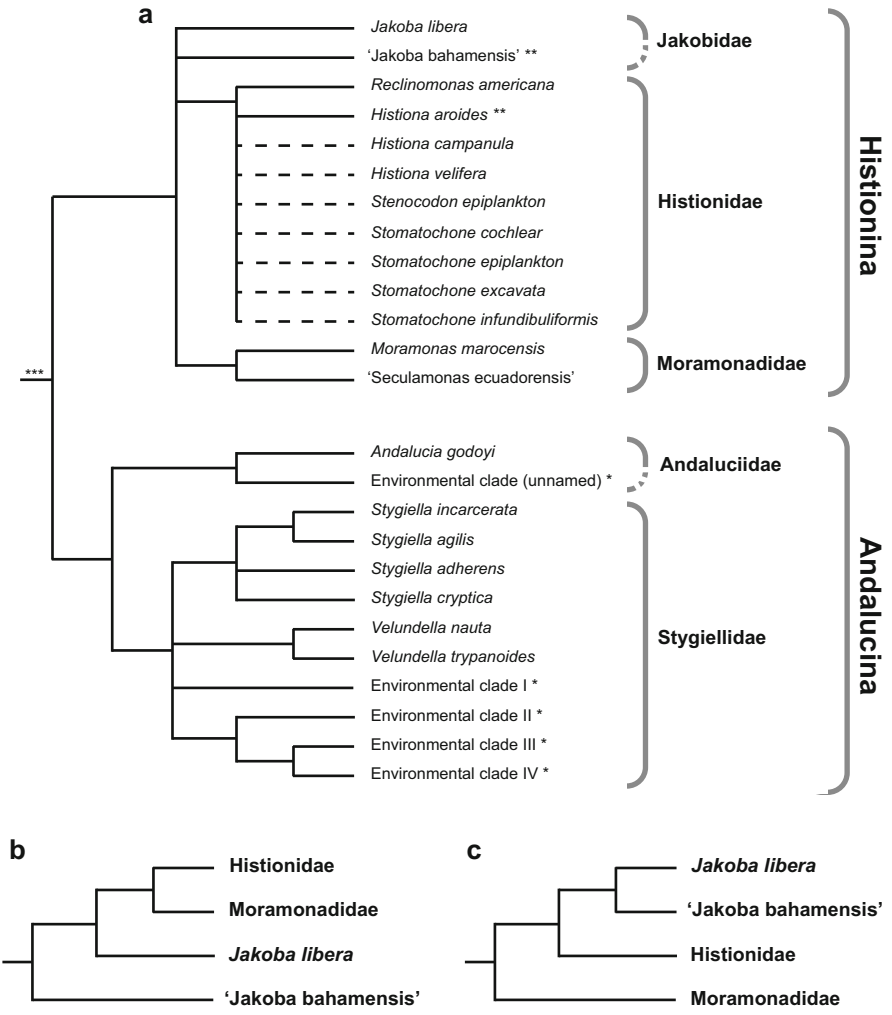

Fig. 6 Inferred phylogenetic relationships within Jakobida. (**a**) Summary phylogeny, based mainly on analyses of SSU rDNA by Pánek et al. (2015) and Strassert et al. (2016). Poorly supported branches (<65% bootstrap support in one or both studies) have been collapsed. Single asterisks represent clades containing multiple environmental sequences identified by Pánek et al. (2015); isolated environmental sequences have been excluded. Double asterisks represent species for which there are no published SSU rDNA sequences, which have been placed on the basis of multiprotein phylogenies inferred from nucleus- or mitochondrion-encoded sequences (see text). The monophyly of Jakobida (basal branch with triple asterisk) is not recovered in SSU rDNA phylogenies, but is well supported by phylogenomic analyses (see text). Dashed lines represent species for which no molecular data are available, whose positions are inferred from morphological considerations; (**b**) phylogenetic relationships within Histionina as recovered by most analyses of nuclear genes (see text); (**c**) relationships within Histionina inferred from mitochondrial genome phylogenies (e.g., Burger et al. 2013; Strassert et al. 2016)

unclear. Molecular phylogenies of nucleus-encoded proteins typically place *Jakoba bahamensis* as the deepest branch within Histionina and not specifically related to *Jakoba libera* (Hampl et al. 2009; He et al. 2014; Pánek et al. 2015; Rodríguez-Ezpeleta et al. 2007; Simpson et al. 2008; see Fig. 6b). By contrast, phylogenies of mitochondrion-encoded proteins recover *Jakoba* sensu lato as a clade, albeit with a very deep divergence between *Jakoba libera* and *Jakoba bahamensis*, and place Moramonadidae (e.g., *Seculamonas ecuadoriensis*) in the more deeply diverging position (Burger et al. 2013; Strassert et al. 2016; see Fig. 6c).

Importance for Mitochondrial Evolution

As discussed above, jakobid mitochondrial genomes encode subunits of a bacterial-type $\alpha_2\beta\beta'\sigma$ RNA polymerase, whereas all other studied eukaryotes have a single-subunit phage-type enzyme of separate evolutionary origin as their only known mitochondrial RNA polymerase. It appears that jakobids have retained this ancestral feature of the prokaryotic symbiont that became the mitochondrion, while it was replaced in all other eukaryotes. Several scenarios might explain this remarkable phylogenetic distribution (Simpson and Roger 2004; Simpson et al. 2006).

One possible scenario is that jakobids are a very early-diverging eukaryote lineage. After the divergence of jakobids, a common ancestor of all other living eukaryotes then acquired the phage-type RNA polymerase by lateral gene transfer (LGT) and lost their now-redundant bacterial-type RNA polymerase. This hypothesis is intuitively appealing, but is difficult to reconcile with the probable close phylogenetic relationship of jakobids with Heterolobosea and Euglenozoa (see above), since these latter two groups are known to have the phage-type RNA polymerase (Clement and Koslowsky 2001; Cermakian et al. 1996). This scenario would be tenable only if the eukaryotic tree should be rooted on jakobids. This would mean that the apparent Jakobida-Heterolobosea-Euglenozoa-*Tsukubamonas* clade recovered in phylogenomic analyses (Discoba; see above) is actually the basal grade for all living eukaryotes. There is no independent evidence positively supporting a jakobid rooting of the eukaryote tree (and see Derelle et al. 2015, for example, for phylogenetic evidence that the root of the eukaryote tree is more likely to lie elsewhere).

A second scenario is that the phage-type RNA polymerase has moved between eukaryote lineages through multiple events of LGT, each time replacing the bacterial-type RNA polymerase. This is less parsimonious (how much less depends on the position of the root of the eukaryote tree), but does not require that jakobids are a uniquely early-diverging lineage. For example, the scenario could be reconciled with jakobids being the sister group to Heterolobosea and Euglenozoa if it is supposed that the common ancestor of the latter two lineages was the recipient of one of these LGT events.

A third scenario supposes that it is actually the phage-type RNA polymerase that is ancestral for living eukaryotes and that the bacterial-like RNA polymerase was

more recently transferred from a bacterium into the mitochondrial genome of an ancestor of jakobids. The transfer of protein-coding genes into mitochondrial genomes is uncommon, but documented (e.g., Bergthorsson et al. 2003; Pont-Kingdon et al. 1998), including in the jakobid *Andalucia* (He et al. 2016; see above). A considerable difficulty with this scenario is that the bacterial-type RNA polymerase is a multi-subunit enzyme, and several genes would need to be transferred at once. In fact, *rpoA* in jakobids (where present) is located in its expected position within an apparent vestige of the proteobacterial alpha operon (Burger et al. 2013; Lang et al. 1999a, b), which does not include the other *rpo* genes. This supports an ancestral origin of *rpoA* rather than a recent acquisition of a set of *rpo* genes through LGT.

A fourth possibility, and perhaps the most plausible at present, is that the last common ancestor of eukaryotes had both bacterial-type and phage-type mitochondrial RNA polymerases (Stechmann and Cavalier-Smith 2002). Under this scenario, the bacterial RNA polymerase was subsequently lost in most eukaryotic lineages, but not in jakobids, which may or may not have lost the phage-type polymerase instead. This scenario does not require that the jakobids be uniquely deep-branching eukaryotes (assuming that multiple independent losses of bacterial RNA polymerase are plausible), but does imply an extended period where both polymerases are maintained together by eukaryotes.

Indirect evidence supporting this fourth scenario was presented by Shutt and Gray (2006a, b). They noted that mitochondrial RNA polymerase is only one of several nucleus-encoded mitochondrial replication/transcription proteins of possible phage origin. For example, the mitochondrial replicative helicase "Twinkle" is related to gp4 from T7 phage. Shutt and Gray (2006a) proposed that all of the phage-related proteins were acquired together, perhaps from an integrated prophage in the proteobacterial symbiont that became the mitochondrion. This model implies that jakobids would have originally had all the phage-type proteins and likely still have some or all of them. Indeed, transcripts encoding Twinkle are produced by *Seculamonas ecuadoriensis* and *Jakoba bahamensis* (Shutt and Gray 2006b). Shutt and Gray (2006a) suggest that the original function of the phage-type RNA polymerase in eukaryotes was not conventional transcription, but instead generating primers for mitochondrial DNA replication. Subsequently this enzyme was co-opted to also act as the transcriptional mitochondrial RNA polymerase, replacing the bacterial-type enzyme that originally performed this function. This co-option presumably happened several times in eukaryote evolution, and jakobids represent the only known lineage in which this did *not* occur. Appealingly, this model provides a plausible explanation as to why both polymerases could have been maintained simultaneously by early eukaryotes – they originally had different functions. Furthermore, an analogous situation occurs in the plastids of land plants, in which two different RNA polymerases transcribe different sets of plastid-encoded protein-coding genes (Gray and Lang 1998). One polymerase is of the bacterial type, while the other is of the phage type, and was apparently derived from mitochondrial RNA polymerase by gene duplication during the history of land plants.

Coda: Malawimonads

The first synthetic account of jakobid flagellates by O'Kelly (1993) included an "undescribed jakobid" from freshwater that differed from *Jakoba*, *Reclinomonas*, and *Histiona* in having discoidal mitochondrial cristae and an anterior microtubular root. This organism was later described formally as *Malawimonas jakobiformis* (O'Kelly and Nerad 1999). A related organism has been studied for more than a decade under the names *Malawimonas californiana*, *M. californiensis*, and *M. californianus* (e.g., Gray et al. 2004; Rodriguez-Ezpeleta et al. 2007; Russell et al. 2005), but still awaits formal description. An additional species of malawimonad has recently been characterized (Heiss et al. unpublished).

Like jakobids, malawimonads are small flagellates with two flagella (Fig. 7a, b) and a feeding groove supported by the "typical excavate" architecture (O'Kelly and Nerad 1999; Simpson 2003). Malawimonads, however, do not show the multilayered structure to the "C" fiber that is characteristic of jakobids, and the "dorsal fan" of microtubules mostly originates in association with the anterior "R3" microtubular root (which is absent in jakobids – see above). Malawimonads either have a pair of vanes on the posterior flagellum, as in most other "typical excavates" (Heiss et al. unpublished), or have a single vane on the ventral side of the axoneme, not

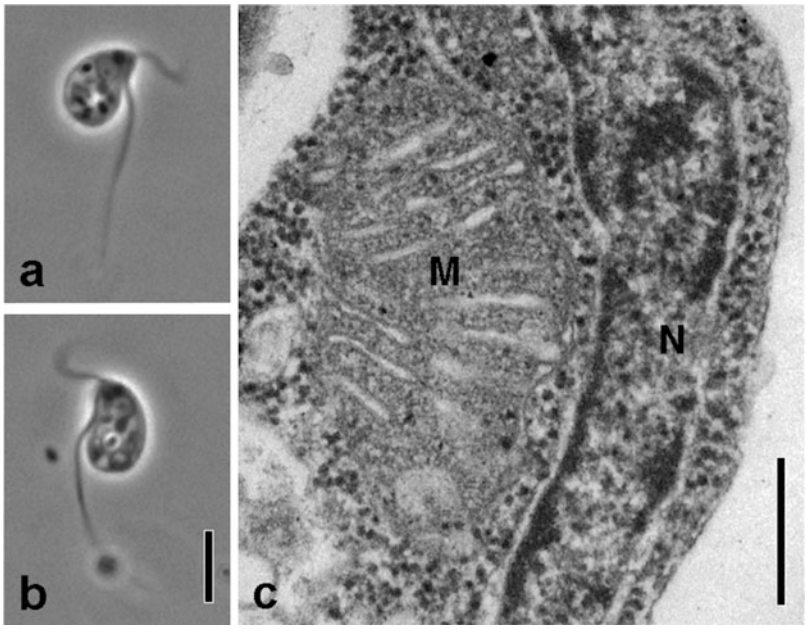

Fig. 7 Undescribed malawimonad "isolate 249": (**a**, **b**) Phase contrast light micrographs of living cells; (**c**) transmission electron micrograph showing mitochondrion with discoidal cristae and a narrow profile through the nucleus. *M* mitochondrion, *N* nucleus; scale bar in **b** represents 5 μm for **a** and **b**. Bar in **c** represents 250 nm (**a**, **b** Images by AGBS, **c** Image by A.A. Heiss)

the dorsal side as in jakobids (O'Kelly and Nerad 1999). Overall, the cell cytoskeleton of malawimonads more closely resembles that of *Carpediemonas* and other *Carpediemonas*-like organisms (CLOs), which are typical excavates that belong to the anaerobic Metamonada clade and are especially closely related to diplomonads and retortamonads (Simpson and Patterson 1999; Simpson et al. 2002, 2006; Yubuki et al. 2007; see ▶ Retortamonadida (with notes on *Carpediemonas*-Like-Organisms and Caviomonadidae)). The discoidal mitochondrial cristae noted by O'Kelly (1993) are indeed a distinctive characteristic of malawimonads as a whole (Fig. 7c). The mitochondrial genomes of *Malawimonas jakobiformis* and *Malawimonas californiana* have been sequenced (Gray et al. 2004). They are relatively gene rich, but contain many fewer genes than the mitochondrial genomes of jakobids, and in particular they lack genes encoding subunits of bacterial-type RNA polymerase (Gray et al. 2004).

Molecular phylogenies have not resolved the position of malawimonads within eukaryotes. Analyses of small numbers of nucleus-encoded genes typically (but not always) place malawimonads as close relatives of metamonads, either as the sister group to Metamonada as a whole or as sister to Preaxostyla (oxymonads and trimastigids; Simpson et al. 2006, 2008). As of early 2016, most phylogenomic analyses place malawimonads separately from other excavates, sometimes as sister to other obscure groups without close affinities to well-studied taxa, for example, collodictyonids (Derelle and Lang 2012; Derelle et al. 2015; Hampl et al. 2009; Rodríguez-Ezpeleta et al. 2007; Zhao et al. 2012). Nonetheless a close relationship with metamonads and/or other excavates has been recovered under certain specific conditions, in particular the exclusion of many rapidly evolving taxa (Burki et al. 2009; Hampl et al. 2009; Rodríguez-Ezpeleta et al. 2007). Irrespective, phylogenies of SSU rDNA, tubulins, 5–7 nucleus-encoded proteins, and phylogenomic analyses all concur that malawimonads are not specifically related to jakobids (Edgcomb et al. 2001; Hampl et al. 2009; Rodríguez-Ezpeleta et al. 2007; Simpson et al. 2002; 2006, 2008). The similarities between jakobids and malawimonads apparently reflect the ancestral morphology of "excavate" protists, or perhaps convergence, and not a close phylogenetic relationship.

Acknowledgments Thanks to Michael Gray (Dalhousie University), Michelle Leger (Dalhousie University), Marek Eliáš (University of Ostrava) and Tomas Pánek (University of Ostrava) for constructive comments, and B. Franz Lang (Université de Montréal) and Jürgen Strassert (University of British Columbia) for discussions. The author gratefully acknowledges the support of the Canadian Institute for Advanced Research (CIfAR), program in Integrated Microbial Biodiversity.

Heterolobosea

28

Tomáš Pánek, Alastair G. B. Simpson, Matthew W. Brown, and Betsey Dexter Dyer

Abstract

Heterolobosea is a group of ~150 described species of heterotrophs, almost all free living. Many are "amoeboflagellates" with a three-phase asexual life cycle, centered on trophic amoebae that can reversibly transform into flagellates (some of which undertake phagocytosis and/or division) and cysts. The amoebae are usually lobose, with "eruptive" pseudopodia. Flagellates typically have two or four near-parallel flagella and, if phagocytic, a feeding groove and/or elongate cytostome. Some taxa have simpler lifecycles, for example, *Vahlkampfia* spp. apparently lack flagellates, while *Percolomonas* and *Stephanopogon* lack amoebae. *Stephanopogon*, uniquely, has numerous flagella in rows like the kineties of ciliates. Acrasids, meanwhile, are terrestrial "slime molds" in which amoebae aggregate to form stalked fruiting bodies. The mitochondria are often enveloped in endoplasmic reticulum and usually have discoidal cristae, while the Golgi apparatus lacks dictyosomal stacking. Most flagellates have a "doubled" flagellar apparatus with two sub-identical halves. The flagellar apparatus typically includes a large "R2" microtubular root (or two) and a striated rhizoplast. Most heteroloboseans are marine, freshwater, or terrestrial aerobes, but the group shows considerable ecological breadth, for example,

Psalteriomonadidae and *Creneis* are anaerobes, three groups are (mostly) obligate halophiles, and many species are thermophiles. The best-known genus is *Naegleria*. *Naegleria gruberi* is a cell biology model (e.g., for flagellar apparatus development). *Naegleria fowleri* is a facultative human pathogen responsible for primary amoebic meningoencephalitis (PAM). This infection is usually acquired from warm water via the nasal passages; it is extremely rare but almost always fatal.

Summary Classification

●**Heterolobosea**
●●**Pharyngomonada** (*Pharyngomonas*)
●●**Tetramitia**
●●●**Acrasidae** (e.g., *Acrasis*, *Allovahlkampfia*, *Pocheina*)
●●●**Creneidae** (*Creneis*)
●●●**Gruberellidae** (*Gruberella*, *Stachyamoeba*)

●●●**Percolatea**
●●●●**Percolomonadidae** (*Percolomonas*)
●●●●**Stephanopogonidae** (*Stephanopogon*)
●●●**Psalteriomonadidae** (e.g., *Harpagon*, *Psalteriomonas*, *Sawyeria*)
●●●**Tulamoebidae** (*Pleurostomum*, *Tulamoeba*)
●●●**Vahlkampfidae*** (e.g., *Heteramoeba*, *Naegleria*, *Tetramitus*, *Vahlkampfia*)

*Vahlkampfidae is known to be highly paraphyletic.

Introduction

General Characteristics

The taxon Heterolobosea, Page and Blanton, 1985 (Excavata: Discoba), unites a diverse array of heterotrophic amoeboflagellates, amoebae, flagellates, and certain "slime molds" (the acrasids) that had previously been studied in relative isolation from one another (Page and Blanton 1985; Roger et al. 1996; Yubuki and Leander 2008; Brown et al. 2012a; Harding et al. 2013). Typical heteroloboseans are amoeboflagellates that have distinct amoeba and flagellate stages. In most species the amoeba stage can also transform into a cyst, resulting in a characteristic three-phase life cycle, with amoebae as the central phase (Fig. 1). This life cycle is likely an ancestral feature of Heterolobosea (Harding et al. 2013); however, many lineages seem to have lost the ability to form flagellates, or, conversely, do not form amoebae in culture (see Page 1988; Patterson et al. 2000; Pánek and Čepička 2012). Heterolobosean amoebae are typically limax, with eruptive pseudopodial formation, characterized by sudden outwards (and lateral) bulging during locomotion (Page 1978; Page and Blanton 1985). Flagellates usually possess two or four flagella. They often have a feeding groove and a generally reduced version of the flagellar apparatus cytoskeleton of "typical excavates" (Simpson 2003; Brugerolle and Simpson 2004; Park and Simpson 2011; Pánek et al. 2014b), but there are several exceptions, with the multiflagellated "pseudociliate" *Stephanopogon* being particularly notable (Yubuki and Leander 2008). The acrasids differ from other heteroloboseans in that they form multicellular sorocarps through an aggregative process (Fig. 2), which is

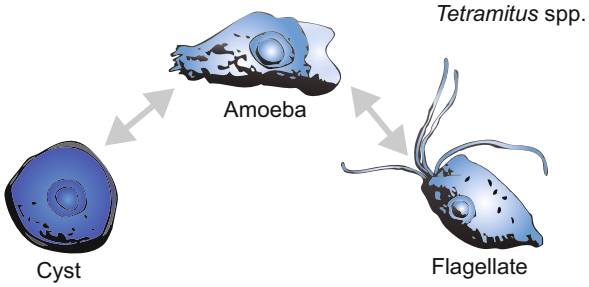

Fig. 1 Typical three-phase life cycle of Heterolobosea, as seen in the genus *Tetramitus*, with amoebae as the central phase

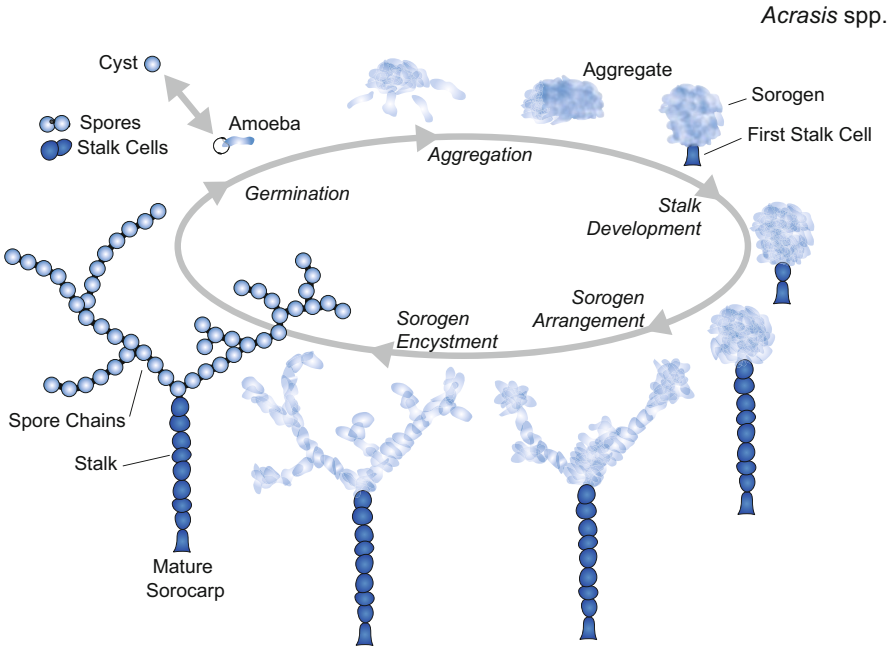

Fig. 2 Life cycle of acrasids, as seen in the genus *Acrasis*, with acrasoid sorogenesis. Mature sorocarp arranged as a branched structure with several chains of spores. Sorocarp displays basal stalk cells (*dark blue*) with distal spore cells (*light blue*). Spores germinate as limax amoebae. Amoebae may form cysts, which can germinate as amoebae. Amoebae aggregate to form small mounds. When aggregation ceases, cells in aggregate encyst to become the stalk, with a mass of amoebae (sorogen) remaining on top. Cells of the sorogen align into chains and then encyst to become spores. Developmental process descriptions are italicized. Names of structures are in regular font

somewhat similar to that seen in dictyostelid slime molds (Brown et al. 2012a; Brown and Silberman 2013; see ▶ Dictyostelia).

Almost all known heteroloboseans are free-living microbivores. *Naegleria fowleri* is a facultative parasite of humans that causes fatal meningoencephalitis (Carter 1970). Despite advances in drug treatment and supportive care, the mortality rate associated with the disease has remained over 95% (http://www.cdc.gov/parasites/naegleria/general.html; Siddiqui and Khan 2014). A close relative, *Naegleria gruberi*, is a useful cell biology model for examining development of the flagellar apparatus (Lee 2010; Fritz-Laylin and Fulton 2016). Heterolobosea have also attracted attention because of their ecological diversity, as the group includes many thermophiles, several clades of halophiles, and a considerable diversity of anaerobes, in addition to mesophilic soil-dwelling, freshwater, and marine forms (e.g., Reeder et al. 2015; Park and Simpson 2011; Pánek et al. 2012). Currently, the group comprises ~150 described species and 35 genera assigned to nine families and two main clades, Pharyngomonada and Tetramitia. Pharyngomonada is a

plesiomorphic group that contains a single described genus, *Pharyngomonas*, most isolates of which are halophilic amoeboflagellates. Tetramitia is morphologically and ecologically much more diverse and includes almost all described heterolobosean species.

Occurrence

Heteroloboseans have been reported from all continents, including Antarctica, and contribute to microbial communities from tropical to polar regions. Most (~86 species including all 47 *Naegleria* spp.) have been reported from soil and freshwater. Other species inhabit a wide range of habitats, including thermal springs, hypersaline brines, anoxic sediments, intestinal tracts of animals, bat guano, acidic rivers, and marine and brackish sediments. The human pathogen *Naegleria fowleri* is amphizoic; its primary habitat is warm bodies of freshwater (Visvesvara et al. 2007). Some other species are suspected to be opportunistic pathogens of animals (see De Jonckheere 2011). Culture-based approaches continue to reveal new heterolobosean species and genera (e.g., Brown et al. 2012a; Pánek et al. 2012, 2014a, b; Geisen et al. 2015; Park and Simpson 2016; Tyml et al. 2016). By contrast, environmental PCR-based methodologies have not yet contributed significantly to our knowledge of the occurrence and diversity of Heterolobosea in nature. The limited detection of Heterolobosea in such studies is almost certainly due to primer bias (Murase et al. 2014).

Literature and History of Knowledge

Although Heterolobosea has been formally recognized as a group for only three decades (Page and Blanton 1985; Roger et al. 1996), some organisms now classified as Heterolobosea were first described more than 150 years ago. Perty (1852) introduced the genus *Tetramitus* and described the well-known amoeboflagellate *Tetramitus rostratus*. A few decades later, descriptions were published of the acrasids now known as *Pocheina rosea* (Cienkowski 1873) and *Acrasis granulata* (Van Tieghem 1880), as well as an account of *Stephanopogon colpoda* (Entz 1884). These descriptions were based only on light microscopy; hence, their close relationships to each other remained hidden. In fact, they tended to be studied by different researchers; acrasids were examined primarily by mycologists, while amoebae and amoeboflagellates such as *Tetramitus* and *Naegleria* were studied by protozoologists, especially those who focused on amoebae. Meanwhile, the multiflagellated *Stephanopogon* was generally considered to be an unusual ciliate until the 1980s (Lipscomb and Corliss 1982; Patterson and Brugerolle 1988). It was transferred to Heterolobosea only recently, based on molecular phylogenies (Cavalier-Smith and Nikolaev 2008; Yubuki and Leander 2008).

Vahlkampfiid amoebae and amoeboflagellates have been investigated by many authors before the 1970s, with studies of *Naegleria* and *Tetramitus* being quite

extensive (e.g., Bunting and Wenrich 1929; Dingle and Fulton 1966; Droop 1962). Page (1976) placed them into a separate order, Schizopyrenida, within the subclass Gymnamoebia. Two years later, Page (1978) further suggested that Schizopyrenida are closely related to Acrasida because their forms of amoeboid locomotion are similar. This grouping was formalized by Page and Blanton (1985) when they established the class Heterolobosea. This action was bolstered by ultrastructural characteristics shared by acrasids and schizopyrenids, in particular both usually have discoidal mitochondrial cristae and a characteristic mitochondrion/ER complex (Page and Blanton 1985; see below).

Prior to the 1950s, acrasids were associated with the other sorocarpic amoebae that were assigned to Mycetozoa *sensu lato* and were little studied. In 1960, Olive and Stoianovitch described a new species of the genus *Acrasis*, *Acrasis rosea*, established stable culture of this species, and documented its life cycle in detail (Olive and Stoianovitch 1960). On the basis of studies of *A. rosea*, Olive (1975) formally separated class Acrasea from other sorocarpic amoebae. Since then, several species of the genera *Acrasis* and *Pocheina* have been described and studied in detail (Olive et al. 1983; Brown et al. 2010, 2012a).

Until recently, taxonomists studying heteroloboseans have focused primarily on the amoeba and cyst stages. However, there has been an increased emphasis on flagellates over the last couple of decades (e.g., Fenchel and Patterson 1986; Brugerolle and Simpson 2004; Park et al. 2007; Park and Simpson 2011; Pánek et al. 2012). This is in line with a greater scientific interest in heterotrophic flagellates in general and with the realization that Heterolobosea is closely related to certain flagellate groups, especially Euglenozoa (see below).

The establishment of Heterolobosea as a coherent group, and an accurate understanding of its diversity and phylogenetic placement, required the use of electron microscopy and molecular sequencing techniques. The taxon Heterolobosea was primarily based on ultrastructural similarities, such as the discoidal shape of the mitochondrial cristae, the absence of dictyosomes, and the rough endoplasmic reticulum elements that surround the mitochondria (Page and Blanton 1985). Later molecular phylogenetic analyses confirmed the monophyly of the grouping (Roger et al. 1996). Page and Blanton (1985) had primarily distinguished Heterolobosea from other lobose amoebae; however, it was soon suggested that they had a closer evolutionary connection to Euglenozoa on the basis of cristae structure, as well as similarities of mitosis (Patterson 1988). A specific relationship between Heterolobosea and Euglenozoa was subsequently confirmed by molecular phylogenetics and phylogenomic analyses (e.g., Baldauf et al. 2000; Rodríguez-Ezpeleta et al. 2007; Hampl et al. 2009). Molecular studies, primarily SSU rDNA phylogenies, have also helped to reveal the relationships between particular heterolobosean lineages and to place within Heterolobosea some taxa of previously uncertain affinity (*Pleurostomum*, *Stephanopogon*; Park et al. 2007; Yubuki and Leander 2008), or newly discovered protists with bizarre morphology, specifically the amoeboid flagellate *Creneis carolina* (Pánek et al. 2014b).

Conversely, ultrastructural studies and/or phylogenetic analyses also clearly showed that some traditional heterolobosean genera are paraphyletic or polyphyletic, e.g., some nominal species originally assigned to *Tetramitus* (Vahlkampfiidae) have been transferred to *Trimastix*, then *Paratrimastix*, which are genera of Preaxostyla (Brugerolle and Patterson 1997; Bernard et al. 2000; Zhang et al. 2015; see ▶ Preaxostyla), while others have ultimately been transferred to other genera in different families within Heterolobosea, such as *Percolomonas* (Percolomonadidae; Fenchel and Patterson 1986) and *Harpagon* (Psalteriomonadidae; Pánek et al. 2012). Many purely amoeboid species were originally assigned to a single genus, *Vahlkampfia*, but some of these are now classified in *Paravahlkampfia*, or *Neovahlkampfia* on the basis of molecular phylogenetic information (Brown and De Jonckheere 1999), or, in the case of *Vahlkampfia anaerobica* (Smirnov and Fenchel 1996), transferred to *Monopylocystis* (Psalteriomonadidae; Pánek et al. 2012). One special case is *Pharyngomonas salina*, which was first described by Entz (1904) as *Trichomastix salina*. Kirby (1932) transferred this species to the *Tetramitus*, then Larsen and Patterson (1990) transferred it to the genus *Percolomonas*, and, finally, Cavalier-Smith and Nikolaev (2008) accommodated it in a newly established genus, *Pharyngomonas*. Recent molecular phylogenetic studies also revealed that some presumed acrasids in fact belong to different eukaryotic supergroups; *Fonticula* is an opisthokont (Brown et al. 2009), *Copromyxa* belongs to Amoebozoa (Brown et al. 2011), and *Guttulinopsis* has now been placed in Rhizaria, along with the peculiar amoeba *Rosculus*, previously also considered to be a heterolobosean (Brown et al. 2012b; Bass et al. 2016).

Naegleria is the best known and most studied genus within Heterolobosea. In 1899, Schardinger discovered an amoeba that was able to transform into a flagellate and called it *Amoeba gruberi* (Schardinger 1899; Alexeieff 1912) then suggested a new genus name for this organism – *Naegleria*. Before 1970, *Naegleria gruberi* was studied mainly as a model organism for amoeba-to-flagellate transformation (e.g., Willmer 1956; Dingle and Fulton 1966; Fulton and Dingle 1967). The genus attracted much more attention when Rodney Carter described *Naegleria fowleri* as an agent causing primary amebic meningoencephalitis (PAM) in humans and mice (Carter 1970). Since then, another 45 nominal species of *Naegleria* have been described and isolated from different freshwater habitats from all over the world (see De Jonckheere 2002, 2014); currently, ~30% of all described heterolobosean species belong to the genus *Naegleria*. *Naegleria fowleri* is the only species known to cause classic PAM in humans, although *Naegleria australiensis* and *N. italica* produce disease in experimental animals (see De Jonckheere 2011). Visvesvara et al. (2009) proposed that some cases of nonfatal PAM in humans could be caused by *Paravahlkampfia francinae*, another heterolobosean species.

The nuclear and mitochondrial genomes of both *N. gruberi* and *N. fowleri* have recently been published (Fritz-Laylin et al. 2010; Herman et al. 2013; Zysset-Burri et al. 2014; GenBank AF288092). The metabolism of *N. gruberi* has been inferred *in silico* using the genome data and seems to be extremely versatile. Although

considered to be fully aerobic, some important anaerobic genes have been identified as well (Fritz-Laylin et al. 2010; Opperdoes et al. 2011). Potential pathogenicity factors in *N. fowleri* have also been noted (Herman et al. 2013; Zysset-Burri et al. 2014). Some transcriptomic data are available from several other species of Heterolobosea (*Percolomonas cosmopolitus*, *Pharyngomonas kirbyi*, *Psalteriomonas lanterna*, *Stachyamoeba* sp. ATCC 50324, *Sawyeria marylandensis*), and the mitochondrial genomes of *Acrasis kona* ATCC MYA3509 and *Stachyamoeba* sp. ATCC 50324 have also been studied (Barberà et al. 2010; De Graaf et al. 2009; Fu et al. 2014; Harding et al. 2016; Rodríguez-Ezpeleta et al. 2007; Valach et al. 2014; http://data.imicrobe.us/sample/view/2025; http://data.imicrobe.us/sample/view/2029).

Practical Importance

As noted above *Naegleria fowleri* causes a disease in humans (Carter 1970) that is usually known as primary amoebic meningoencephalitis, or naegleriasis (see Visvesvara et al. 2007). This is a rare, but extremely acute, fulminant, necrotizing, and hemorrhagic meningoencephalitis that leads to death in most cases (>95%). Amoebae invade the body via intact or disrupted nasal mucosa, migrate across the cribriform plate to the brain via the olfactory nerves, and incite meningoencephalitis with rapid cerebral edema, resulting in cerebellar herniation (see Visvesvara 2010; Siddiqui and Khan 2014). Initial symptoms start about 5 days after infection (range 1–7 days) and may include headache, fever, nausea, or vomiting. Later symptoms can include stiff neck, confusion, loss of balance, seizures, and hallucinations. The disease progresses rapidly following the onset of symptoms and usually causes death within about five days (http://www.cdc.gov/parasites/naegleria/general.html). Although *N. fowleri* has been isolated in all continents except Antarctica (De Jonckheere 2011, 2014), most of the ~250 confirmed cases have been reported in developed regions (Southern USA, Europe, Australia), which is likely due to underreporting in developing countries. *Naegleria fowleri* typically infects people when they swim in warm freshwater lakes, or hot springs, or when inadequately chlorinated swimming pool water or contaminated tap water enters their nose, e.g., due to religious and cultural practices such as use of unboiled tap water in nasal cleansing equipment (Bartrand et al. 2014; De Jonckheere 2014; Siddiqui and Khan 2014).

Two other species, *Naegleria italica* and *Naegleria australiensis*, are pathogenic for experimental animals, but no human infections are recorded (see De Jonckheere 2014). Visvesvara et al. (2009) isolated a distantly related heterolobosean, *Paravahlkampfia franciae*, from the cerebrospinal fluid of a patient with typical symptoms of naegleriasis. No other protists, viruses, or bacteria were detected. This amoeba destroyed mammalian cell cultures, but did not kill experimental animals after intranasal inoculation. Some other heterolobosean are occasionally reported in studies of amoebic infections associated with keratitis; however, pathogenicity has not been clearly demonstrated (Aitken et al. 1996; Alexandrakis et al. 1998; Dua et al. 1998; Ozkoc et al. 2008).

Habitats and Ecology

Feeding and Locomotion

Most heteroloboseans feed primarily on bacteria, though in practice, amoebae are likely to consume diverse prey. For example, *Naegleria fowleri* has the ability to engulf yeasts and even human cells (John et al. 1985; Visvesvara et al. 2007). Cannibalism has been reported in some species, including *Pseudovahlkampfia emersoni* (Sawyer 1980) and *Acrasis rosea* (Olive and Stoianovitch 1960). Acrasids may feed on yeasts and conidia of ascomycetes (Olive and Stoianovitch 1960; Olive et al. 1983). Members of the genus *Stephanopogon* feed primarily on surface-associated protists, including pennate diatoms, and a variety of small flagellates (e.g., *Rhynchomonas*, *Ancyromonas*), but will also eat yeast in culture as well as bacteria (Lipscomb and Corliss 1982; Patterson and Brugerolle 1988; Yubuki and Leander 2008; Lee et al. 2014).

Heterolobosean amoebae are raptorial feeders that move relatively rapidly when compared to amoebae of some other eukaryotic groups. They are probably firmly associated with substrates most of the time, rather than being unattached and free floating.

Flagellates usually feed, although in some amoeboflagellates, notably *Naegleria*, this form instead serves as a transient motile stage (see below). Trophic flagellates usually possess a conspicuous feeding groove, and synchronized flagellar beating creates a feeding current that carries suspended particles to it. Flagellates can capture prey when swimming or can temporarily adhere to the substrate. *Harpagon descissus*, for example, attaches to surfaces by the posterior end of the cell (Pánek et al. 2012), while in *Percolomonas cosmopolitus* one of the four flagella is much longer than the cell and anchors to the substrate (Fenchel and Patterson 1986). The two anterior flagella of *Pharyngomonas kirbyi* often mediate attachment, while the two posterior flagella generate the feeding current (Park and Simpson 2011). *Percolomonas cosmopolitus* ingests food particles at the posterior end of the groove (Fenchel and Patterson 1986), while *Pharyngomonas* possesses a cytopharynx that opens into the groove's anterior portion (Kirby 1932; Park and Simpson 2011). Several genera (e.g., *Tetramitus*, *Heteramoeba*, *Pleurostomum*, and *Tulamoeba)* have retained just a short groove-like region in the anterior of the cell, or lack a feeding groove altogether, but feed using a long tubular cytostome (Droop 1962; Darbyshire et al. 1976; Kirby et al. 2015; Park et al. 2007). Some heterolobosean flagellates swim relatively rapidly, especially those with many flagella (*Creneis carolina*; *Psalteriomonas lanterna*).

Stephanopogon species differ from other heterolobosean flagellates in their basic feeding and locomotion. Although capable of swimming, they usually crawl rapidly along surfaces using their many ventral flagella. They use a well-defined anterior feeding apparatus to feed raptorially on surface-associated microbes (Yubuki and Leander 2008; Lee et al. 2014).

Acrasid amoebae have the ability to aggregate to make sorocarps, with chains of spores or a globular spore mass perched atop a stalk composed of cells

(Brown et al. 2012a). It is not known how often acrasids form sorocarps in the natural environment. Sorocarps presumably develop in response to the exhaustion of food or some other environmental cue and provide a means of dispersal by air or animals. Starvation may be induced on a Petri dish, which is where the most reliable observations of acrasids have actually been made (Olive 1975). It seems likely from such observations that sorocarps form in the morning, perhaps after a period of amoebal growth in the morning dew. Individual amoebae of acrasids are also able to form cysts, termed "microcysts," that are similar to the cysts of other heterolobosean. Microcyst formation, rather than sorocarp development, may predominate when moisture is insufficient to allow continued growth.

Habitats

Most heterolobosean species and genera have been reported from freshwater habitats or soils (~86 described species, 17 genera). However, many heterolobosean live in marine or brackish sediments (~30 species, 15 genera). Marine/freshwater transitions have been relatively common at the suprageneric level, but are rarely apparent within a single genus – in most possible exceptions, sequence data are not available, and the current generic assignments may be spurious (*Stachyamoeba lipophora*, *Percolomonas sulcatus*, *Vahlkampfia dumnonica*). One clear exception is *Harpagon salinus*, which actually branches as sister to two other *Harpagon* spp. living in freshwater habitats (Pánek et al. 2014a). Studies of anaerobic heterolobosean (Psalteriomonadidae) have shown that there are no marine/freshwater transitions reported within individual species, while at least two such transitions took place over the evolutionary history of the family Psalteriomonadidae (Pánek et al. 2012, 2014a).

Acrasids live in terrestrial environments. *Acrasis* spp. have been cultured from a variety of dead plant parts (seeds, pods, berries, inflorescences) and occasionally from the bark of living trees (see Brown et al. 2012a). *Acrasis granulata* was isolated from a beer yeast culture (van Tieghem 1880).

Heterolobosea make up a large proportion of the heterotrophic protist species recorded from extremely hypersaline habitats, including (near-) saturated brines (see Hauer and Rogerson 2005; Park et al. 2009). At least three heterolobosean lineages (*Pharyngomonas*, Tulamoebidae, and *Euplaesiobystra*) appear to be largely or entirely composed of halophiles (Park et al. 2009; Park and Simpson 2011, 2015). Strains of *Pharyngomonas salina*, *Pharyngomonas kirbyi*, *Pleurostomum flabellatum*, *Tulamoeba peranophora*, *Tulamoeba bucina*, and *Euplaesiobystra hypersalinica* have been shown experimentally to grow in media of at least 20% salinity (Park et al. 2007, 2009; Harding et al. 2013; Park and Simpson 2011; Kirby et al. 2015).

At least two groups, Psalteriomonadidae and Creneidae, adapted to life in anoxic and microoxic habitats. Psalteriomonadidae is quite a common group in anoxic sediments, both marine and freshwater; 16 species have been described (Pánek et al. 2012, 2014a; Murase et al. 2014). The taxon Creneidae currently contains a

single species, the recently described *Creneis carolina* (Pánek et al. 2014b). The mitochondrial derivatives of these anaerobic Heterolobosea do not possess cristae, and they function as hydrogenosomes in three studied psalteriomonads (Broers et al. 1993; De Graaf et al. 2009; Barberà et al. 2010).

Naegleria sp. and *Paravahlkampfia* sp. have been detected in habitats with pH <3 using environmental PCR approaches (Sheehan et al. 2003; Amaral Zettler et al. 2002), while *Tetramitus thermacidophilus* was actually isolated from an acidic hot spring. This species grows at pH from 1.2 to 6.0, with an optimal pH of 3.0 (Baumgartner et al. 2009). Recently, Reeder et al. (2015) showed that *T. thermoacidophilus* can be a dominant bacterivore in this type of environment.

Several heteroloboseans, including the three pathogenic *Naegleria* species (see above), survive and divide in temperatures around 40–45 °C (De Jonckheere 2014). *Marinamoeba thermophila*, *Fumarolamoeba ceborucoi*, *Euplaesiobystra hypersalinica*, and the undescribed species "BB2" have been shown to grow at 50 °C (De Jonckheere et al. 2009, 2011b; Park et al. 2009; Harding et al. 2013), while *T. thermacidophilus* and *Oramoeba fumarolia* will grow at temperatures up to 54 °C (Baumgartner et al. 2009; De Jonckheere et al. 2011a). There are also a few reports on psychrophilic species adapted to cold environments. The growth optimum of *Vahlkampfia signyensis* is 10 °C, and the cells die when the temperature exceeds 20 °C (Garstecki et al. 2005). *Tetramitus vestfoldii* was isolated from the microbial mat of a brackish Antarctic lake and grows at 5 °C (Murtagh et al. 2002).

Some heteroloboseans have been found in animal intestinal tracts or associated with microbial infections, including *Allovahlkampfia* sp. (Ozkoc et al. 2008), *Naegleria* spp. (De Jonckheere 2014; Dyková et al. 2006), *Paravahlkampfia* spp. (Schuster et al. 2003; Visvesvara et al. 2009), *Percolomonas sulcatus* (Brugerolle and Simpson 2004), *Pseudovahlkampfia emersoni* (Sawyer 1980), and *Tetramitus ovis* (De Jonckheere and Brown 2005a). So far, parasitologists have paid almost no attention to endobiotic heteroloboseans other than *Naegleria*. Recently, a new species, *Neovahlkampfia nana*, was isolated from degraded gill tissue from rainbow trout (Tyml et al. 2016), but it is unclear whether this organism is a true ecto- or endobiont.

Characterization and Recognition

General Characteristics

Amoebae

Almost all heterolobosean amoebae are cylindrical and more-or-less monopodial (i.e., limax), and usually move relatively rapidly via broad hyaline bulges (Fig. 3a–g, j). The sudden "eruptive" formation of these hyaline bulges distinguishes them from most lobopodial limax amoebae from the taxon Amoebozoa. They are able to feed by phagocytosis using their pseudopodia. Some *Naegleria* spp., including *N. fowleri*, are known to produce sucker-like "amebostomes" as special structures

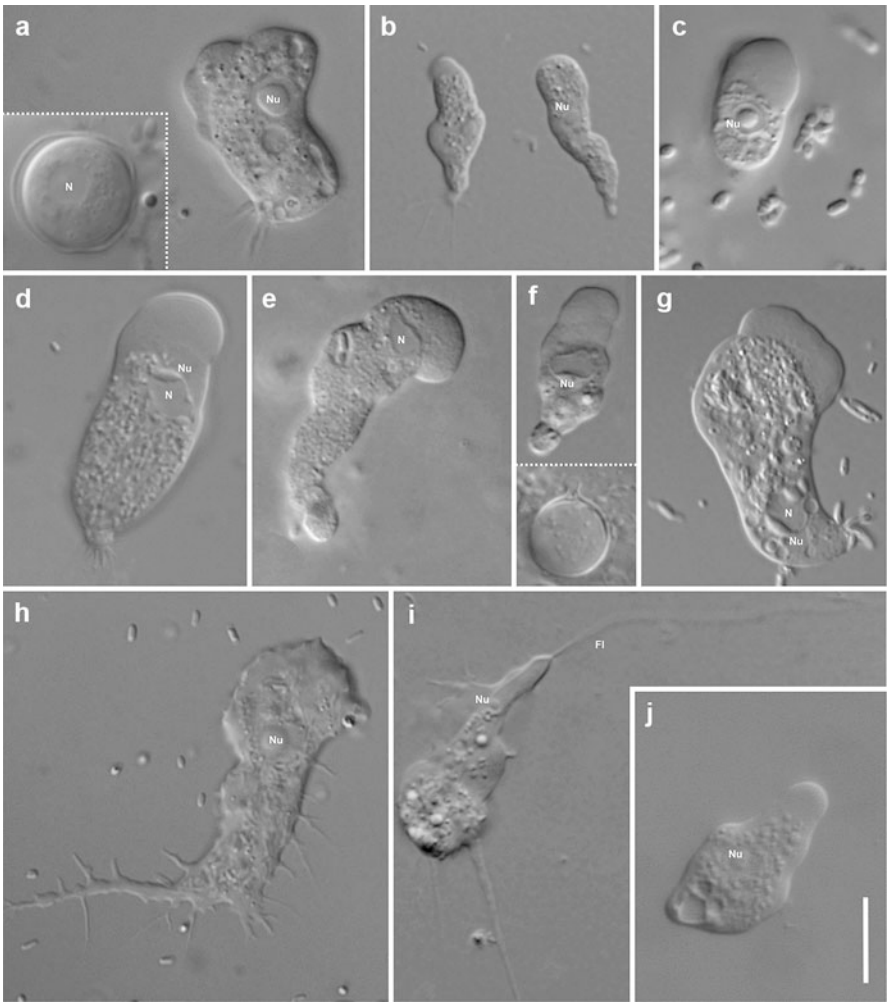

Fig. 3 Light micrographs of living heteroloboseans in amoeba and cyst stages. All micrographs are differential interference contrast: (**a**) *Tetramitus* sp. cyst and amoeba stage; amoeba with clearly visible central nucleolus and long filiform pseudopodia in the cell's posterior. (**b**) *Neovahlkampfia damariscottae* strain CCAP 1588/7. (**c**) *Naegleria* sp. strain H1N; amoeba with central nucleolus. (**d**) *Selenaion koniopes*; amoeba with parietal nucleoli. (**e**) *Pseudoharpagon longus* strain EVROS1; border between hyaloplasm and granuloplasm is less apparent than in other heterolobosean amoebae. (**f**) *Monopylocystis* spp. cyst and amoeba stage; amoeba of *M. elegans* strain EVROS1M with parietal nucleoli and cyst of *M. visvesvarai* strain TSUKIMV with single conspicuous pore with a plug. (**g**) *Psalteriomonas lanterna* strain BUKITLA; amoeba with parietal nucleoli. (**h**) *Pharyngomonas turkanaensis* strain LO; amoeba stage. (**i**) *Creneis carolina* strain PC4AM; amoeboid cell with single flagellum. (**j**) *Acrasis kona*. *Abbreviations: N* nucleus, *Nu* nucleolus. Scale bar represents 10 μm (**a** image by Yana Eglit; **c** by Petr Táborský; **f** (cyst) by Ivan Čepička; **h** by Tommy Harding)

for phagocytosis (John et al. 1984). Amebostomes vary in size depending on prey (John et al. 1985; Visvesvara et al. 2007).

Amoebae of the deep-branching taxon *Pharyngomonas* differ from typical heterolobosean amoebae because they are flattened, with an undulate or crenulated anterior edge. Some of them trail long filiform pseudopodia from the posterior end, and they generally move slowly (Fig. 3h). More typical eruptive pseudopodial formation has been observed in some *Pharyngomonas* strains, however, particularly under conditions of stress (Harding et al. 2013; Plotnikov et al. 2015). *Stachyamoeba lipophora* is also able to form two distinct morphotypes of amoebae. One is a typical limax form with eruptive lobopodia, while the other is rather flattened, with spine-shaped pseudopodia produced from an anterior hyaline zone (Page 1975, 1987). The amoeboid stage of *Creneis carolina* produces an extremely flattened, hyaloplasmic pseudopodium at the anterior end; no eruptive bulges have been observed (Fig. 3i). In addition, *C. carolina* is the only known heterolobosean that maintains flagella in the amoeboid stage (Pánek et al. 2014b).

Flagellates

Heterolobosean flagellates typically possess either two flagella (e.g., *Heteramoeba*, *Euplaesiobystra*, *Pleurostomum*, most *Naegleria* spp.) or four flagella (e.g., *Pharyngomonas*, *Percolomonas*, *Harpagon*, *Pseudoharpagon*, most *Tetramitus* spp.). These usually arise apically or subapically at the anterior end of the feeding apparatus, where present (Fig. 4a–d). Only a few heterolobosean species have a different number of flagella in a single mastigont. *Creneis carolina* possesses just a single flagellum in its amoeboid stage, but more than ten flagella in a distinct multiflagellate stage (Figs. 3i and 4h). *Tetramitus jugosus* and *Oramoeba fumarolia* flagellates possess two flagella, but cells with more flagella (up to ten in *O. fumarolia*) were also reported in these species (Darbyshire et al. 1976; De Jonckheere et al. 2011a). Most flagellates of *Pseudoharpagon longus* possess five flagella, while 20% of cells have more than five flagella (typically ten in two clusters, see Fig. 4e). *Psalteriomonas lanterna* has four nuclei and four mastigonts, each with four flagella, and four feeding grooves (Broers et al. 1990; Fig. 4f, i). *Trimastigamoeba philippiensis* is unusual because its four flagella arise from the bottom of a gullet-like tube (Bovee 1959).

The feeding groove arises subapically in most heteroloboseans (e.g., *Percolomonas*, *Harpagon*, *Pseudoharpagon*, *Psalteriomonas*, *Pharyngomonas*). *Tetramitus* and *Heteramoeba* instead possess a groove-like region that opens anteriorly, while *Pleurostomum* and *Tulamoeba* have a long tubular cytostome only. Most *Naegleria* spp. have no groove-like structure remaining.

Representatives of the genus *Stephanopogon* have little in common with other heterolobosean flagellates in terms of general morphology. *Stephanopogon* cells are vase shaped with a flattened "neck" region and dorsoventrally flattened (Fig. 4g). The ventral side of the cell bears numerous flagella (several dozen to more than 100),

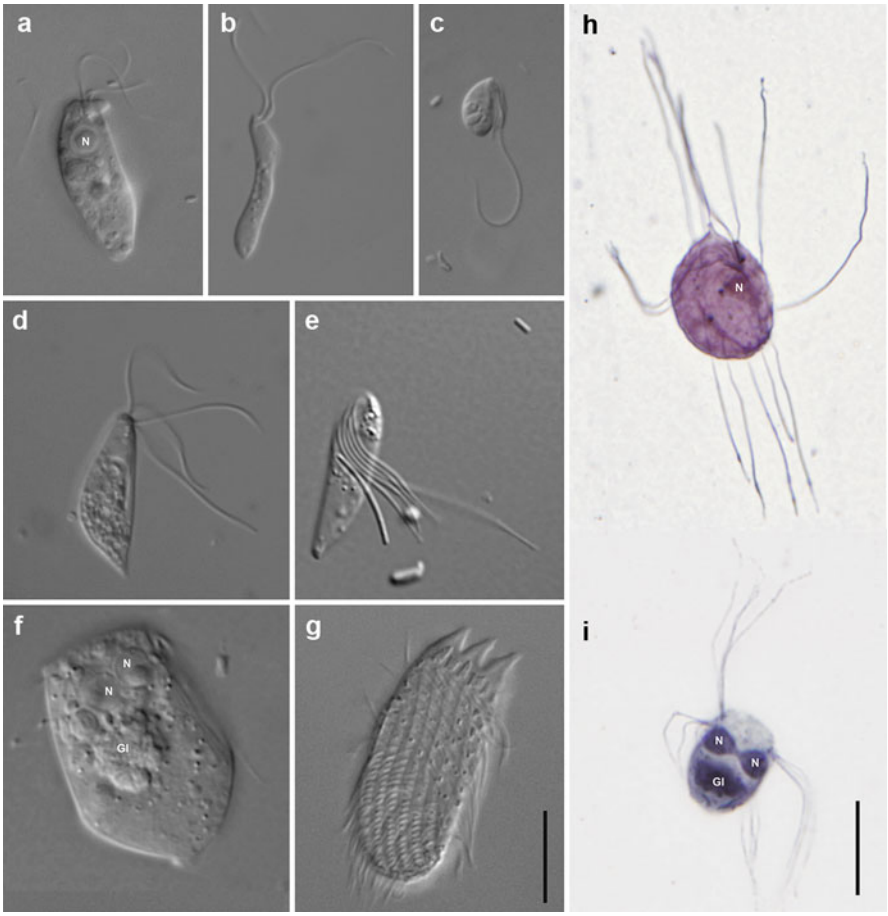

Fig. 4 Light micrographs of heteroloboseans in the flagellate stage. (**a**–**g**) Differential interference contrast images of live cells, (**h**–**i**) protargol-stained cells: (**a**) *Tetramitus* sp. (**b**) *Tulamoeba peronaphora*. (**c**) *Percolomonas cosmopolitus*. (**d**) *Pharyngomonas kirbyi*. (**e**) *Pseudoharpagon longus* strain EVROS1. (**f**) *Psalteriomonas lanterna* strain BUKITLA; (**g**) *Stephanopogon pattersoni*. (**h**) *Creneis carolina* strain PC4AM; multiflagellate. (**i**) *Psalteriomonas lanterna* strain KORTUN. *Abbreviations*: *Gl* globule of aggregated hydrogenosomes, *N* nucleus, *Nu* nucleolus. Scale bars represent 10 μm (**a** image by Yana Eglit; **d** by Jong Soo Park; **g** by Won Je Lee)

while just a few flagella arise from the dorsal side, mainly near the base of the "neck" (Yubuki and Leander 2008). The cytostome is slit shaped, with a bulging dorsal lip, and is accompanied by large ventral "barbs" in most species (Yubuki and Leander 2008; Patterson and Brugerolle 1988; Lipscomb and Corliss 1982; Lee et al. 2014; see Fig. 4g).

Cysts

Cyst stages are spherical or subspherical and usually have distinct outer and inner layers (i.e., an ectocyst and endocyst, see Fig. 3a, f). Some heterolobosean cysts have no pores and presumably excyst by wall rupture (e.g., *Paravahlkampfia* spp., some *Tetramitus* spp.); others have one or more pores that penetrate either both layers (e.g., *Naegleria*, *Pernina*) or just the endocyst (*Euplaesiobystra hypersalinica*). Mature cysts of *Selenaion koniopes* are covered by numerous granules about 100 nm across, which are visible by electron microscopy (Park et al. 2012).

Acrasids form two types of cysts – individual microcysts and spore cells of the fruiting bodies (Fig. 5a, b). Spores are distinguished by the presence of "hilae," disc-shaped structures that connect adjacent spore cells in the sorocarp (see below). Hilae are absent in microcysts, which are rounded.

Acrasid Sorocarps

Members of the Acrasidae may develop a simple multicellular fruiting body (sorocarp, Fig. 5c–e). The cells in the mature sorocarp are differentiated into two types: basal stalk cells and distal spore cells. They do not undergo programmed cell death, however, and stalk cells retain viability. The complexity of the sorocarp varies among species, from elaborate arborescent sorocarps to simple uniseriate chains of spores, to globose sori. The sorocarp structure can be used to identify the species within the group (Brown et al. 2010, 2012a).

Life Cycle

Typical Amoeboflagellates

The classic heterolobosean life cycle consists of three distinct forms: amoeba, flagellate, and cyst (Fig. 1). The amoeba stage plays a central role since it is able to encyst and transform (reversibly) to the flagellate form. The flagellate may be purely a dispersal stage, incapable of feeding. However, flagellates of many amoeboflagellates are capable of feeding and division, and a clone can often exist as flagellates for numerous generations (e.g., *Tetramitus*, *Heteramoeba*, *Monopylocystis*, *Pseudoharpagon*, *Pharyngomonas* – Bunting and Wenrich 1929; Droop 1962; Harding et al. 2013; Pánek et al. 2012; Plotnikov et al. 2015). This three-phase life cycle, with the central role of the amoeba stage, is probably ancestral for Heterolobosea since it has been reported from both major clades, Pharyngomonada and Tetramitia (Harding et al. 2013).

The life cycle of *Naegleria gruberi* has been studied in detail. The main active stage is the amoeba, which has no flagella and no basal bodies or cytoplasmic microtubules (Fulton and Dingle 1971). It is capable of both feeding and division. Under stress conditions (e.g., changes in temperature or osmolarity, or starvation), the amoebae rapidly transform into cysts, or flagellates. The highly resistant cysts are

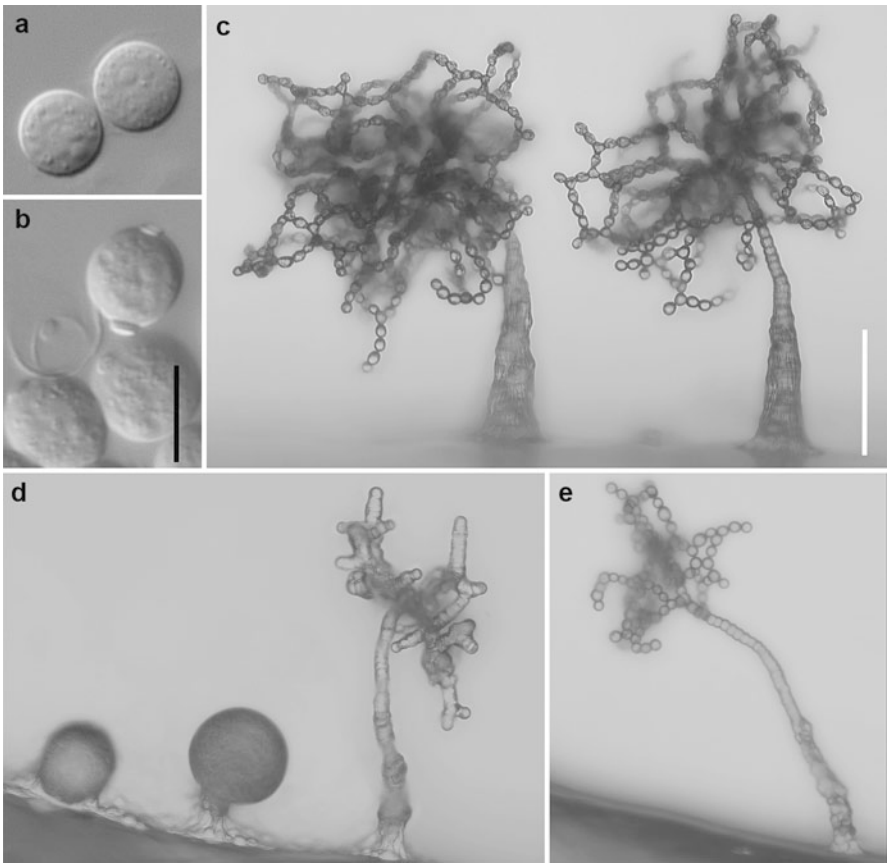

Fig. 5 Light micrographs of *Acrasis kona* in different life stages. (**a**, **b**) Differential interference contrast, (**c**–**e**) bright-field micrographs. (**a**) Round cysts. (**b**) Spores with prominent hilae. (**c**) Sorocarps with a thick-based stalk that is tapered to a uniseriate row of stalk cells; highly complex branching of the sorocarp. (**d**) Developing sorocarps in various stages. From *left* to *right*: early sorogen before stalk formation, sorogen atop a developed short stalk, and a sorocarp about to sporulate. (**e**) Mature sorocarp. Scale bars represent 10 μm (**a**, **b**) 100 μm (**c**–**e**), respectively

double walled, with three or more plugged pores. Excystation is achieved by dissolving the plugs. The cells excyst in the amoeba form.

The flagellate of *N. gruberi* is a temporary stage that persists only for a few hours and has no ability to divide or feed; it instead plays a role in dispersal (Preston and King 2003). During amoeba-to-flagellate transformation, the entire microtubular cytoskeleton of the flagellate is formed *de novo*. Fulton and Dingle (1971) examined 250 sections through a number of *N. gruberi* cells during various phases of this transformation, and only observed basal bodies in cells fixed 55 min or more after initialization. Similarly, fluorescence microscopy examinations by Walsh (2007) identified the first putative basal bodies 50–55 min after the onset of transformation,

although some other microtubules were detected earlier. Recently, Fritz-Laylin et al. (2016) showed that basal body assembly is actually a two-step process. The first basal body is assembled *de novo* within 40 min from the initiation of differentiation. The second basal body is then assembled adjacent to the elongating first basal body ("mentored" or "templated" assembly) over the next 10 min. Some authors argue for the existence of a transient duplicating complex that provides a site for the *de novo* assembly of the next generation of basal bodies (Lee et al. 2015). Transformation also involves the formation of the microtubular roots and non-microtubular elements of the flagellar apparatus, such as the rhizoplast (see below). The whole transformation process takes ~120 min.

Flagellates in nutrient-rich medium revert to amoebae by kinetid dedifferentiation; they lose their fixed shape and resorb their flagellar apparatus completely (Fulton 1977, 1983). In some other *Naegleria* spp. (*N. minor* and *N. robinsoni*), the juvenile flagellates possess four flagella and divide once to form biflagellate cells (De Jonckheere 2002).

Acrasids

The life cycle of acrasids includes the distinctive process of aggregative sorocarp formation (sorogenesis). The limax-type amoebae resemble other heterolobosean amoebae; they live solitarily, feed, multiply, and can encyst. During sorogenesis, they begin to aggregate and form a simple multicellular stage; the signalling mechanism is unknown. During this process, cells retain their individuality (i.e., no plasmogamy occurs), although they are covered by a common extracellular slime sheath. Aggregated amoebae form a "sorogen" – a mass of undifferentiated amoeboid cells that are in process of fruiting. Eventually, sorogens begin to rise from the substratum as amoeboid cells, then encyst to form the cuboidal cells of the stalk. Generally, acrasid sorogenesis follows one of two patterns – acrasoid and pocheinoid (Brown et al. 2012a). In acrasoid sorogenesis (Fig. 2), the sorogen usually begins to invaginate and lobe to form finger-like projections (though lobing does not occur in small sorogens; the sorogen simply elongates). These projections elongate and branch as the amoeboid cells maneuver themselves into a single line while still remaining within the slime sheath. Once the cells forming these branches are in single rows, they round up and form walls to become spores. The acrasoid fruiting structure ranges from a single chain of spores supported by a uniseriate stalk (a single row of stalk cells) to a large sorus of branching chains of spores perched on a stalk composed of several rows of stalk cells. In the pocheinoid type of sorogenesis, the spore mass instead remains globose; the sorocarp develops directly into this rounded mass of spores without forming chains or branches.

The thin slime sheath is often missing from around the spore chains, but generally remains over the stalk cells. Most isolates will not form sorocarps in either constant light or darkness; they require instead a dark period with a strain-specific minimal length of about 8 h (Reinhardt 1968).

The acrasid *Pocheina flagellata* also forms flagellates, but only upon germination of the stalk cells and spores and then only if the germinating cell has first undergone

mitosis. If the cell fails to divide, germination yields a single amoeboid cell (Olive et al. 1983). The flagellate cells become amoebae within 24 h. Amoebae are not known to convert directly to flagellates, but given the paucity of data, this transformation cannot be discounted. Flagellates have two flagella that appear to be apical, but their exact point of insertion and orientation during swimming has been difficult to observe. The elongated flagellates bear pellicular surface striations and a longitudinal groove (Olive et al. 1983).

Exceptions to the Typical Life Cycles

Differences in the presence of certain stages in the life cycle have been reported for different species within a single genus and even for different strains of a single species. For example, although most *Naegleria* and many *Tetramitus* species are known to produce flagellates, attempts to induce amoeba-to-flagellate transformation *in vitro* have been unsuccessful for others (e.g., Darbyshire et al. 1976; De Jonckheere et al. 2001; De Jonckheere 2007). Strains of particular species known to produce flagellates (*Psalteriomonas lanterna*, *Heteramoeba clara*, *Willaertia magna*, some *Tetramitus* spp.) or cysts (*Percolomonas cosmopolitus*) were observed to lose these abilities after prolonged cultivation (Broers et al. 1990; Droop 1962; Fenchel and Patterson 1986; Page 1988). In addition, the abundance of transformed flagellates depends on the type of bacterial prey (shown in *Oramoeba fumarolia*; De Jonckheere et al. 2011a). Recently, it has been found that members of some genera previously considered to be purely amoebae or flagellates are, in fact, able to form all three life stages, e.g., *Pharyngomonas* (Harding et al. 2013), *Pseudoharpagon* (Pánek et al. 2014a), *Tulamoeba* (Kirby et al. 2015), and *Monopylocystis* (Pánek et al. 2014a). Based on these results, one could speculate that most Heterolobosea currently known as strict flagellates are capable of forming amoebae under certain conditions. However, the closely related genera *Percolomonas* and *Stephanopogon* probably truly lost the amoeba stage, at least as a central stage in the life cycle; interestingly, members of both genera are able to encyst from the flagellate stage, which is atypical among Heterolobosea (Fenchel and Patterson 1986; Lwoff 1936; Raikov 1969).

The life cycle of *Stephanopogon* is very unusual since the number of nuclei within a flagellate cell increases during its life and only "mature" cells with several to many nuclei will encyst. Before germination from the cyst, the cell undergoes cytokinesis, which results in the formation of several daughter cells, each possessing a single nucleus that is subsequently duplicated prior to excystation (Lwoff 1936; Raikov 1969). The life cycle of *Creneis carolina* is even more atypical (Pánek et al. 2014b). It includes an amoeboid flagellate stage with 1–2 long anterior flagella and a flagellate with more than 10 flagella. The amoeboid flagellate is the main trophic stage in culture. The multiflagellate stage possesses two anterior flagella (which are probably homologous to the flagella of the amoeboid cell) and multiple lateral ones. No true cysts or aflagellated amoebae have been observed. This means that *Creneis carolina* apparently has multiple distinct life history stages, but none of them resembles those of typical heteroloboseans.

Nuclei, Mitosis, and Sex

Most heteroloboseans possess one nucleus, with a central or subcentral nucleolus (e.g., Balamuth et al. 1983; Page 1984; Park and Simpson 2011; Park et al. 2009; Schuster 1975; Tyml et al. 2016). By contrast, peripheral nucleolar material or parietal nucleoli are seen in *Selenaion*, *Heteramoeba*, *Stachyamoeba lipophora*, and Psalteriomonadidae, as shown by both light and electron microscopy (Carey and Page 1985; Droop 1962; Pánek et al. 2012, 2014a; Page 1975; Park et al. 2012; see Fig. 3d, f, g). In addition, a few multinucleate species have been described (*Fumarolamoeba ceborucoi*, *Gruberella flavescens*, *Pseudovahlkampfia emersoni*, *Psalteriomonas lanterna*, *Stephanopogon* spp.; Broers et al. 1990; De Jonckheere et al. 2011b; Lee et al. 2014; Page 1984; Sawyer 1980).

All examined heterolobosean species have closed intranuclear orthomitosis, in which the nuclear membrane remains intact until separation of the daughter nuclei and the intranuclear mitotic spindle displays axial symmetry (see Page and Blanton 1985). On the other hand, the fate of the nucleolus during mitosis differs among lineages. The nucleolus disintegrates during mitosis in *Acrasis rosea*, *Gruberella flavescens*, *Stachyamoeba lipophora*, and probably also *Pocheina flagellata* (Olive et al. 1983; Page 1978). The nucleolus persists through mitosis in other studied heteroloboseans (including *Naegleria*, *Tetramitus*, *Pernina*, and *Pocheina rosea*) and divides into two polar masses (Balamuth et al. 1983; El Kadiri et al. 1992; Olive et al. 1983; Schuster 1975). The nucleolus of *Naegleria gruberi* contains 3,000–5,000 copies of a 14 kbp circular plasmid that carries the 18S, 28S, and 5.8S rRNA genes (Clark and Cross 1987; Maruyama and Nozaki 2007). Because the nuclear chromosomes do not contain copies of these genes, it is essential that each daughter nucleus obtains a suitable portion of these plasmids during nucleolar division. The fate of the nucleolus and the structure and formation of mitotic spindle during mitosis have been studied in detail in *Naegleria pringsheimi* by confocal microscopy (Walsh 2012). This study suggests that specific nucleolar binding sites for microtubules allow mitotic spindle formation and attachment, and that spindle elongation drives nucleolar division.

The question of the sexuality of Heterolobosea has not been fully resolved yet. An isoenzyme study encompassing several dozen strains of *Naegleria lovaniensis* uncovered strong evidence of genetic recombination (Pernin et al. 1992). The presence of meiosis-associated genes in the genome of *Naegleria gruberi* was documented by Fritz-Laylin et al. (2010). Later, two key genes encoding proteins involved in gamete- and nucleus fusion (HAP2 and GEX1) were also identified in this genome (Speijer et al. 2015). A few studies have described cell fusion between heterolobosean flagellates and amoebae. Bunting (1926) documented adherence and fusion of *Tetramitus rostratus* flagellates by light microscopy, but did not report nucleus fusion. Frequently, a pair of fusing *Tetramitus* flagellates consisted of one very small and one normal-sized individual. Similarly, amoebae of *Acrasis rosea* were seen to produce anastomoses, or to fuse (Olive et al. 1961; Olive 1963). Droop (1962) studied sexual processes in the amoeboflagellate *Heteramoeba clara*. He performed crossing experiments with clonal cultures of flagellates that

all derived from a culture established from a single amoeba cell. He established six cultures that only produced flagellates (no amoebae observed over 4 months). These cultures were crossed with each other, and amoebae reappeared in certain combinations of cultures. This pattern was consistent with the existence of two mating types, with amoebae being produced only in crosses of flagellates of opposite mating types.

Ultrastructure

The Golgi apparatus does not show a classic stacked dictyosomal form. There are multiple mitochondria, which (in aerobic forms) have flattened cristae that are generally reported as discoidal and in some cases clearly take the form of rigid, pedicellate discs (Fig. 6a; Page and Blanton 1985; Fenchel and Patterson 1986; Lee et al. 2014). Anaerobic forms have mitochondrion-related organelles that lack cristae, although single crista-like structures have been reported in *Pseudoharpagon pertyi* (Fig. 7a; Pánek et al. 2014a). Many heteroloboseans show a close association of mitochondria and endoplasmic reticulum (Fig. 6b), and this was originally considered characteristic of Heterolobosea (Page and Blanton 1985). This arrangement is not seen in a number of unrelated species and genera, however (e.g., *Pharyngomonas* spp., *Stephanopogon* spp., *Percolomonas cosmopolitus*, and *Pleurostomum flabellatum;* Fenchel and Patterson 1986; Patterson and Brugerolle 1988; Park et al. 2007; Park and Simpson 2011; Lee et al. 2014; see Fig. 6b). Putative peroxisomes with a single membrane and a paracrystalline inclusion have been reported from *Pharyngomonas kirbyi* (Park and Simpson 2011) and *Selenaion koniopes* (Park et al. 2012). Various electron-dense organelles bounded by a single membrane have been observed, for example, the "black bodies" of *Naegleria* spp. and *Selenaion koniopes*, which are of unclear function (Stevens et al. 1978; Park et al. 2012), and the "dense bodies" of *Pseudoharpagon pertyi* (Pánek et al. 2014a).

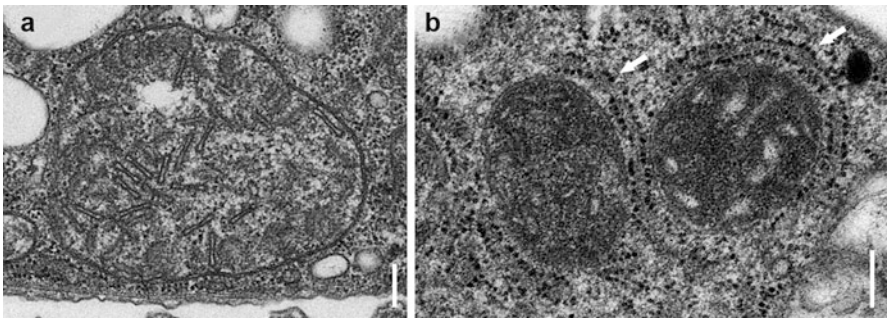

Fig. 6 Electron micrographs of mitochondria of heteroloboseans. (**a**) *Stephanopogon pattersoni* (Stephanopogonidae), showing rigidly discoidal cristae, but an absence of endoplasmic reticulum envelopment of the mitochondria. (**b**) *Selenaion koniopes* (*incertae sedis*; clade VII), showing rough endoplasmic reticulum envelopment of the mitochondria (*arrows*), but note the less defined form of the cristae. Scale bars represent 200 nm (**a** image by Won Je Lee; **b** by Jong Soo Park)

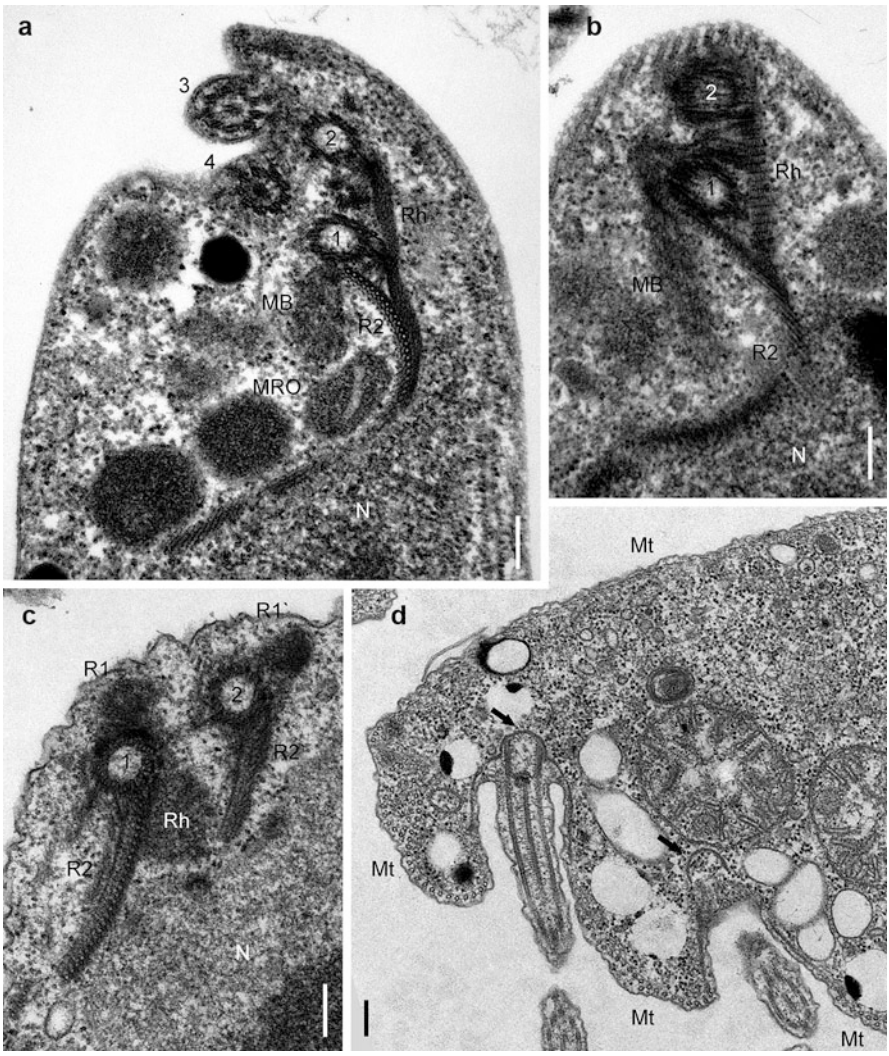

Fig. 7 Electron micrographs of the flagellar apparatus of heterolobosean. (**a**) *Pseudoharpagon pertyi* (Psalteriomonadidae) showing the R2 microtubular root supported by the rhizoplast (Rh) on one face, and the I fiber (not labelled) on the other. Note the mitochondrion-related organelles (MRO) of this anaerobe. (**b**) *Pseudoharpagon pertyi*, showing substructure of the rhizoplast and position of the microfibrillar bundle (MB). (**c**) *Pharyngomonas kirbyi* (Pharyngomonada) showing a well-developed instance of "doubled flagellar apparatus" organization, with similar microtubular root systems associated with basal body 1 (R1, R2) and basal body 2 (R1′, R2′). Note the well-developed R1 (and R1′) and diffuse rhizoplast homolog (Rh), which are particular to Pharyngomonada among Heterolobosea. The R1 and R1′ roots are sectioned obliquely here and individual microtubules are not visible. (**d**) *Stephanopogon pattersoni* (Stephanopogonidae), showing sections through two rows of flagella, with *arrows* indicating the dense material that underlies each individual basal body. Note the abundant microtubules (Mt) supporting the cell membrane, especially between the flagellar rows. *Abbreviations: 1* Basal body 1; *2* Basal body 2; *3* Basal body 3; *4* Basal body 4; *MB* Microfibrillar bundle, *MRO* Mitochondrion-related organelles, *Mt* microtubules, *N* nucleus, *R1* Root 1; *R1′* Root 1′; *R2* Root 2, *R2′* Root 2′, *Rh* Rhizoplast. Scale bars represent 200 nm (**c** image by Jong Soo Park)

Endoplasmic reticulum vesicles containing aggregations of dense material were reported in *Naegleria* spp. and *Selenaion koniopes* cells. These structures probably contain cyst wall material that is secreted from the cell during encystation (Chávez-Munguía et al. 2009; Park et al. 2012). The cytoplasm of many species contains rounded lipid droplets.

Most heteroloboseans have either two or four near-parallel basal bodies lying close together in a single mastigont (Fig. 7a–c). Heterolobosean flagellates have a peculiar "doubled" flagellar apparatus; in cells with two basal bodies, each is associated with a broadly similar set of microtubular and non-microtubular elements (Brugerolle and Simpson 2004; Park et al. 2007). In cells with four basal bodies, these form two parallel pairs, with each pair then supporting a similar set of associated cytoskeletal elements (Fig. 7c; Brugerolle and Simpson 2004; Park and Simpson 2011). In almost all cases, one of these two sets (the more posterior) is more extensive than the other; they are inferred to be developmentally linked (at least in forms with dividing flagellates) with the more anterior set transforming into the fully developed posterior set during the next round of cell division. This general organization was probably ancestral for Heterolobosea and is found today both in Pharyngomonada and many Tetramitia (except that the flagella within each pair are not parallel in *Pharyngomonas*; see below and Park and Simpson (2011)). The more developed unit of the flagellar apparatus usually includes just a single large flagellar microtubular root, now understood to represent "R2," which is associated with the posterior-most basal body (BB1, inferred to be the "eldest"; see Fig. 7a–c). The immature unit includes a (usually) reduced version of R2 (called R2` here), which is associated with basal body 2 (BB2; see Fig. 7c).

The R2 root is typically curved in cross section. It is supported on its concave face by a lattice-work "I" fiber and on the convex face by a rhizoplast system that takes the place of the "A" fiber seen in other excavates (Fig. 7a, c; Brugerolle and Simpson 2004). The rhizoplast is an elongated paracrystalline structure with regular striations (Fig. 7b). There is generally a single rhizoplast system that branches proximally to connect basal bodies BB1 and BB2, as seen in the biflagellated *Naegleria* or tetraflagellated *Harpagon* (Brugerolle and Simpson 2004); however, there can be two separate rhizoplasts, each for one pair of flagella and R2 (*Percolomonas sulcatus*; Brugerolle and Simpson 2004), or even a branching complex of rhizoplasts that extend in different directions through the cytoplasm, as reported in *Tetramitus rostratus* (Balamuth et al. 1983; Brugerolle and Simpson 2004). Purification and indirect immunofluorescence staining of the *Naegleria gruberi* rhizoplast suggested that it contains proteins homologous to UNC-119 proteins, which are best known for their expression in metazoan neural tissues, including photoreceptor cells (Chung et al. 2007). A microfibrillar bundle is "strung" across the concave face of the R2 in some taxa, notably psalteriomonads and *Percolomonas* (Fig. 7a, b; Broers et al. 1990; Fenchel and Patterson 1986; Brugerolle and Simpson 2004). The R2 root often splits into two portions to support the margins of the feeding groove, where present (Broers et al. 1990; Brugerolle and Simpson 2004; Park and Simpson 2011). The R2′ typically has an I fiber but is much shorter and typically does not split into

inner and outer portions (though *Percolomonas sulcatus* is an exception; Brugerolle and Simpson 2004).

Flagellates of the deep-branching taxon Pharyngomonada have some unusual features in their flagellar apparatus that may represent retentions of plesiomorphic features. The arrangement of basal bodies in a pair is orthogonal, not (near-) parallel as in other heteroloboseans. Pharyngomonads have retained a long R1 microtubular root with attached multilaminate C fiber originating from BB1, as seen in "typical excavates" such as the closely related jakobids (Park and Simpson 2011); because of the doubled flagellar apparatus, there is also an R1` with C fiber originating from BB2, which is actually somewhat larger than R1 (Fig. 7c). These R1 and R1′ elements join the left portion of R2 to support the left margin area of the feeding groove. Their rhizoplast homologue is not striated and not elongated (Fig. 7c). More uncertainly, the R2/I system of *Pharyngomonas* also possesses a spur-like element possibly homologous to the B fiber of other excavates (Park and Simpson 2011), although a similar structure is also seen in *Creneis* (Pánek et al. 2014b).

The cytoskeleton of *Stephanopogon* is very different from that of other heterolobosean flagellates (Fig. 7d). The ventral flagella are arranged in more-or-less longitudinal rows superficially similar to the kineties typical of ciliates. Each flagellum lies in a small depression that is supported by a ring of short, spaced microtubules. These originate from a cone-like complex of electron-dense material that surrounds the (very short) basal body. A sheetlike extension of the same or similar material passes underneath the basal body and extends to connect to the next basal body in the row (Patterson and Brugerolle 1988; Yubuki and Leander 2008; Lee et al. 2014). The few dorsal flagella are mostly arranged in pairs, though one of the flagella in a pair can be a stub (Yubuki and Leander 2008). The regions between the flagellar rows are supported by longitudinal ribbons of microtubules (Fig. 7d). The cytostome is lined by regularly spaced longitudinal microtubules. The cytoplasm surrounding the cytostome contains an array of rods, each made up of a block of cross-linked microtubules. Very large numbers of small electron-dense secretory vesicles (often referred to as extrusomes) are present in the cytostomes lips and between the longitudinal microtubules of the cytostome (Patterson and Brugerolle 1988; Yubuki and Leander 2008; Lee et al. 2014).

Hohl and Hamamoto (1968, 1969) described the ultrastructure of the sorogenic cells of *Acrasis rosea*. Numerous spherical-to-oblong granules, perhaps representing pigment granules, were present. Bundles of microfilaments in pseudopod-like extensions were found in the sorogenic cells. The nucleoli of sorogenic cells appeared to have three components: (i) dispersed, round masses of granular material; (ii) intensely staining homogeneous bodies found within the dispersed masses; and (iii) a large round mass of finely granular material. The dispersed mass contained parallel stacks of lamellar elements. This complex nucleolar structure has not been observed in either *Acrasis* trophic amoebae (Hohl and Hamamoto 1968) or those of other acrasids. Three-colored carotenoid pigments were detected in *A. rosea* (Fuller and Rakatansky 1966). One of these was identified as the xanthophyll torulene. The unidentified pigments were (i) a yellow-green carotenoid and (ii) an orange

carotenoid that had some characteristics of a xanthophyll, with the latter being the major pigment.

Taxonomy and Systematics

Page and Blanton (1985) proposed the taxon Heterolobosea to unite schizopyrenid amoebae/amoeboflagellates and acrasids, based on the presence of eruptive lobopodia, discoidal mitochondrial cristae, and the absence of stacked Golgi bodies. Fenchel and Patterson (1986) then included in Heterolobosea the newly described genus *Percolomonas*. *Percolomonas* initially housed flagellates with no known amoeba stage that had previously been assigned to the genus *Tetramitus* (whose type species is a well-known schizopyrenid amoeboflagellate). Most authors now use the name Heterolobosea for the entire clade containing all descendants of the last common ancestor of the genus *Naegleria* and *Pharyngomonas*, i.e., including both Pharyngomonadea and Tetramitia (e.g., Hampl et al. 2009; Park and Simpson 2011; Adl et al. 2012; Brown et al. 2012a; Pánek et al. 2012; Harding et al. 2013; Plotnikov et al. 2015). Contrarily, Cavalier-Smith and co-workers have used the name Percolozoa for the same clade (Cavalier-Smith 1993; Cavalier-Smith and Nikolaev 2008). They divide the phylum Percolozoa into four classes: Pharyngomonadea (*Pharyngomonas*), Percolatea (*Percolomonas*, *Stephanopogon*), Lyromonadea (*Psalteriomonadidae*), and Heterolobosea *sensu* Cavalier-Smith (1993). The latter three classes are united within the subphylum Tetramitia. In this chapter, we prefer the former "broad" concept of Heterolobosea (Heterolobosea *sensu lato*): Firstly, the restricted concept of Heterolobosea (i.e., *sensu* Cavalier-Smith 1993) refers explicitly to a paraphyletic group (Cavalier-Smith and Nikolaev 2008). Secondly, there is now good evidence that the common ancestor of all Heterolobosea *sensu lato* was an amoeboflagellate with the ability to form eruptive pseudopodia, which had discoidal mitochondrial cristae, but lacked discrete dictyosomes. This is mostly consistent with the original concept of Heterolobosea (see Page and Blanton 1985; Harding et al. 2013).

The internal classification of Heterolobosea has changed dramatically since 1985, with many new lineages having been described or transferred to the group. Cavalier-Smith and Nikolaev (2008) proposed the division of Heterolobosea *sensu lato* into two subphyla, Pharyngomonada and Tetramitia, and this is now widely accepted (e.g., Pánek and Čepička 2012). Pharyngomonada and Tetramitia both represent clades in SSU rDNA phylogenies (Cavalier-Smith and Nikolaev 2008; Harding et al. 2013). Synapomorphies of Tetramitia include a specific 17-1 helix in the secondary structure of the SSU rRNA molecule (Cavalier-Smith and Nikolaev 2008; Nikolaev et al. 2004) and, possibly, (near-)parallel basal bodies (Cavalier-Smith and Nikolaev 2008; Park and Simpson 2011). Isolate "BB2" (ATCC strain PRA-19) is an undescribed thermophilic amoeba with typical heterolobosean characteristics that remains *incertae sedis* within Heterolobosea. Phylogenetic analyses of SSU rDNA sequences indicate that isolate "BB2" might represent the sister lineage to all other Heterolobosea, or be specifically related to *Pharyngomonas*, but statistical support

either way is very low (Harding et al. 2013). An amoeba referred to as *Soginia* (a *nomen nudum*) was inferred to be a possible deep branch within Heterolobosea based on multigene phylogenies (Parfrey et al. 2010), but this is almost certainly because the SSU rDNA attributed to this organism actually derives from a gregarine (Cavalier-Smith 2015).

Pharyngomonada currently contains a single genus, *Pharyngomonas*, in its own family, Pharyngomonadidae, and class, Pharyngomonadea; these taxa currently refer to an identical set of species as Pharyngomonada and are sometimes used instead of Pharyngomonada to denote the whole group (Adl et al. 2012; Park and Simpson 2016).

Based on phylogenetic analyses of SSU rDNA sequences, Tetramitia can be divided into seven well-supported major clades that have been defined by Pánek et al. (2012, 2014a). Unfortunately, relationships between these clades remain unresolved and thus, no phylogenetic classification of subphylum Tetramitia into monophyletic classes has been proposed. Eight families of Tetramitia are currently recognized: Acrasidae van Tieghem 1880, Creneidae Pánek et al. 2014, Gruberellidae Page and Blanton 1985, Percolomonadidae Cavalier-Smith 2008 (in Cavalier-Smith and Nikolaev 2008), Psalteriomonadidae Cavalier-Smith 1993, Stephanopogonidae Corliss 1961, Tulamoebidae Kirby et al. 2015, and the paraphyletic Vahlkampfiidae Jollos 1917. Future work will hopefully allow resolution of Vahlkampfiidae into a series of monophyletic taxa. A full list of genera, divided by higher taxa, is given in Table 1. More details of the correspondence between this taxonomy and the phylogenetic structure within Heterolobosea are given in section "Evolutionary History" (see below).

Maintenance and Cultivation

Most heterolobosean amoebae and flagellates have been cultivated on bacterial prey or on nutrient-enriched media that fosters the growth of bacteria. *Naegleria gruberi* is the only heterolobosean amoeba that has been grown on a chemically defined medium (Fulton et al. 1984). Amoebae are frequently grown on agar plates (though many can also be cultivated in liquid media), while flagellates are typically maintained in liquid media. Smirnov and Brown (2004) give detailed methods for cultivation of soil amoebae in general (not just heteroloboseans), including recipes for various media and recommendations for inoculation. *Protocols in Protozoology* (Lee and Soldo 1992) is also a good source for detailed information on the cultivation of freshwater and marine amoebae.

Techniques for examining amoeba-to-flagellate transformation have been reviewed by Page (1976) and Fulton (1977). However, the precise conditions for transformation have been determined for very few species, the best known being *Naegleria gruberi*. In general, high-nutrient conditions are optimal for the feeding and dividing amoeba stage, and drastic dilution of nutrients induces the flagellate stage (e.g., by suspension in distilled water, sometimes for extended periods).

Table 1 Full list of heterolobosean genera, divided by higher taxon. Number of described species, typical habitats, and availability of SSU rDNA sequences are indicated

[b]Vahlkampfiidae is currently a nonmonophyletic and essentially artificial assemblage

Anaerobic Heteroloboseans

Anaerobic amoebae and flagellates can be isolated from marine, brackish, or freshwater sediments. A typical strategy is to initially inoculate approximately 2 ml of sample into 9 ml of relatively rich sterile medium in 15 ml culture tubes (Pánek et al. 2012). Freshwater strains are isolated in Sonneborn's *Paramecium* medium (ATCC medium 802, solution 1) or 3% LB medium. Marine and brackish strains are isolated in seawater 802 medium (ATCC medium 1525) or 5% TYGM-9 medium (ATCC medium 1171) prepared with sterilized seawater. The strains are maintained in xenic agnothobiotic cultures at room temperature and subcultured once a week.

Halophilic Heteroloboseans

Halophilic and halotolerant heteroloboseans have usually been isolated in, and grown on, liquid medium consisting of 'Medium V' (Park 2012; previously known as 'AS medium'), typically at 10–25% final salinity (Park et al. 2007, 2009, 2012; Park and Simpson 2011, 2015; Harding et al. 2013). Halotolerant forms such as *Selenaion koniopes, Tulamoeba bucina* and *Pharyngomonas* strain RL have also been grown in seawater-strength media (e.g., f/2, Smaltz-Pratt medium or sterilised seawater), or in Page's Amoeba Saline (PAS, Page 1988) supplemented with double the NaCl concentration of seawater (2X SPAS; ~7% salinity; Park et al. 2012; Kirby et al. 2015; Plotnikov et al. 2015). Media are enriched with a carbon source to support growth of prokaryote food (often sterile barley grains and/or 0.05–1% v/v LB medium; 1.5 g/L yeast extract also used). In the case of some lower salinity media, separately grown *Pseudomonas fluorescens* or *Escherichia coli* have been added directly, usually instead of the organic enrichment. Some strains have been isolated or cultivated as amoebae on 1–2% agar plates made with Medium V at 10–25% final salinity, 2X SPAS medium, or f/2, and supplemented with separately grown bacteria (*E. coli or Salinivibrio* sp.) as a food source (Park et al. 2012; Harding et al. 2013). Subculturing is typically performed every 2–4 weeks, or longer.

Stephanopogon

Only a few *Stephanopogon* strains have been cultivated. Lipscomb (see Lipscomb and Corliss 1982) maintained a strain of *Stephanopogon apogon* for a few months (albeit with a low growth rate) using filtered seawater, split peas, and unidentified bacteria. Nerad established *Stephanopogon apogon* in monoxenic culture in ATCC medium 1405, using the kinetoplastid nanoflagellate *Rhynchomonas nasuta* as a food source; *S. apogon* has subsequently been cryopreserved (Culture: ATCC

50096). Yubuki and Leander (2008) temporarily maintained a low-abundance culture of *Stephanopogon minuta* with a standard f/2 seawater medium and a small pennate diatom (*Nitzschia* sp.) as a food source, while Lee et al. (2014) cultivated the similar *Stephanopogon pattersoni* indefinitely in sterile seawater enriched with 1% LB media together with the nanoflagellate *Ancyromonas* (and prokaryotes).

Acrasids

Acrasis spp. are most commonly encountered on dead attached plant parts and *Pocheina rosea* on the bark of living trees. For *Acrasis*, dead and decaying plant parts (inflorescences, berries, pods, fruits, etc.) still attached to the plant should be collected in paper sacks. The material is torn into small fragments and placed on Petri plates prepared with weak malt-yeast agar ('wMY agar'; 0.002 g malt extract, 0.002 g yeast extract, 0.75 g K_2HPO_4, 15 g bacteriological agar, 1.0 L deionized water; see Brown et al. 2010). A small drop of water is then placed on each piece of collected plant substrate and left to air-dry with the Petri dish lid on. The plant materials and surrounding agar surfaces should be examined microscopically after 3–5 days. If the sorocarps of acrasids are observed, the end of an insect minuten needle can be used to collect spore chains, best done under a dissecting microscope. The spores should then be placed on wMY agar with a streak of the yeast *Rhodotorula mucilaginosa* added for food (in the case of *Acrasis rosea*). Other yeasts, some bacteria, and conidial fungi have also been used as food sources for *Acrasis* spp. (Olive and Stoianovitch 1960; Olive et al. 1961; Reinhardt 1968). The orange growth of the *Acrasis* amoebae, cysts, and sorocarps will become apparent among the pink yeast colonies within a few days. *Allovahlkampfia* spp. can be grown on bacteria; however, sorocarps may be induced through the addition of sterilized bark pieces soaked in a slurry of *R. mucilaginosa* and water (Brown et al. 2012a). Cultures may be transferred by cutting out a block of agar containing amoebae, cysts, or fruiting bodies and placing it in a streak of *R. mucilaginosa* on a plate of wMY (for more abundant growth, the inoculum block can be pushed along the yeast streak to spread the amoebae, cysts, and spores). Isolation plates and cultures should be kept in either natural or artificial day-night light conditions for sorocarp formation.

Species of *Pocheina* are cultured with great difficulty (Olive et al. 1983). *Pocheina* is frequently encountered on pine bark in moist chambers. Pieces of bark from living trees should be placed on a wMY agar Petri dish and wetted with sterile distilled water. The bark should be examined with a dissecting microscope for the minute pink or orange sorocarps that appear after 1–4 days. The sorocarps are removed with a needle; the sori alone can be removed by touching them with a block of agar on the end of a needle. It is difficult to germinate stalk cells and spores, but germination may occur if entire sorocarps are placed on a malt extract-yeast extract medium at pH 5.5 with 0.75% agar. Fungi, yeast, and bacteria must also be isolated from the bark. Sorocarp formation may occur on the wMY agar, or on sterilized

pieces of bark on agar. *Pocheina* is usually found repeatedly on bark collections from the same tree, allowing continued collections for trials with various food organisms.

Evolutionary History

Evolutionary Position and Significance; History and Present Understanding

Early SSU rDNA phylogenies of eukaryotes had indicated that heterolobosean were amongst the deepest-branching lineages within eukaryotes, especially mitochondrion-bearing lineages (Hinkle and Sogin 1993). Cavalier-Smith (1993) suggested that the heterolobosean (under the name Percolozoa; see "Taxonomy and Systematics") were especially important to understanding the evolutionary transition between primitive eukaryotic cells and modern cells with classical mitochondria, peroxisomes, and a stacked Golgi apparatus. He proposed that heterolobosean were a group at the base of mitochondrion-bearing eukaryotes that primitively lacked dictyosomes and stemmed from, or included, the lineage in which mitochondria were acquired. Notably, Cavalier-Smith emphasized that *Psalteriomonas vulgaris* (syn. *Lyromonas vulgaris* – see Pánek et al. 2012) differed from other Heterolobosea (and resembled primitive eukaryotes) in lacking classical mitochondria (Broers et al. 1993), while *Psalteriomonas lanterna* was originally thought to possess both hydrogenosomes (associated with methanogenic prokaryotes) and "modified mitochondria" located throughout the cytoplasm and surrounded by rough endoplasmic reticulum (Broers et al. 1989, 1990).

The hypothesis that certain anaerobic eukaryotes (e.g., diplomonads, archamoebae, and microsporidia) represent amitochondrial, deep-branching lineages has now been abandoned; further research confirmed that the ancestor of eukaryotes possessed mitochondria (Roger et al. 1998; Embley and Hirt 1998; Dolezal et al. 2006) as well as a stacked Golgi apparatus (Mowbrey and Dacks 2009; Klute et al. 2011). Also, subsequent phylogenetic analyses showed clearly that psalteriomonads are a clade that branches well within Heterolobosea and must descend from heterolobosean with aerobic mitochondria (Park and Simpson 2011; Harding et al. 2013; Pánek et al. 2012, 2014a, b). Further, De Graaf et al. (2009) demonstrated that the organelles of *Psalteriomonas* are two different morphs or developmental stages of hydrogenosomes, rather than two distinct types of organelles.

Further, it is now clear that the deepest-branching eukaryote lineages cannot be reliably identified based on rooted SSU rDNA phylogenies (Philippe et al. 2000). Instead, phylogenetic analyses over the last 15 years, especially of multiprotein and phylogenomic datasets, have shown that Heterolobosea is closely related to Euglenozoa (Baldauf et al. 2000; Rodríguez-Ezpeleta et al. 2007; Hampl et al. 2009; Kamikawa et al. 2014). In analysis with broad taxon sampling of other lineages, Heterolobosea and Euglenozoa emerge as sister taxa within the Discoba

clade (Heterolobosea, Euglenozoa, Jakobida, and *Tsukubamonas*; Rodríguez-Ezpeleta et al. 2007; Hampl et al. 2009; Kamikawa et al. 2014), albeit the precise position of *Tsukubamonas* is not settled.

Internal Phylogeny

The internal phylogeny of Heterolobosea, as currently understood, is based largely on SSU rDNA data (plus ITS1, ITS2, and 5.8S rDNA in case of genus *Naegleria* – De Jonckheere 2004). Two major lineages of Heterolobosea have been described: Pharyngomonada, which contains just a single genus, and Tetramitia, which contains most heteroloboseans. Based on SSU rDNA analyses, Pánek et al. (2012, 2014b) divided Tetramitia into seven well-supported major clades (I-VII). No morphological synapomorphies are described for most of these clades, and the relationships between them remain largely unclear (see Fig. 8). Furthermore, the positions of the "BB2" lineage and of *Creneis carolina* remain unresolved in SSU rDNA phylogenies (Harding et al. 2013; Pánek et al. 2014b) and including the divergent *Creneis carolina* sequence in SSU rDNA analyses decreases statistical support for Tetramitia clades VI and IV. Molecular data from some other taxa with peculiar morphology are not available (e.g., *Trimastigamoeba*).

Tetramitian clades I and VII are each represented by just one or two described species: *Neovahlkampfia damariscottae* and *N. nana* (Vahlkampfiidae *pro parte*) for clade I (Tyml et al. 2016) and *Selenaion koniopes* (Heterolobosea *incertae sedis*) for clade VII. SSU rDNA analyses indicate that these two clades might represent deep-branching lineages within Tetramitia. These are also the only two major clades of Tetramitia for which no flagellates have been reported.

Tetramitian clade II unites acrasid slime molds, which produce sorocarps and allovahlkampfiid amoebae (*Allovahlkampfia*, *Solumitrus palustris*). The evolution of sorocarpic multicellularity appears to precede the last common ancestor of tetramitian clade II (Brown et al. 2012a). Thus the name Acrasidae or Acrasida may be used for this clade. There appears to be some potential for the loss of sorocarpy, as only one isolate of *Allovahlkampfia* has been observed to produce sorocarps (*Allovahlkampfia spelaea* isolate BA; Brown et al. 2012a). However the lack of records of sorocarps in other allovahlkampfiids may simply be because the culture conditions were not conducive to fruiting. The monophyly of the genus *Pocheina* is currently uncertain, because *Pocheina rosea* has been tentatively synonymized with *Acrasis rosea* (Brown et al. 2012a) and *Pocheina flagellata* was reported to transform into flagellates, unlike other described acrasids (Olive et al. 1983). This opens a question about the phylogenetic position of *Pocheina flagellata*, but no molecular data are currently available.

Tetramitian clade III includes *Naegleria*, *Willaertia*, *Marinamoeba* (Vahlkampfiidae *pro parte*), and Tulamoebidae (*Pleurostomum*, *Tulamoeba*). While *Naegleria* is a freshwater lineage, members of Tulamoebidae are halophilic or extremely halotolerant (Kirby et al. 2015), and *Marinamoeba thermophila* is a

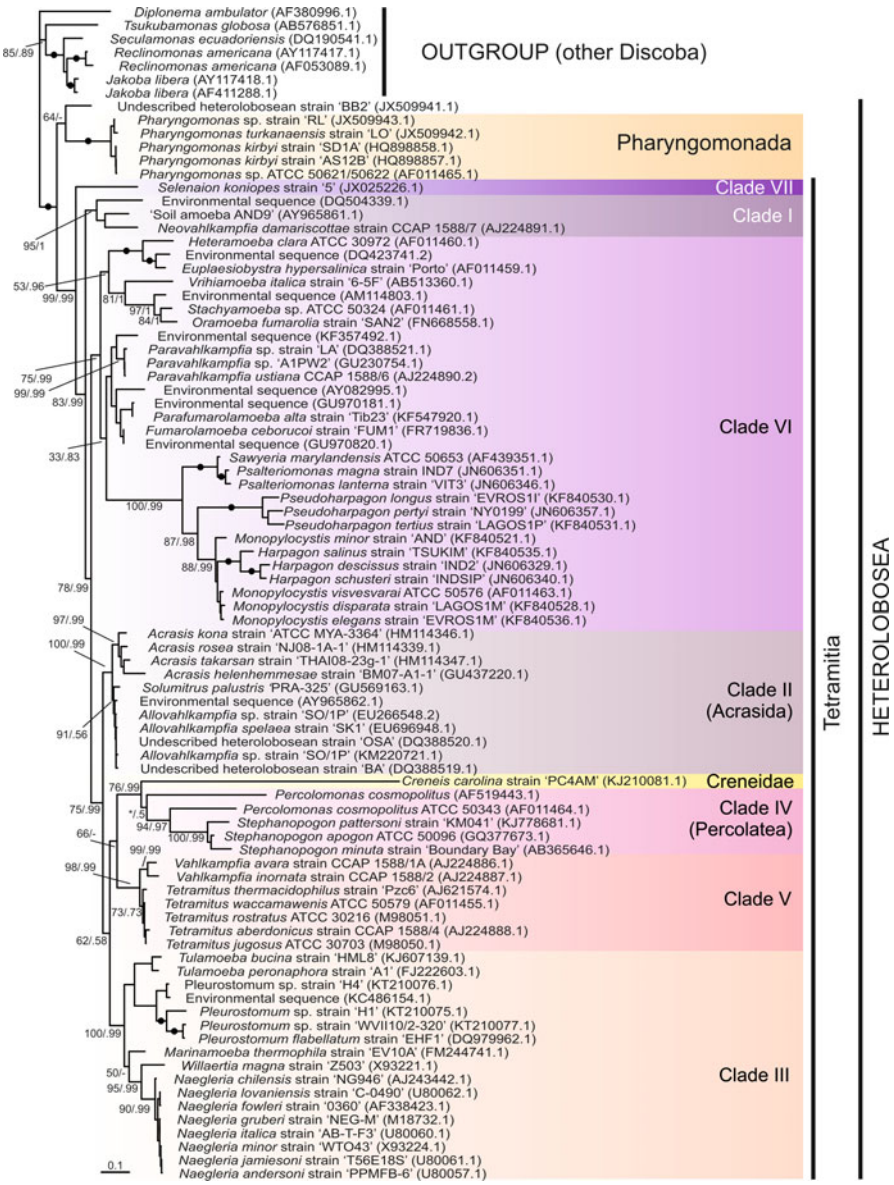

Fig. 8 SSU rDNA phylogeny of Heterolobosea. The tree is based on 1,283 well-aligned positions. The topology was inferred in RAxML version 8.2.8 using maximum likelihood with the GTRGAMMA model and 500 rapid bootstraps. The values represent RAxML bootstrap percentages followed by PhyloBayes posterior probabilities. Absolute statistical support (100/1) is indicated by *black dots*. Values lower than 50% or 0.5 are marked by "–." Bayesian analysis was performed using PhyloBayes MPI version 1.5a with the GTR CAT model (maxdiff 0.94, minimum effective size 100, number of cycles excluded from convergence checks 1,000)

marine amoeba that does not grow in high salinities, but is thermophilic (De Jonckheere et al. 2009).

Tetramitian clade VI, or Percolatea *sensu* Cavalier-Smith and Nikolaev (2008), is represented by two genera of flagellates, *Percolomonas* (Percolomonadidae) and *Stephanopogon* (Stephanopogonidae). Members of these two genera are the only heteroloboseans able to encyst as flagellates. They probably descend from a common ancestor that lost the amoeba stage. Yubuki and Leander (2008) identified two possible morphological synapomophies of Percolatea, but reexamination in light of new data indicates that neither feature is likely to define this clade (Lee et al. 2014).

Tetramitian clade V currently includes the genera *Vahlkampfia* and *Tetramitus* (both Vahlkampfiidae *pro parte*). Genus *Vahlkampfia* comprises several species with no known flagellate stage. The close relationship of some species has been confirmed by molecular methods, but some others are classified as *Vahlkampfia* based only on the absence of a flagellate stage (e.g., the marine *Vahlkampfia dumnonica*); their real phylogenetic position is uncertain. Species of the genus *Tetramitus* are extremely diverse in terms of morphology and ecology. Thus, they were assigned to multiple different genera in the past (e.g., *Adelphamoeba*, *Didascalus*, *Learamoeba*, *Paratetramitus*, *Singhamoeba*). Currently, these names are considered to be junior synonyms for *Tetramitus*, based mainly on molecular sequence comparisons (Brown and De Jonckheere 1999; De Jonckheere et al. 1997; De Jonckheere and Brown 2005b).

Tetramitian clade VI is a diverse lineage that includes some endobiotic taxa (*Paravahlkampfia* spp., representing Vahlkampfiidae *pro parte*), obligate anaerobes (Psalteriomonadidae), and halophiles/thermophiles (*Euplaesiobystra hypersalinica*), as well as non-thermophilic aerobes that inhabit freshwater/soil (*Vrihiamoeba*, *Parafumarolamoeba*) or marine/brackish habitats (*Heteramoeba*).

Fossil Record

The size and lack of mineralization of heterolobosean cells makes them poor candidates for fossilization. Nonetheless, cysts that have been identified as similar to those of *Naegleria* have been reported in mid-Cretaceous amber (Waggoner 1993).

The Evolutionary Importance of Heteroloboseans; Selected Cases

The phylogenetic position of Heterolobosea within Discoba makes it an important comparison group for examining the evolution of mitochondrial genomes and information systems. This is because jakobids have the most bacterial-like mitochondrial genomes known (Burger et al. 2013; see ▶ Jakobida), while Euglenozoa have aberrant mitochondrial genetic information systems, with different kinds of extensive gene fragmentation or extensive insertion/deletion RNA editing

(Flegontov et al. 2011). The mitochondrial genomes of *Naegleria* spp. are not particularly unusual, with a moderately large gene complement, while *Acrasis rosea* has a much smaller number of genes. There is no widespread genome fragmentation, and RNA editing in these two genera seems to be restricted to substitution-type editing at six or fewer positions (Rüdinger et al. 2011; Herman et al. 2013; Fu et al. 2014).

Flagella of many eukaryotic lineages undergo a fundamental morphogenetic process called ciliary transformation. During this process, each basal body/flagellum unit passes through a developmental program that requires more than one cell cycle to complete, such that their functional roles can change across generations (e.g., the anterior flagellum in a parent cell becomes the posterior flagellum of one of its daughters; Beech et al. 1991; Heimann et al. 1995; Melkonian et al. 1987; Nohýnková et al. 2006; Perasso et al. 1992; Yubuki and Leander 2012; Yubuki et al. 2013). With this in mind, *Naegleria*'s amoeba-to-flagellate transformation is atypical, because the whole flagellar apparatus, with two different basal bodies, is assembled *de novo* within a single generation (see Fulton and Dingle 1971; Fulton 1993). *De novo* assembly of the whole flagellar apparatus (or equivalent) is not unique for Heterolobosea; it has been described in several other eukaryotic lineages including mammals (see Fritz-Laylin et al. 2016). Nevertheless, *Naegleria* offers a particularly promising system to study *de novo* basal body assembly, as well as the mechanisms regulating the number of centrioles assembled per cell. This process has been studied for more than 45 years in *Naegleria* and protocols for straightforward control of amoeba-to-flagellate transformation have been developed. Furthermore, a genome sequence is available, as well as axenic cultures and well-characterized antibodies to orthologs of basal body components (see Fulton 1970; Fritz-Laylin and Fulton 2016).

Generally, the architecture of the eukaryotic flagellar apparatus is robust and conservative; the main components can be identified and homologized with elements in related taxa based on similar morphology as well as relative position (Yubuki and Leander 2013). For example, the R2 microtubular root has been conserved in many taxa across the tree of extant eukaryotes and has usually retained a similar structure and function (Cavalier-Smith 2013; Heiss et al. 2013; Yubuki and Leander 2013). The recently described *Creneis carolina* appears to be an exception to this rule. Ultrastructural study showed that the R2, or even the entire flagellar root system, has most probably undergone a reversal of chirality relative to the flagellum (Pánek et al. 2014b).

The term "acrasid" has historically included all cellular slime molds (see a timeline of "acrasid" research in Fig. 2 in Brown and Silberman (2013)); however, it is now known that protistan organisms have converged upon an aggregative behavior that ends in a sorocarp structure at least seven times in the evolutionary history of eukaryotes (Brown et al. 2009, 2010, 2011, 2012a, b; Brown and Silberman 2013; Tice et al. 2016). In addition to Acrasidae (which is the only example within excavates), this capability has evolved twice in Amoebozoa (dictyostelids and copromyxids) and once in each of Alveolata (the ciliate genus *Sorogena*), Opisthokonta (*Fonticula*), Stramenopiles (*Sorodiplophrys*), and

Rhizaria (*Guttulinopsis*). Little is currently known about whether there are molecular similarities among these organisms with similar life cycles. In the future, comparative genomics and transcriptomics will help to shed a light on this topic.

Acknowledgments The authors thank the Cyberinfrastructure for Phylogenetic Research Science (CIPRES) Gateway v 3.3, where all phylogenetic analyses were conducted. We also thank Jong Soo Park (Kyungpook National University), Won Je Lee (Kyungnam University), Ivan Čepička (Charles University) Petr Táborský (Charles University), and Yana Eglit (Dalhousie University) for unpublished micrographs. AGBS gratefully acknowledges the support of the Canadian Institute for Advanced Research (CIfAR), program in Integrated Microbial Biodiversity. TP thanks to the Czech Science Foundation project 13-24983S for support.

Euglenida

29

Brian S. Leander, Gordon Lax, Anna Karnkowska, and Alastair G. B. Simpson

Abstract

Euglenids are a group of >1500 described species of single-celled flagellates with diverse modes of nutrition, including phagotrophy and photoautotrophy. The group also encompasses a clade of specialist "primary" osmotrophs (Aphagea) and, very likely, one group of phagotrophs that are ectosymbiont-supporting anaerobes (Symbiontida). Almost all euglenids are free-living. The (usually) one or two emergent flagella have thick paraxonemal (paraxial) rods and originate in a deep pocket/reservoir, while the cell surface is almost always supported by a pellicle of parallel proteinaceous strips underlain by microtubules. Cells with 4–12 strips are rigid; most of those with more strips (typically ~20–40) have them arranged helically and exhibit active cell deformation called "euglenid motion" or "metaboly." Most phagotrophic euglenids are surface-associated bacterivores or eukaryovores that employ a flagellar gliding motility; they are abundant in marine and freshwater sediments. Photoautotrophic species (Euglenophyceae) constitute a single subclade within euglenids and have a plastid (chloroplast) of secondary endosymbiotic origin, with three bounding membranes. The plastid is typically green, with chlorophylls *a* + *b*, and was derived from a chloroplastidan alga related to the Pyramimonadales. Photoautotrophic euglenids move primarily by swimming, and most (members of the taxon Euglenales, e.g., *Euglena*) have a single emergent flagellum and are generally restricted to fresh and brackish waters.

Introduction

Euglenids (sometimes referred to as "euglenoids") are a prominent group of free-living, aquatic flagellates, usually with one or two active flagella. Most of the >1500 descibed species are unicells that are 5–50 μm in length; a few are larger. Almost all are motile, either by swimming or by surface-associated gliding on the flagella or cell body.

Euglenida represents one of three major subgroups within the Euglenozoa, along with ▶ Kinetoplastea and Diplonemea, which they resemble in several conspicuous ways. For example, as in kinetoplastids, the flagella are inserted at the base of a deep pocket (also known as the reservoir), and active flagella are conspicuously thickenend due to the presence of paraxonemal (paraxial) rods. The mitochondrial cristae are also discoidal. However, euglenids are readily distinguishable by their cell surface architecture, which almost always is supported by a pellicle of abutting parallel strips of protein that lie directly under the cell membrane (Fig. 1). Cells with many helically arranged strips (>20) are often capable of a characteristic squirming or pulsing form of active cell deformation called "euglenid motion" or "metaboly," which is effected by sliding of adjacent strips.

Euglenids are notable for their diverse modes of nutrition, including phagotrophy (consumption of particles, especially other cells), osmotrophy (absorbtion of organic molecules), and photoautotrophy (photosynthesis) (Figs. 2, 3, 4, and 5). Among the phagotrophs, there is a convenient, if imperfect, distinction drawn between predominantly "bacterivorous" taxa, which have rigid pellicles with 12 or fewer strips and tend to be smaller in size, and predominantly "eukaryovorous" taxa that have pellicles with many strips, are usually flexible, and tend to be larger. The latter typically consume microbial eukaryotes, including unicellular algae. Meanwhile, some phototrophic forms are apparently also capable of pinocytosis, or even

phagotrophy of eukaryotic algae in the case of the deep-branching phototroph *Rapaza* (Yamaguchi et al. 2012).

The "bacterivores" include the petalomonads (Petalomonadida), which glide with a forward-directed flagellum (e.g., *Petalomonas*, *Notosolenus*), and "ploeotiids," which glide on the posterior/ventral flagellum (e.g., *Ploeotia*, *Keelungia, Entosiphon*) (Fig. 2a, b). The eukaryovores include some taxa that glide primarily on a forward-directed anterior flagellum (i.e., similarly to petalomonads; Fig. 2c). An example is the well-known genus *Peranema*, and these organisms are referred to here as "peranemids." Other eukaryovores resemble ploeotiids in gliding on the posterior flagellum; the best known example is *Anisonema,* and these are referred to here as "anisonemids" (Fig. 2d). The unusual phagotroph *Neometanema* normally "skids" along surfaces rather than gliding (Fig. 2e). Ploeotiids and peranemids appear to be paraphyletic groups, the anisonemids may be as well.

Photoautotrophic euglenids are phylogenetically less diverse than phagotrophs, although more species have been described. Most are elongate, flexible cells that

swim using one or (more rarely) two emergent flagella (e.g., *Eutreptia*, *Euglena*; Fig. 3a, b). Other commonly encountered forms are rigid cells with various cell shapes (e.g., *Phacus*; Fig. 3c) and cells that are enclosed in an extracellular lorica but are nonetheless capable of swimming (*Trachelomonas* and *Strombomonas*; Fig. 3d).

Among the osmotrophs, there are "primary osmotrophs" (the Aphagea, e.g., *Rhabdomonas*, *Distigma*, and *Astasia*; Fig. 4a, b), which descended from within eukaryovorous lineages, and "secondary osmotrophs," which are a polyphyletic collection of species and strains that descended from various photoautotrophs. Secondary osmotrophs now tend to be assigned to predominantly photoautotrophic genera, reflective of their evolutionary histories (see "Taxonomy").

The existence of both phagotrophic and photoautotrophic species led to euglenids being examined both as plant-like and animal-like life-forms. Among other things this resulted in competing classification schemes under the International Code of Botanical Nomenclature and the International Code of Zoological Nomenclature (i.e., they are "ambiregnal taxa" – see Patterson and Larsen 1992). Of course euglenids are neither plant nor animal, so the group does not fall neatly within the archaic plant-animal dichotomy. Photoautotrophic euglenids in fact acquired photosynthesis via a secondary endosymbiosis involving a chloroplastidan green alga (see below). The morphological and behavioral diversity of the group is also exceptional and provides compelling illustrations of major events in evolution, such as the punctuated effects of secondary endosymbiosis and changes in underlying developmental mechanisms (Leander et al. 2007; see "Evolutionary History").

Several photoautotrophic and osmotrophic species are bloom-formers in nutrient-rich conditions and are useful indicators of environmental pollution. Phagotrophic species are ubiquitous primary consumers and are likely to be important components of microbial food webs, especially in sediments. A few euglenids have been used as model systems for addressing a wide variety of questions in basic cell biology and physiology and as teaching aids. *Euglena gracilis*, for instance, is familiar to nearly every student who has taken a general biology course in high school, college, or university.

Literature and History of Knowledge

Knowledge of euglenids extends back to the late 1600s and involves several of the pioneers of eukaryotic microbiology. Photoautotrophic euglenids were among the organisms documented by Leeuwenhoek. In the eighteenth century, O.F. Mueller described some species, though he assigned them to non-euglenid genera. The first genera of photoautotrophs were introduced in the early nineteenth century by Ehrenberg, notably *Euglena* (1830), *Cryptoglena* (1832), *Colacium* (1835), and *Trachelomonas* (1835). By the mid-twentieth century, the number of described species had increased markedly, and several other important freshwater genera were introduced (*Phacus* Dujardin 1841, *Lepocinclis* Perty 1849, *Monomorphina* Mereschkowski 1877, *Strombomonas* Deflandre 1930) as well as two marine genera (*Eutreptia* Perty 1852 and *Eutreptiella* Da Cunha 1913). Accounts of osmotrophic

and phagotrophic euglenids accumulated in the nineteenth century, with genera introduced or regularized by Ehrenberg, Dujardin (1841; e.g., *Anisonema*, *Ploeotia*), Perty (1852), and Stein (1878), among others. In the mid-late twentieth century, monographic accounts of freshwater species, based on light microscopy, were produced by Gojdics (1953), Huber-Pestalozzi (1955), Pringsheim (1956), Popova (1966), Popova and Safonova (1976), Starmach (1983), and Tell and Conforti (1986). Those monographic studies were mainly focused on photoautotrophic species. Leedale's 1967 book "*Euglenoid flagellates*" summarized the ultrastructural and biochemical/cell physiological information available at the time for the group, and Buetov (1968) summarized research on *Euglena*.

Despite this long history, a considerable number of species and several genera have been described since the original publication of the *Handbook of Protoctista* (e.g., Larsen and Patterson 1990; Lee and Patterson 2000; Triemer et al. 2006; Linton et al. 2010; Bennett et al. 2014). Among the most important advances was the definition of the anaerobic Symbiontida, including the first descriptions of *Postgaardi* and *Bihospites* (Fenchel et al. 1995; Yubuki et al. 2009; Breglia et al. 2010; Fig. 4c), though as discussed below, the case that symbiontids are euglenids is not fully settled and some authors currently treat them as a separate group within the Euglenozoa (Cavalier-Smith 2016). As with most other groups of protists, the advent of molecular phylogenetics has resulted in considerable taxonomic and systematic changes, especially in the last ~15 years. Important syntheses and revisions of photoautotrophic euglenids include Marin et al. (2003), Linton et al. (2010), Kim et al. (2010), Karnkowska et al. (2015) and Kim et al. (2015), and Preisfeld et al. (2001) for osmotrophic euglenids. The phylogenetic relationships and systematics of phagotrophic euglenids remain much more poorly understood and are currently in a state of flux (Lax and Simpson 2013; Cavalier-Smith 2016; Cavalier-Smith et al. 2016).

Practical Importance

Euglenids are not known to cause disease in humans or livestock; rare possible cases of parasitism by euglenids involve noneconomic organisms such as tadpoles and gastrotrichs (Wenrich 1924; Brumpt and Lavier 1924; Kisielewska et al. 2015). However, some bloom-forming photoautotrophic euglenids have been shown to produce neurotoxins that can cause widespread fish die-offs in freshwater aquaculture facilities (Zimba et al. 2004, 2010).

A couple of species of euglenids have been exploited as model systems for biological research. For example, *Euglena gracilis* has been investigated for the production of important compounds (Krajčovič et al. 2015) such as vitamins A, C, and E (e.g., Takeyama et al. 1997; Fujita et al. 2008); polyunsaturated fatty acids (e.g., Korn 1964; Wallis and Browse 1999; Meyer et al. 2003); the carbohydrate paramylon (e.g., Santek et al. 2009; Rodríguez-Zavala et al. 2010; Shibakami et al. 2012); and wax esters (e.g., Inui et al. 1982; Teerawanichpan and Qiu 2010; Tucci et al. 2010; Dasgupta et al. 2012). *Euglena gracilis* can be grown in a wide range of

conditions: autotrophically or heterotrophically on various carbon sources (or both), under a broad range of pH values, and in high concentrations of cadmium, chromium, lead, mercury, and zinc. Therefore, it can be used for bioremediation of polluted waters (Krajčovič et al. 2015).

Habitats and Ecology

Phagotrophic euglenids are widespread in marine, brackish, and freshwater sediments. These cells glide within the spaces between sand grains and within the narrow interface between mud and the water column. They can compose up to 85% of the biomass of bacterivorous flagellates in certain aerobic freshwater, marine, and brackish sediments and are presumably important predators in these ecosystems (Boenigk and Arndt 2002; Dietrich and Arndt 2000). Despite clear microscopical evidence of their presence, phagotrophic euglenids are suspiciously rare in many environmental sequencing datasets from sediments (e.g., Forster et al. 2016). Similarly phototrophic euglenids are poorly represented in freshwater environmental surveys (e.g., Simon et al. 2015). A possible reason for this contradiction might be that euglenids often have divergent and expanded SSU rRNA gene sequences, including the V4 region that is routinely used in environmental surveys. Divergence can result in "universal" primers not binding efficiently. Additionally, many euglenids exhibit such enlarged V4 regions that they cannot be fully sequenced using current high-throughput sequencing technology (Busse and Preisfeld 2002; Karnkowska-Ishikawa et al. 2013). To address these problems (in photoautotrophic euglenids at least), careful investigation of possible DNA barcodes was recently performed, and specific primers were proposed for the V2–V3 and V4 regions of the SSU rDNA (Łukomska-Kowalczyk et al. 2016).

Phagotrophic euglenids are mostly raptorial feeders on other microbial cells, although it is documented that some act as detritivores (e.g., consume cytoplasm and organelles from large ruptured cells), and at least one species, *Dolium sedentarium*, is a sessile "ambush" predator (Larsen and Patterson 1990). As discussed above, it has become common to divide phagotrophic euglenid taxa into "bacterivores" and "eukaryovores," based on morphological correlates of food preference and phylogenetic position. The bacterivores (petalomonads and ploeotiids) are rigid cells with few pellicular strips and tend to be relatively small (most are <25 μm long). The rigidity of the pellicle constrains them by gape limitation; thus they feed on small prey, primarily prokaryotes. The eukaryvores (e.g., "peranemids" and "anisonemids") are mostly slightly-to-highly flexible cells with unfused and more numerous pellicular strips, and they also tend to be larger (most are >20 μm long). As a consequence, they are typically capable of consuming larger prey items in both absolute and relative terms, such as large eukaryotic cells. For example, Chen (1950) documented that *Peranema trichophorum* can engulf whole *Euglena gracilis* cells, which are almost as large as themselves. Many eukaryovorous euglenids specialize in consuming benthic microalgae, especially pennate diatoms (e.g., Lee and Patterson 2000).

Despite the usefulness of this phylogenetic bacterivore/eukaryovore dichotomy, it is not a clear-cut autecological distinction. For example, it is documented that many rigid species that are phylogenetically grouped with "bacterivores" are quite capable of consuming eukaryotic cells; *Ploeotia*/*Serpenomonas costata* is known to eat yeast in culture (Linton and Triemer 1999), and large petalomonads and ploeotiids are not infrequently observed with food vacuoles containing the remains of algae (e.g., Larsen and Patterson 1990; Lax and Simpson 2013; see Fig. 5a). In fact, *Dolium*, a rigid cell with six pellicular strips, ingests whole pennate diatoms (Larsen and Patterson 1990).

Phototrophic lineages mainly inhabit the water column of freshwater environments. Extremely large and vermiform species have reduced flagella and often inhabit the interface between the sediment and water column (Leander and Farmer 2000b; Esson and Leander 2008) (Fig. 1g). Only a few phototrophs inhabit the marine plankton (e.g., the Eutreptiales), however, several species are found in brackish water and estuaries, either in sediments or in the water column. Some species migrate vertically in marine sand, in coordination with tidal and diurnal cycles (e.g., *Euglena rustica*). These species are usually found in high abundance and form easily visible green patches in marine sand during low tides (Brown et al. 2002).

The deep-branching euglenophycaean *Rapaza viridis* has an interesting, if little-studied autecology. The sole known isolate is a mixotroph that houses an apparently functional euglenid plastid (see below), but also feeds on cells of a particular strain of the chloroplastidan alga *Tetraselmis* (Yamaguchi et al. 2012). This feeding is extremely selective (other algae are rejected as prey, including other strains of *Tetraselmis*), but obligate; *R. viridis* could not survive in culture more than ~1 month without prey (Yamaguchi et al. 2012).

Characterization and Recognition

The following is a summary of characteristic morphological features of euglenids. Important systems are covered in more detail in later subsections.

- The best synapomorphy for the group is a pellicle consisting of proteinaceous strips beneath the plasma membrane, associated with microtubules. The pellicle strips are oriented longitudinally in bacterivorous euglenids and usually helically in eukaryovorous, photoautotrophic, and osmotrophic euglenids. The strips are secondarily longitudinal in some rigid photoautotrophs (e.g., *Phacus*) and primary osmotrophs (e.g., *Menoidium*).
- Cells usually have two heterodynamic flagella that originate within an anteriorly-directed flagellar pocket. One flagellum extends anteriorly or anterio-laterally, but historically has been called the "dorsal" flagellum; the other, the "ventral flagellum," bends to run posteriorly. In most photoautotrophs, most osmotrophs, and a

few phagotrophs, only the dorsal flagellum is emergent, while the ventral flagellum is reduced in length and confined to the flagellar pocket (or is absent altogether).

- The flagellar pocket in photoautotrophic species is modified into a "reservoir" (equivalent to the flagellar pocket sensu stricto) and a narrower cylindrical-shaped "canal" leading to the exterior of the cell.
- The flagella are thickened, sometimes extremely so, due to the presence of paraxonemal (paraxial) rods: As in other Euglenozoa, the rod in the dorsal flagellum has a tubular appearence when viewed in transverse section using TEM, while the rod in the ventral flagellum is a 3-dimensional lattice.
- The flagellar apparatus consists of two basal bodies (ventral and dorsal, representing basal bodies 1 and 2, respectively) and three microtubular roots: the dorsal root (R3), the ventral root (R2), and the intermediate root (R1), as in most other Euglenozoa (numbering for basal bodies and roots after Yubuki and Leander 2013).
- Freshwater lineages have contractile vacuoles associated with the reservoir.
- Photoautotrophic species have green plastids (chloroplasts) containing chlorophylls *a* and *b*. The plastids are surrounded by three membranes and have thylakoids in stacks of three. Pyrenoids are absent in the Phacaceae (*Discoplastis*, *Phacus,* and *Lepocinclis*) and *Euglenaformis*.
- Photoautotrophic species respond to the direction and intensity of light using a shading stigma ("eyespot") and a photosensory swelling at the base of the emergent flagellum.
- Cells have a feeding apparatus consisting of a tube or pocket reinforced longitudinally by microtubules. These originate ultimately from the ventral root, where traced (e.g., Surek and Melkonian 1986; Willey and Wibel 1987). The feeding apparatus in many phagotrophs is further elaborated by four or five electron-dense "vanes" and reinforced by two robust rods partly composed of microtubules. The feeding apparatus in photoautotrophic and osmotrophic species is highly reduced.
- Diverse and dynamic modes of motility are seen, including metaboly, substrate-mediated gliding, and swimming.
- Mitochondria have discoidal (paddle-shaped) cristae (as in other euglenozoans).
- The nucleus has permanently condensed chromosomes and a conspicuous nucleolus.
- The main storage polymer of most euglenids (perhaps all) is paramylon, a distinctive beta-1,3-glucan. Cytoplasmic paramylon granules may be small or extremely large (especially in some photoautotrophic species).
- Extrusomes (ejectile organelles) are common, almost always in the form of "typical" tubular extrusomes, mucocysts, or muciferous bodies.
- The Golgi bodies are usually elaborate, with a large number of cisternae (see Fig. 11a).
- Cytokinesis involves a longitudinal cleavage furrow.

Pellicle and Metaboly

The best synapomorphy for the Euglenida is a novel cytoskeleton comprised of parallel proteinaceous strips, underlain by microtubules, that run along the length of the cell (Leander 2004; Leander and Farmer 2000a, 2001a; Leander et al. 2001a, b) (Figs. 1, 5c, d, 6, 7). These elements are positioned immediately beneath the plasma membrane and are closely associated with cisternae of the endoplasmic reticulum. Collectively, this ultrastructural system is referred to as the euglenid pellicle.

The number of individual strips varies from 4 or 5 in some petalomonads to 120 in some very large euglenophytes (Esson and Leander 2008). Bacterivores (petalomonads and ploeotiids) have 12 or fewer longitudinal strips (often 8 or 10) that are fused to form a rigid pellicle. Eukaryovores (e.g., peranemids and anisonemids) have 20 to about 60 strips that are usually helically arranged and slide to allow metaboly; photoautotrophic (and secondarily osmotrophic) euglenids have 16–120 helically arranged strips, and most are capable of metaboly (Leander et al. 2007). However, some photoautotrophs (and secondary osmotrophs) have

secondarily become rigid and have longitudinally arranged strips. The earliest diverging primary osmotrophs (e.g., *Distigma*) have about 20 helically arranged strips and are metabolic; however, some lineages became rigid and now have fewer strips (e.g., 14) that run more longitudinally and that are often fused into a continuous proteinacous layer around the cell (e.g., *Menoidium* and *Rhabdomonas*; Leander et al. 2001b; Fig. 7f).

The strips are composed mostly of a family of proteins called "articulins" (Marrs and Bouck 1992). In general, the main frame of each pellicle strip is "S-shaped" in cross section and consists of an arch region and a heel region that defines a groove (Leander et al. 2007; Leander and Farmer 2001a) (Fig. 6). Adjacent strips articulate along their lateral margins; the strip arch overlaps with the heel of a neighboring strip, giving the surface of euglenid cells a striated appearance (Fig. 6).

The articulation zones between adjacent strips allow the dynamic changes in cell shape called "metaboly," "euglenoid motion," or "euglenoid movement" (Fig. 4a, b). They also facilitate cytoskeletal replication prior to cell division (i.e., cytokinesis). Metaboly is observed in most cells that have a large number of pellicle strips (16 or more). As well as serving a secondary locomotory role, metaboly is thought to facilitate the ingestion of large food particles, such as other eukaryotic cells, in eukaryovorous phagotrophs (Leander 2004; Leander et al. 2001, 2007; Yamaguchi et al. 2012).

In photoautotrophic and secondary osmotrophic lineages, the frame of each strip contains periodic arrays of projections that branch laterally from the heel (Leander et al. 2001b, 2007; Leander and Farmer 2001a). The projections of one strip articulate with the projections of an adjacent strip beneath the arches (Fig. 6). The projections that branch beneath the arch of an adjacent strip, so-called prearticular projections, and those that branch beneath the arch of the same strip, so-called postarticular projections, can vary considerably in robustness: some lineages possess delicate threadlike projections; some species possess more robust toothlike projections; and some species possess projections that form robust continuous plates (Fig. 6). Euglenid cells with more delicate strips tend to demonstrate more dramatic degrees of metaboly (Fig. 5); euglenid cells with robust strips tend to be rigid, or nearly so (Angeler et al. 1999; Leander 2004; Leander et al. 2001b, 2007; Leander and Farmer 2001a) (Fig. 7). Phagotrophic and primary osmotrophic euglenids lack strip projections altogether.

The euglenid pellicle is multigenerational; each strip or cohort of strips represents a different cytokinetic event in the history of any particular cell (Esson and Leander 2006, 2008; Leander et al. 2007; Yubuki and Leander 2012). Prior to cytokinesis, the number of pellicle strips around the cell periphery doubles. Each daughter cell (usually) inherits the same number of pellicle strips as the parent cell in a semiconservative manner. During strip doubling, new strips emerge within the articulation zones between mature strips. In the photoautotrophic euglenids, the newly produced pellicle strips do not extend to the posterior tip of the cell and consequently form whorled surface patterns of strip termination (Esson and Leander 2006, 2008; Leander and Farmer 2000a; Leander et al. 2001b). Strips that terminate before reaching the posterior tip of the cell occupy a relative position along the length of

the cell called a "whorl." The number of posterior whorls varies between different species, ranging from one to four. In some species, the whorls themselves can be dissociated into one or more subwhorls (Esson and Leander 2008; Leander and Farmer 2000a; Leander et al. 2001b; Yubuki and Leander 2012). Comparative analyses of the strip termination patterns in several different species have provided important insights into the developmental processes associated with the control and evolutionary diversification of the euglenid pellicle (Esson and Leander 2006, 2008; Leander and Farmer 2000a; Leander et al. 2001b; Yubuki and Leander 2012).

Variation in the number of strips within many species (though usually with a strong mode) indicates that strips are not necessarily distributed evenly during cell division. For instance, a parent cell with 40 strips doubles the number of strips to 80 prior to cell division. In most cases, the two daughter cells will each receive 40 strips and recover the number that was present in the parent cell. In other cases, the daughter cells might receive some other proportion, such as 38 and 42 or 36 and 44. It is also possible that strip duplication is not always faithful; for instance, a parent cell with 40 strips might only produce 39 new strips, in which case the daughter cells will receive 39 and 40 strips, respectively.

Permanent strip duplication events refer to cases where a cell duplicates its strips but fails to divide. Permanent strip halving events refer to cases where a cell divides without duplicating its strips. The distribution of strip numbers found in euglenids suggests that these events happened several times during the evolution of the group (see "Evolutionary History").

Flagella and Locomotion

Most euglenids possess two heterodynamic flagella that emerge from the flagellar pocket. A few lineages have more than two (e.g., some Eutreptiales have four flagella; McLachlan et al. 1994), and some have highly reduced flagella, giving the appearance of one or none when viewed with the light microscope (Figs. 2, 3, 4, and 5). Euglenids possess paraxonemal (paraxial) rods within the flagella that run alongside the 9 + 2 microtubular axoneme (Fig. 8a, b). The paraxonemal rods make euglenid flagella conspicuously thick when viewed under the light microscope (e.g., Fig. 5b); the thickest flagellum can approach or exceed 1 μm width in many larger cells, especially in large phagotrophic euglenids (e.g., Larsen and Patterson 1990). The paraxonemal rod in each flagellum has a different structure: the rod in the ventral flagellum has a latticelike structure, and the rod in the dorsal flagellum has, at core, a whorled structure that appears tubular in transverse sections (Fig. 8a, b). A major component of both structures are the paraxonemal rod proteins PAR1 and PAR2, whose genes arose through duplication prior to the divergence of euglenids and kinetoplastids (Talke and Preisfeld 2002).

Euglenid flagella characteristically have very thick investments of fine hairs, which generally emerge in horizontal (or shallowly helical) rows of tufts associated with the flagellar axoneme and/or paraxonemal rod (Bouck et al. 1978; Dawson and Walne 1991; Hilenski and Walne 1985; Mignot 1965, 1966) (Fig. 8). These hairs

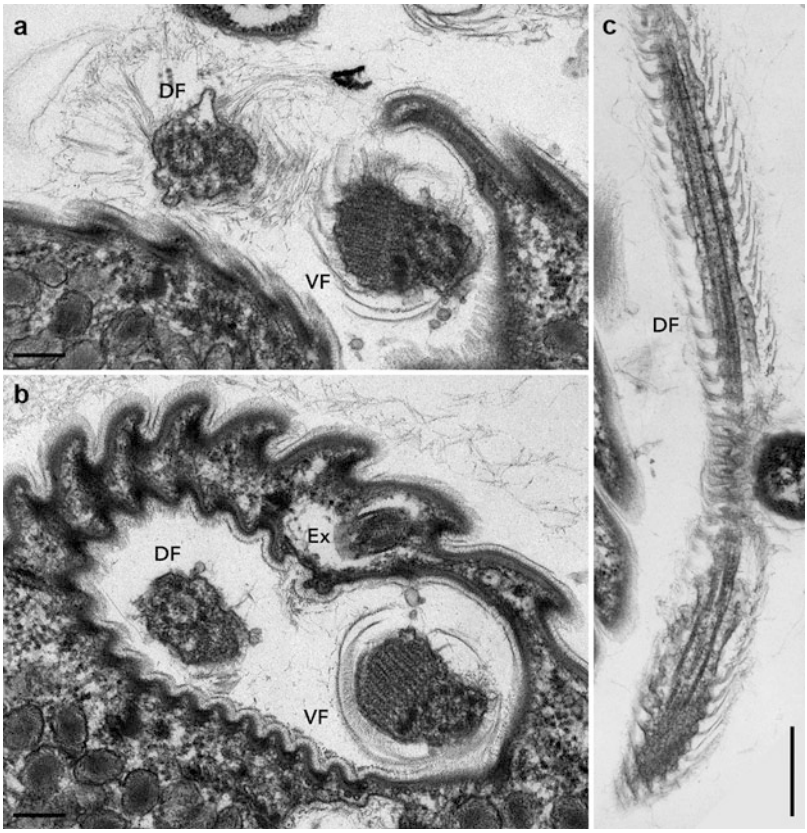

Fig. 8 Transmission electron micrographs of flagella. (**a**, **b**) Near-transverse sections of the proximal portions of the dorsal/anterior flagellum (*DF*) and ventral/posterior flagellum (*VF*), showing the paraxonemal rods (tubular in *DF*, latticed in *VF*) and the flagellar hairs. Note also the oblique section of an undischarged tubular extrusome (*Ex*); *Neometanema parovale*. (**c**) Longitudinal view of dorsal/anterior flagellum (distal end to top of page), showing flagellar hairs; *N. parovale*. Scale bars: **a**, 200 nm; **b**, 200 nm; **c**, 500 nm. typically lie oriented with their distal ends pointing toward the distal end of the flagellum (Fig. 8c). In addition, emergent flagella may have a single longitudinal row of bundles of larger hairs, which can be several micrometers long; these hairs are best studied in the sole emergent flagellum of Euglenean photoautotrophs such as *Euglena* (e.g., Leedale 1967; Bouck et al. 1978; Melkonian et al. 1982). The phototroph *Eutreptia*, which has two emergent flagella, has these rows of bundles of long hairs on both flagella (Dawson and Walne 1991), as, apparently, does the biflagellated primary osmotroph *Distigma proteus* (Leedale 1967), while the

peranemid eukaryotroph *Peranema* has them on the anterior flagellum only (Hilenski and Walne 1985). Petalomonads have sparser arrangements of flagellar hairs than other euglenids and/or finer hairs (though data is limited; Cann and Pennick 1986; Lee and Simpson 2014b), while flagellar hairs have not been reported at all in symbiontids (Yubuki et al. 2009).

In phagotrophic lineages, the flagella are heterodynamic, with one flagellum (i.e., the dorsal/anterior flagellum) held ahead of the cell, while the other flagellum (i.e., the ventral, recurrent, or posterior flagellum) bends backward and extends posteriorly from the cell, often within a ventral groove or sulcus (Figs. 2b–e, 5b). The hairs and paraxonemal rods of these flagella facilitate gliding motility across substrates (Saito et al. 2003). In petalomonads and peranemids, the dorsal/anterior flagellum is involved in gliding. During this gliding most of the anterior flagellum is held stiffly against the substrate, but the tip is in constant motion and functions as a sensory apparatus (Figs. 2a, c and 5a). In these cells the posterior/ventral flagellum is shorter and thinner than the anterior flagellum; in some cases it lacks a paraxonemal rod, does not emerge from the reservoir, or is completely absent (e.g., Cann and Pennick 1986; Lee and Simpson 2014b). In ploeotiids and anisonemids, only the posterior flagellum is involved in gliding, and the whole anterior flagellum sweeps from side to side; in these cells the anterior flagellum is almost always thinner and usually shorter than the posterior flagellum (Figs. 2b, d, e and 5b). Some phagotrophic euglenids also use the anterior flagellum like a hook to shovel prey cells into the feeding apparatus (Breglia et al. 2013).

Most osmotrophic and photoautotrophic euglenids primarily move using swimming motility (Leander 2004). They usually possess an emergent dorsal flagellum that extends from the canal and is highly dynamic, while the reduced ventral flagellum does not emerge from the canal and is inactive. The emergent flagellum beats in an organized and consistent pattern that takes the form of a "figure-eight" or a lasso. This beat pattern pulls the euglenid cell through the water column (Leander 2004). By contrast, eutreptialean photoautotrophs possess two emergent flagella that both beat during swimming (some primary osmotrophs also have two emergent flagella).

Although phagotrophic euglenids are usually poor swimmers, the symbiontid *Postgaardi* swims with a spiralling motion (Simpson et al. 1997), while the anisonemid-like *Neometanema* normally moves by rapidly "skidding" (i.e., swimming while maintaining physical contact with the substrate), powered by beating of the anterior/dorsal flagellum (Lee and Simpson 2014a; see Larsen and Patterson 1990, 2000). Conversely, gliding is seen in some photoautotrophic euglenids (Euglenophyceae), but gliding cells typically hold the cell body against the substrate, not the flagellum (which is often greatly shortened).

Flagellar Apparatus

The flagellar axonemes are anchored by basal bodies that are situated at the base of the flagellar pocket: the ventral flagellum originates from the ventral basal body, and

the dorsal flagellum originates from the dorsal basal body. A striated fiber connects both basal bodies. Three microtubular roots extend from the basal bodies: the dorsal root extends from the lateral side of the dorsal basal body, the ventral root extends from the lateral side of the ventral basal body, and an intermediate root extends from the medial side of the ventral basal body and thus lies initially between the basal bodies (Yubuki and Leander 2012). In the universal numbering system for the eukaryotic flagellar apparatus, the ventral basal body represents basal body 1, and the dorsal basal body is basal body 2 (i.e., the dorsal basal body is predicted to transform into the ventral basal body during cell division; Moestrup 2000). Meanwhile the dorsal root represents R3, the ventral root R2, and the intermediate root R1 (Yubuki and Leander 2013, noting that the identification of the roots in Moestrup 2000 was inaccurate). This flagellar apparatus constitutes the organizing center from which several other cytoskeletal elements arise – such as the microtubules associated with the cell surface (or pellicle), which originate in association with the dorsal root, and the central microtubules of the feeding apparatus, which, when traced, prove to originate from the ventral root (Belhadri et al. 1992; Belhadri and Brugerolle 1992; Farmer and Triemer 1988; Hilenski and Walne 1985; Leander 2004; Shin et al. 2001, 2002; Simpson 1997; Solomon et al. 1987; Surek and Melkonian 1986; Willey and Wibel 1985; Yubuki and Leander 2012).

Feeding Apparatus

Phagotrophic euglenids have feeding apparatuses that range from relatively simple microtubule-reinforced pockets or tubes (MtR pockets) to highly complex systems of rods and vanes (Leander et al. 2007; Triemer and Farmer 1991a, b). One major group of bacterivorous euglenids, petalomonads, have MtR pockets, with some of the reinforcing microtubules likely derived from the ventral root of the flagellar apparatus via the MtR structure (although this connection has not been proved yet in any species; Lee and Simpson 2014b). Ploeotiids (e.g., *Ploeotia* and *Entosiphon)* and eukaryovorus euglenids possess feeding apparatuses that are much more complex. These include two robust rods composed of ordered arrays of microtubules embedded within an amorphous matrix (Triemer and Farmer 1991a; Linton and Triemer 1999). In *Entosiphon*, one of the rods bifurcates near the anterior end of the cell and gives the impression of three feeding rods in transverse view (Triemer and Fritz 1987; Leander et al. 2007). The feeding rods in ploeotiids typically extend the entire length of the cell, as do those of some eukaryovorous euglenids, like *Dinema*. By contrast, the feeding rods are confined to the anterior third of the cell in eukaryovorous euglenids that are capable of extreme metaboly, such as *Peranema*, *Urceolus*, and *Jenningsia*. A smaller "accessory rod" is sometimes positioned along the lateral margin of each feeding rod in both bacterivorous and eukaryovorous euglenids (Nisbet 1974; Breglia et al. 2013). Between the two feeding rods are four to five plicate or lamellar vanes, depending on the species.

The action of the feeding apparatus has been studied in some detail in *Entosiphon*; when a prey cell is about to be ingested, the rods of the feeding

apparatus protrude from the anterior end of the cell, and the vanes twist open like the blades of a pinwheel (Triemer and Fritz 1987). When the feeding apparatus retracts, the vanes twist back into their original position, gripping and internalizing the prey in the process. Although most phagotrophic euglenids ingest their prey whole, some euglenids (e.g., *Peranema*) can also feed by myzocytosis (Triemer 1997). This mode of feeding is vampire-like, in that the feeding rods pierce the prey cell, allowing the cell contents to be sucked into a phagosomal vacuole within the euglenid. The feeding apparatuses present in photoautotrophic and osmotrophic euglenids are highly reduced, corresponding to the switch from predominantly phagotrophic modes of nutrition to photoautotrophy and surface absorption, respectively (Leander et al. 2001a; Shin et al. 2002; Surek and Melkonian 1986; Willey and Wibel 1985).

Plastids (Chloroplasts)

Photoautotrophic euglenids (Euglenophyceae) evolved once from eukaryovorous euglenid ancestors that established a secondary endosymbiosis with green algal prey cells (Gibbs 1978; Leander 2004). These algae were related to the prasinophyte *Pyramimonas* (Turmel et al. 2009; Hrdá et al. 2012). The chloroplasts of euglenophytes are themselves green, are surrounded by three membranes, and possess thylakoids in stacks of three (Fig. 9). Most euglenid plastids contain a conspicuous pyrenoid (a region containing RuBisCO protein), although the small disc-shaped plastids of *Discoplastis*, *Lepocinclis*, *Phacus*, and *Euglenaformis* lack pyrenoids altogether (Figs. 3, 9a, c). Carbohydrate storage in the form of paramylon granules is also often associated with the pyrenoids, but is also distributed throughout the cytoplasm (Fig. 9a). Plastids with conspicuous paramylon caps on both sides

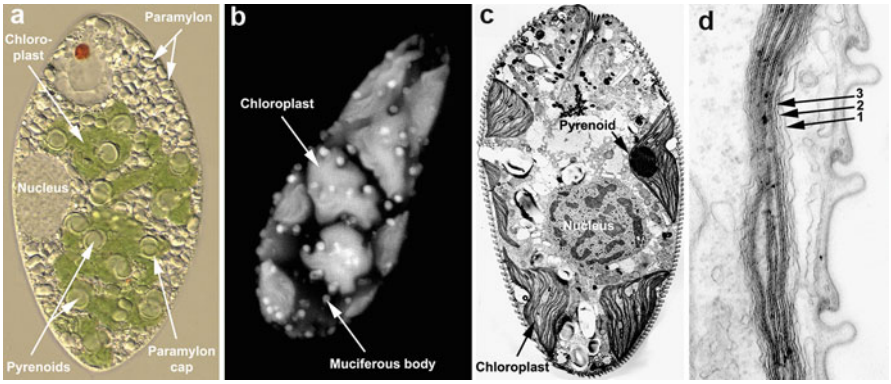

Fig. 9 Light and electron micrographs showing the general ultrastructure of chloroplasts (i.e., plastids) in *Euglena*. (**a**) Light micrograph showing paramylon, pyrenoids, chloroplasts, and the nucleus. (**b**) Confocal micrograph showing autofluorescence and the spatial distribution of chloroplasts and muciferous bodies. (**c**) Low magnification transmission electron micrograph showing the nucleus, pyrenoid, and chloroplasts. (**d**) High magnification transmission electron micrograph showing three membranes surrounding the chloroplast

of the pyrenoid are referred to as being "diplopyrenoidal" and on the one side as "haplopyrenoidal" (Brown et al. 2003; Monfils et al. 2011).

The number and morphology of euglenid plastids are very diverse (e.g., shield-shaped, disc-shaped, and star-shaped) and reflect evolutionary relationships, different stages in cell development and environmental conditions. Some photoautotrophic euglenids are known to switch nutritional modes and survive in the dark, whereby the plastids become "bleached" over time. Several different groups of photoautotrophic euglenids include species that have independently lost photosynthesis (e.g., *Euglena quartana*, *Euglena longa*, and *Lepocinclis cyclidiopsis;* Triemer and Farmer 2007; Bennett and Triemer 2014). Plastids with reduced genomes still exist in at least some of these secondary osmotrophs (e.g., *Euglena longa*, Hachtel 1998; see below).

The plastid genome of the model species *Euglena gracilis* was sequenced more than 20 years ago (Hallick et al. 1993). The genome is surprisingly large (~143 kb) but not because of the gene repertoire, which is relatively small (97 predicted genes), but due to extensive noncoding DNA sequence, including an enormous number of introns (~150). For comparison, the representative prasinophyte *Pyramimonas parkeae* has only one intron (Turmel et al. 2009). The next sequenced plastid genome was that of the secondarily non-photosynthetic species *Euglena longa* (Gockel and Hachtel 2000). This is about half the size of the *E. gracilis* plastid genome due to the loss of all genes encoding photosynthesis-related proteins, except for the *rbc*L gene encoding the large subunit of RuBisCO. The *E. longa* plastid genome is required for cell growth and viability (Gockel et al. 1994; Gockel and Hachtel 2000; Hadariová et al. 2016).

Fifteen more plastid genomes have been sequenced since 2010, covering most of the genera of Euglenophyceae (Bennett et al. 2012, 2014; Hrdá et al. 2012; Wiegert et al. 2012, 2013; Pombert et al. 2012; Bennett and Triemer 2015; Dabbagh and Preisfeld 2017; Kasiborski et al. 2016). Comparative studies revealed that they have very similar complements of protein-coding genes; however, there have been major changes in gene arrangement. The most striking differences are the numbers of introns. Two early-diverging Eutreptiales have few introns (7–23; Hrdá et al. 2012; Pombert et al. 2012; Wiegert et al. 2012), the only sequenced representative of Phacaceae (*Phacus orbicularis*) has 67, and representatives of Euglenaceae have 53–150. The pattern of intron proliferation observed in the Euglenophyceae corresponds with the number of identified maturases (Eutreptiales, 1; Phacaceae, 2; Euglenaceae, 3), which are possibly involved in intron mobility (Kasiborski et al. 2016).

Photoreception

Euglenophytes (and most secondary osmotrophs) can respond to the intensity and direction of light and orient themselves in the water column accordingly (Kuznicki et al. 1990). Photoreception is accomplished by an apparatus consisting of a photosensory swelling at the base of the emergent dorsal flagellum and a closely

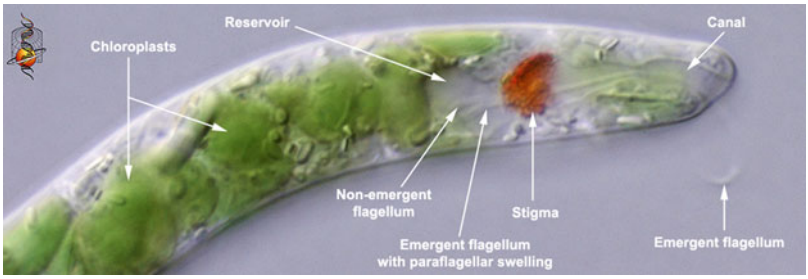

Fig. 10 Labeled light micrograph showing the photoreceptor apparatus in a photoautotrophic euglenid, consisting of an expanded reservoir, a canal, a paraflagellar swelling near the base of the emergent flagellum, and a shading stigma (i.e., eyespot). Credit: Linda Amaral Zettler and David Patterson

associated shading structure composed of orange or red carotenoids, called the "stigma" or "eyespot" (Fig. 10). The stigma of euglenids is positioned near the base of the flagellar pocket/reservoir. Interestingly, it lies in the cytoplasm, instead of being embedded within the plastid as in most other photosensory algae (e.g., within the green algae, dinoflagellates, and chrysophyceans). The stigma shades one side of the flagellar swelling; as the cell rotates through the water, the swelling can detect the direction of the most intense light source. The behavior of the swimming flagellum will then respond in a way that allows the cell to maintain a position in the water column that is optimal for photosynthesis.

There is evidence of a photosensory swelling and stigma in the phagotrophic eukaryovorous euglenid *Urceolus* (Leander et al. 2001a). This putative photoreception apparatus in *Urceolus* might enable it to maintain a position in light regimes favoured by its algal prey. There is no evidence that *Urceolus* has or had plastids, but it was inferred to be a close relative of Euglenophyceae in analyses of morphological data (Leander et al. 2001a), and thus it is possible that its putative photoreception apparatus is homologous to that of photoautotrophic euglenids.

Mitochondria

The mitochondria are distinctive in having stalked, paddle-shaped cristae, usually referred to as "discoidal" cristae (Fig. 11b). They are homologous to the discoidal cristae of ▶ Kinetoplastea and probably those of ▶ Heterolobosea. The mitochondrion of *Euglena gracilis* forms a large reticulated network (Pellegrini 1980). This conformation may be widespread among euglenids, although numerous separate elongated mitochondria are reported in some taxa (e.g., *Peranema*; Roy et al. 2007; Leedale 1967). The anaerobic symbiontids retain conspicuous mitochondria-related organelles; these have a homogeneous matrix, and profiles through them generally lack cristae altogether (Simpson et al. 1997; Yubuki et al. 2009; Fig. 11g). Nonetheless, a few flattened crista-like structures have been seen in *Bihospites bacati* (Breglia et al. 2010).

The mitochondrial genome of euglenids is not well understood. For example, it is only recently that the mitochondrial genome of *E. gracilis* was fully sequenced (Dobakova et al. 2015). This consists of a heterogeneous population of DNA molecules roughly 1–10 kb long (Spencer and Gray 2010; Dobakova et al. 2015) and houses just seven protein-coding genes, while the mitochondrial ribosomal RNAs are encoded as multiple fragments (Spencer and Gray 2010; Dobakova et al. 2015). No evidence of kinetoplastid-type RNA editing or RNA-editing machinery was found in *Euglena* (Dobakova et al. 2015). Nonetheless, transmission electron micrographs of the petalomonads *Petalomonas cantuscygni* and *Notosolenus urceolatus* show fibrous compacted inclusions within the mitochondria that are similar in appearance to the kDNA inclusions present in kinetoplastids (Leander et al. 2001a; Lee and Simpson 2014b). This fibrous nature was not seen in a subsequent study of *P. cantuscygni* (perhaps due to fixation differences); however, some small circular DNA molecules were observed in electron micrographs of mtDNA preparations, along with many larger linear molecules (Roy et al. 2007). Therefore, it is currently unclear whether the mitochondrial genomes of some deep-branching euglenids might contain "minicircles" (encoding "guide rRNA" genes) like those found in ▶ Kinetoplastea.

Extrusomes

Some typical bacterivorous euglenids display thick-walled "tubular extrusomes," often with cruciate central filaments, that are similar to those present in a few diplonemids and free-living kinetoplastids (Brugerolle 1985; Schuster et al. 1968). These extrusomes were studied in detail in the ploeotiid *Entosiphon sulcatum* (Mignot 1966; Mignot and Hovasse 1973). They are also present in all described symbiontids; *Bihospites,* Postgaardi, and *Calkinsia* (Breglia et al. 2010; Simpson 1997; Yubuki et al. 2009; Fig. 11c, d). Where well documented, these extrusomes are highly elongated in the undischarged state (>2 μm; see Fig. 11c) and expand in length during discharge into an open lattice structure (Breglia et al. 2010; Mignot 1966; Simpson et al. 1997). Their function has not been studied directly, but presumably they operate in predation or in protection from predation. A homologous but modified form is seen in some eukaryovorous euglenids. These are usually shorter, have a dense central region when in the undischarged state (Lee and Simpson 2014a; see Fig. 8b), and exhibit less length expansion upon discharge, where known (Hilenski and Walne 1983). They have been found in *Teloprocta*/*Heteronema scaphurum*, in *Neometanema parovale*, and in *Peranema trichophorum*, where they are called mucocysts (Breglia et al. 2013; Hilenski and Walne 1983; Lee and Simpson 2014a; Mignot 1966).

Mucilaginous bodies called "mucocysts" are present in two subclades within *Euglena* and might be homologous to the extrusomes of phagotrophic euglenids. Mucocysts of photoautotrophic euglenids sit beneath pores positioned in rows within the articulation zones between the pellicle strips (Leander et al. 2001b; Esson and Leander 2008). The number of strips between the rows of mucosyst pores is variable,

which makes them suitable diagnostic characters at the species level (Leander et al. 2001b; Kosmala et al. 2009).

Tubular extrusomes have not been observed in petalomonads, instead various globular membrane-bounded bodies have been imaged or illustrated in ultrastructural reports (see Lee and Simpson 2014b). The only detailed study is in *Notosolenus urceolatus*, where the bodies are pill-shaped or rounded, about 0.5 μm in diameter and have a dense axial core (Fig. 11e). Typically, several are present in the anterior portion of the cell. It was proposed that these organelles represent a class of extrusome that is not homologous to the tubular extrusomes of other euglenozoans, but discharge has not been observed (Lee and Simpson 2014b).

The symbiontid *Bihospites* possesses ejectile ectosymbionts, known as epixenosomes, in addition to tubular extrusomes (Breglia et al. 2010). These epixenosomes are verrucomicrobial bacteria and are closely related to similar defensive symbionts reported earlier in certain ciliates (Petroni et al. 2000). In *Bihospites* the epixenosomes lie in rows between the rod-shaped epibiotic bacteria (see "Habitats and Ecology") and discharge by rapidly unwinding a central filament structure (Breglia et al. 2010).

Extracellular Structures

Conspicuous extracellular structures enclosing the main cell body are rare in euglenids. A strikingly thickened glycocalyx is present in several taxa, including *Neometanema* and several osmotrophs (Lee and Simpson 2014a). Most spectacularly, a group of photoautotrophic euglenids comprising *Trachelomonas* and *Strombomonas* produce a globular organic lorica that may be smooth or decorated with spines. The lorica has a single opening for the flagellum, and the cells locomote by swimming. The primary component of the lorica is mucus (Hilenski and Walne 1983; Mignot 1966), and during its development, the lorica slowly becomes thicker and ornamented. Iron and manganese are the main nutrients necessary for the lorica formation (e.g., Pringsheim 1953; Singh 1956). Differences in lorica formation between *Trachelomonas* and *Strombomonas* (Brosnan et al. 2005) are concordant with molecular phylogenetic data showing two distinct genera of loricate euglenids (e.g., Brosnan et al. 2005; Ciugulea et al. 2008). The sister group to the loricates is *Colacium*, which also has the ability to produce copious amounts of mucus, but instead forms mucilaginous stalks and dendroid colonies (Leedale 1967).

The Nucleus, Reproduction, and Cytokinesis

Euglenids cells usually have a single, large nucleus during interphase. The nucleus typically has a conspicuous subcentral nucleolus and large amounts of permanently condensed chromatin. This chromatin may give the nuclear material a lumpy appearance when viewed by light microscopy (Fig. 5e) and appears electron dense in transmission electron micrographs (Fig. 11f, g; see also Fig. 9c).

The nuclear genome organization of euglenids exhibits some bizarre features; rRNA genes are extrachromosomal, circular molecules, with thousands of copies per cell (Cook and Roxby 1985; Ravel-Chapuis 1988). Moreover, three types of introns are present in euglenid genomes; in addition to conventional spliceosomal introns, both noncanonical introns (for which a splicing mechanism is unknown) and so-called intermediate introns have been documented (Canaday et al. 2001; Milanowski et al. 2014). All euglenid species studied so far add a noncoding capped spliced-leader (SL) RNA to nucleus-encoded mRNAs via spliceosome-dependent *trans*-splicing (Frantz et al. 2000; Kuo et al. 2013), a process also reported in the other groups of Euglenozoa: kinetoplastids (Walder et al. 1986) and diplonemids (Sturm et al. 2001, Gawryluk et al. 2016). Full sequencing of the nuclear genome of *Euglena gracilis* is in progress but has been hindered by the genome size (approximately 2 Gb) and the high percentage of repetitive regions (O'Neill et al. 2015; see also EuglenaDB https://sites.dundee.ac.uk/euglenadb/). Furthermore, the nuclear DNA contains the unusual base "J," which makes up approximately 0.2% of all the bases (Dooijes et al. 2000) and hampers sequencing.

Asexual reproduction in euglenids occurs by mitosis followed by cytokinesis. The basal bodies and associated flagellar root system replicate first, followed by the feeding apparatus (if present) and then the pellicle. In many species the probasal bodies form early in interphase, such that they are present alongside the flagellated basal bodies in most cells within a population (e.g., *Entosiphon*; Solomon et al. 1987; *Peranema*; Hilenski and Walne 1985).

The mechanics of mitosis in euglenids was summarized at the level of light microscopy by Leedale (1967) and at the ultrastructural level by Triemer and Farmer (1991a). As with many protists, the nuclear envelope persists throughout mitosis, and the nucleolus does not break down but elongates and divides (in a few species, there are multiple nucleoli that divide separately; Leedale 1967; Zakryś 1986). The chromosomes are usually reported as permanently condensed (see above) but attached to the nuclear envelope prior to mitosis; they detach to assemble loosely at the division plane during metaphase (though spindle microtubules connect to the chromosomes before detachment in *Anisonema*; Triemer 1985). The relative timing of this assembly on one hand, and the process of chromosome replication through the separation of sister chromatids on the other, reportedly varies from species to species (Leedale 1967). The mitotic spindle system is intranuclear, with microtubules originating against the nuclear envelope. Almost all accounts indicate the presence of multiple subspindles originating from different foci around each pole of the dividing nucleus (Triemer and Farmer 1991a). Separation of the chromosomes is initially due to elongation of the nucleus rather than shortening of the spindle microtubules, which only happens near the end of anaphase; Triemer and Farmer (1991a) refer to this pattern as a "reversed anaphase A/B sequence." There is normally an association of the poles of the dividing nucleus and the replicated flagellar apparatus, but not always; in *Anisonema* the flagellar apparatus completes replication and begins segregation only after mitosis is well advanced (Triemer 1985).

After the nucleus and cytoskeleon have duplicated, a cleavage furrow forms at the base of the flagellar pocket near the basal bodies and migrates toward the anterior opening, forming two flagellar pockets within the cell. The cleavage furrow subsequently migrates posteriorly down the longitudinal axis of the cell; the posterior tip of the cell is the last part to become cleaved. The cleavage furrow forms between a (mature) parent strip and a newly generated (nascent) strip on two sides of the cell (Esson and Leander 2006). Each daughter cell (usually) contains the same number of pellicle strips as the parent cell (Yubuki and Leander 2012); however, an unequal distribution of strips can also occur during cytokinesis (see above).

Sexuality is almost unknown in euglenids, but Mignot (1962) gave a light microscopy account of a small petalomonad, *Scytomonas pusilla*, that included normal-looking cells behaving as isogametes and undergoing syngamy (i.e., pairs of cells fused, and then their nuclei fused).

Taxonomy

About 1500 species of euglenids are recognized, with the majority being photoautotrophs. The taxonomy of the photoautotrophs was extensively scrutinized over the last 20 years based on molecular and morphological data, and the current assignment of species to genera largely follows phylogeny. Notably, a large number of species that were formerly placed within *Euglena*, but are not closely related, have been given new generic assignments. Conversely, certain genera of secondary osmotrophs have been suppressed on phylogenetic grounds (e.g., *Hyalophacus* – Marin et al. 2003; *Cyclidiopsis* – Bennett and Triemer 2014). The traditional genus *Astasia* turned out to include species of both primary and secondary osmotrophs, but now includes only primary osmotrophs.

Photoautotrophic euglenids, or Euglenophyceae, are a monophyletic group (Marin et al. 2003; Karnkowska et al. 2015; Kim et al. 2015; Cavalier-Smith 2016) comprising the basal monotypic genus *Rapaza* (Yamaguchi et al. 2012), Eutreptiales and Euglenales (here and elsewhere we use the dominant botanical-tradition naming for higher taxa of Euglenophyceae; see Cavalier-Smith 2016 for a recent but particular "zoological" taxonomy for photoautotrophic euglenids). Eutreptiales comprise two predominantly marine genera – *Eutreptia* and *Eutreptiella* – while a third genus, *Tetraeutreptia,* was subsumed within *Eutreptiella* (Marin et al. 2003; Cavalier-Smith et al. 2016). Due to the limited number of taxa and genes used for phylogenetic reconstructions, the genus-level taxonomy is not well resolved within the Eutreptiales and *Eutreptiella* might be paraphyletic (Marin et al. 2003; Cavalier-Smith 2016). The Euglenales is much more diverse and is subdivided into two clades: Phacaceae (with three genera) and Euglenaceae (with eight genera).

The Phacaceae contains *Discoplastis*, *Lepocinclis*, and *Phacus* (Kim et al. 2010; Linton et al. 2010; Karnkowska et al. 2015; Kim et al. 2015). *Discoplastis* was erected to accomodate two species previously classified in the genus *Euglena* (Triemer et al. 2006). *Phacus* and *Lepocinclis* are closely related (Kim et al. 2010;

Linton et al. 2010; Karnkowska et al. 2015; Kim et al. 2015). Both genera have been intensively studied over the last 15 years, with several species transferred from other genera to either *Phacus* (Linton et al. 2010) or *Lepocinclis* (Marin et al. 2003; Kosmala et al. 2005; Bennett and Triemer 2012; Bennett and Triemer 2014). Those taxonomic changes resulted in the loss of morphological characters distinguishing those two genera (Linton et al. 2010). Some phylogenetic analyses have indicated paraphyly of the genus *Phacus* (Kim and Shin 2014; Karnkowska et al. 2015); however, the most comprehensive study (Kim et al. 2015) supported the division into two genera.

The Euglenaceae contains seven monophyletic genera (*Euglenaria*, *Euglenaformis*, *Colacium*, *Cryptoglena*, *Monomorphina*, *Strombomonas*, and *Trachelomonas*) and the paraphyletic *Euglena* (Kim et al. 2010; Linton et al. 2010; Karnkowska et al. 2015; Kim et al. 2015). The earliest branching lineage is the recently established genus *Euglenaformis* (Bennett et al. 2014) with one species, *Euglenaformis proxima* (formerly *Euglena proxima*). The remaining genera form two sister clades. One clade includes *Colacium* and the closely related loricate genera *Trachelomonas* and *Strombomonas*. Marin et al. (2003) proposed merging *Trachelomonas* and *Strombomonas*, but all recent phylogenetic analyses have supported their phylogenetic distinction (Brosnan et al. 2005; Triemer et al. 2006; Ciugulea et al. 2008; Kim and Shin 2008; Kim et al. 2010; Linton et al. 2010; Karnkowska et al. 2015; Kim et al. 2015). The second clade includes the closely related rigid genera *Monomorphina* and *Cryptoglena,* together with *Euglena* and *Euglenaria* (Karnkowska et al. 2015; Kim et al. 2010, 2015; Linton et al. 2010). *Euglenaria* was erected to accommodate three *Euglena* species placed outside the main clade of *Euglena* (Linton et al. 2010). *Euglenaria* is sister to *Monomorphina* and *Cryptoglena* in most phylogenetic analyses (Linton et al. 2010; Kim et al. 2010; Karnkowska et al. 2015), but branched as sister to *Euglena* in one recent study (Kim et al. 2015). The taxonomy of the genus *Euglena* is the most problematic because species which did not fit morphologically into other genera were assigned to it, resulting in an amalgam of species. Currently, two species of *Euglena* fall outside the main well supported *Euglena* clade: *E. archaeoplastidiata* (Kim and Shin 2008; Kim et al. 2010; Karnkowska et al. 2015; Kim et al. 2015) and *E. velata* (Karnkowska-Ishikawa et al. 2012; Kim et al. 2015).

The genera *Euglenamorpha* and *Hegneria*, which were originally observed in tadpole guts, are not represented in any molecular phylogenetic trees. Therefore, their validity and phylogenetic positions are questionable.

Most of the species of phototrophic euglenids were described in the nineteenth and twentieth centuries based solely on morphology. Thousands of taxa have been described (~3000 including forms and varieties according to AlgaeBase: http://www.algaebase.org) because of the great morphological diversity of euglenid cells. The species-level taxonomy of the group is riddled with duplications and re-descriptions, as well as formulations of artificial classification schemes. The advent of DNA sequencing combined with careful morphological investigation allowed some of the taxonomic confusions to be resolved. Many species have been verified, and new taxa have been described to accommodate the observed

molecular and morphological diversity (Bennett and Triemer 2012; Kosmala et al. 2005, 2007a, 2007b, 2009; Karnkowska-Ishikawa et al. 2010, 2011, 2012, 2013, 2014; Kim et al. 2013a, b, 2014; Kim et al. 2016; Linton et al. 2010; Łukomska-Kowalczyk et al. 2015; Shin and Triemer 2004; Zakryś 1997; Zakryś et al. 2002, 2004, 2013).

The primary osmotrophs (Aphagea) are a phlyogenetically cohesive group that includes the Rhabdomonadales (*Menoidium*, *Rhabdomonas*, *Gyropaigne*, *Parmidium*, and *Rhabdospira*) plus *Distigma* and *Astasia* (see above). Both *Distigma* and *Astasia* appear to be paraphyletic at present (Preisfeld et al. 2001; Muellner et al. 2001; Cavalier-Smith 2016).

The taxonomy of phagotrophs is far less well organized than that of photoautotrophic euglenids, partly because sequence information is sparse. Current genus-level taxonomy is a mix of traditional systems that emphasize a few conspicuous morphological characters on one hand (e.g., flagellar number and lengths, degree of flexibility, visibility of the feeding apparatus) and molecular phylogenetic information derived from very few species on the other (plus a small amount of ultrastructural data). The genus-level taxonomy is covered here using the four informal assemblages introduced earlier. Throughout we will use the the predominant "zoological" genus names (but see below).

Petalomonads (Petalomonadida) are probably monophyletic, and this group contains several dozen species assigned to the genera *Petalomonas*, *Notosolenus*, *Calycimonas*, *Sphenomonas*, *Scytomonas*, *Tropidoscyphus*, *Atraktomonas*, the recently created *Biundula*, and perhaps *Dolium* and *Dylakosoma* (Lee and Simpson 2014b; Cavalier-Smith 2016). The boundaries among many of these genera are highly uncertain; the morphological differences between them are often subtle, and some are known to currently represent non-monophyletic groupings (e.g., *Notosolenus*; Lee and Simpson 2014b). Much better DNA sequence coverage of genera and species (including type species) is needed, and it is likely to precipitate considerable changes to the genus-level taxonomy.

Most ploeotiid species, with the exception of *Entosiphon* spp., were descibed within the last 30 years, and most have been included at some point in the genus *Ploeotia* (Larsen and Patterson 1990). However recent phylogenies inferred from SSU rDNA sequences indicate that ploeotiids are genetically diverse and not monophyletic (Lax and Simpson 2013; Chan et al. 2013; Cavalier-Smith 2016; Cavalier-Smith et al. 2016), and the current trend is to recognize several genera in addition to *Ploeotia* (and *Entosiphon*), namely, *Decastava, Keelungia*, *Lentomonas*, and *Serpenomonas* (see Chan et al. 2013; Cavalier-Smith 2016). These are a mix of new taxa and genera that were previously considered as synonyms of *Ploeotia*. The rational distribution of most ploeotiid species to genera awaits further molecular sequence data (e.g., from the type species of *Ploeotia, P. vitrea*).

Peranemids include several genera, namely *Peranema*, *Chasmostoma*, *Urceolus*, and *Jenningsia* (and *Peranemopsis*, a synonym of *Jenningsia* according to Lee et al. 1999), as well as most but not all of the organisms that have typically been assigned to *Heteronema* (see below), including that assigned to the newly proposed *Teloprocta* (Cavalier-Smith et al. 2016). Peranemids in this broad sense

are probably not monophyletic (note that the taxa Peranemia, Peranemida, and Peranemidae have all recently been used to encompass just *Peranema*, *Urceolus, Jenningsia*, and *Peranemopsis*; Cavalier-Smith 2016; but this more restricted "peranemid" assemblage is likely not monophyletic either). As of late 2016, there are sequences available from just two species from this entire assemblage, so the phylogenetic appropriateness of the genus-level taxonomy is difficult to evaluate at present.

The anisonemid assemblage includes *Dinema* and *Anisonema* and, almost certainly, some species currently assigned to *Heteronema* (see below). It is unclear at present whether anisonemids are monophyletic (compare Lax and Simpson 2013; Lee and Simpson 2014a; Cavalier-Smith 2016). The assignment of species to *Anisonema* and *Dinema* is problematic; molecular phylogenies usually recover *Dinema* as non-monophyletic (Lee and Simpson 2014a; Cavalier-Smith 2016), while *Anisonema* has a very diffuse circumscription, to the extent that some species are probably actually ploeotiids.

Neometanema and the taxonomic entity *Semihia* are related to (and possibly derived from) anisonemids, from which they differ by having a distinctive "skidding" motility, although they also retain a supplementary ability to glide (Lee and Simpson 2014a). *Neometanema* and *Semihia* collectively absorb all the euglenid species previously assigned to *Metanema* (e.g., Larsen 1987), which has a zoological homonym, as well as a couple of species of *Heteronema* (see below; Lee and Simpson 2014a). Molecular phylogenetic analysis shows with moderate support that *Neometanema* is closely related to Aphagea (Lax and Simpson 2013; Lee and Simpson 2014a; Cavalier-Smith 2016), and the taxon name Natomonadida has recently been proposed for this grouping, based on the frequent use of swimming locomotion (Cavalier-Smith 2016).

The genus *Heteronema* is particularly problematic. At present it mainly includes "peranemids," but also includes a small number of "anisonemids" (see Larsen and Patterson 1990) even after the recent transfer of species to *Neometanema* (Lee and Simpson 2014a). Although the first described *Heteronema, H. marina* (Dujardin 1841), was some kind of anisonemid (as defined here), the modern concept of the genus comes from Stein (1878) and is based on peranemid species. This switch has long been recognized and tolerated (Larsen and Patterson 1990). Cavalier-Smith (2016) recently proposed returning to Dujardin's earlier concept, but we advocate overlooking this proposal, which is potentially destabilizing for no real gain (and if carried to a logical conclusion, could dramatically affect the application of the genera *Dinema* and/or *Anisonema* as well as *Heteronema)*.

The Symbiontida (synonym Postgaardea – see Cavalier-Smith et al. 2016) encompasses the three genera *Calkinsia*, *Postgaardi*, and *Bihospites*. Each includes a single described species at present (Yubuki et al. 2009; Breglia et al. 2010).

It is important to note that several genera of phagotrophic euglenids have homonyms in botanical taxonomy, and alternative botanical names have been

proposed: *Dinema* = *Dinematomonas*; *Entosiphon* = *Entosiphonomonas*; and *Peranema* = *Pseudoperanema*.

Evolutionary History

The phylogeny of euglenids has been addressed most extensively using nucleotide sequences amplified from ribosomal genes (i.e., small and large subunit rRNA genes) (Brosnan et al. 2003, 2005; Busse et al. 2003; Ciugulea et al. 2008; Karnkowska et al. 2015; Kim and Shin 2008; Kim et al. 2015; Linton et al. 1999, 2000, 2010; Marin et al. 2003; Milanowski et al. 2001, 2006; Montegut-Felkner and Triemer 1997; Müllner et al. 2001; Nudelman et al. 2003; Preisfeld et al. 2001; Triemer et al. 2006; von der Heyden et al. 2004; Zakryś et al. 2002). Although these genes have been helpful in resolving the phylogeny of photoautotrophic euglenids, they do not provide satisfactory phylogenetic signal at deeper levels in the phylogeny (e.g., among the bacterivorous euglenids). Additional evidence for deep-level phylogenetic relationships of euglenids comes from comparative analyses of morphological data and some nucleus-encoded protein genes (e.g., heat shock protein 90), although the latter are still very sparse (Breglia et al. 2007; Leander et al. 2001a, b; Karnkowska et al. 2015; Montegut-Felkner and Triemer 1997; Simpson et al. 2002; Simpson and Roger 2004; Talke and Preisfeld 2002; Cavalier-Smith et al. 2016). These data also confirm the placement of euglenids within the Euglenozoa, as sister to kinetoplastids and diplonemids. Multigene molecular phylogenetic analyses also strongly support the placement of the Euglenozoa as a whole within a clade, the Discoba, that also includes Heterolobosea, Jakobida, and *Tsukubamonas* (e.g., Hampl et al. 2009; Kamikawa et al. 2014).

The following summarizes the current state of knowledge about phylogenetic relationships among euglenids (see also Fig. 12).

- Photoautotrophic euglenids (Euglenophyceae or euglenophytes) are a monophyletic subgroup nested within a paraphyletic assemblage of phagotrophic lineages.
- Euglenophytes with one emergent flagellum (Euglenales) are monophyletic; the Eutreptiales, with two emergent flagella (or rarely more), are their closest relatives. The recently described mixotroph *Rapaza* (also with two emergent flagella) is the deepest branch within euglenophytes.
- *Phacus* and *Lepocinclis* are each probably monophyletic and together form a more inclusive monophyletic group within the euglenophytes; these lineages tend to have 32 pellicle strips, are rigid, show great diversity in cell shape, and possess many small disc-shaped chloroplasts without pyrenoids and dimorphic paramylon grains.

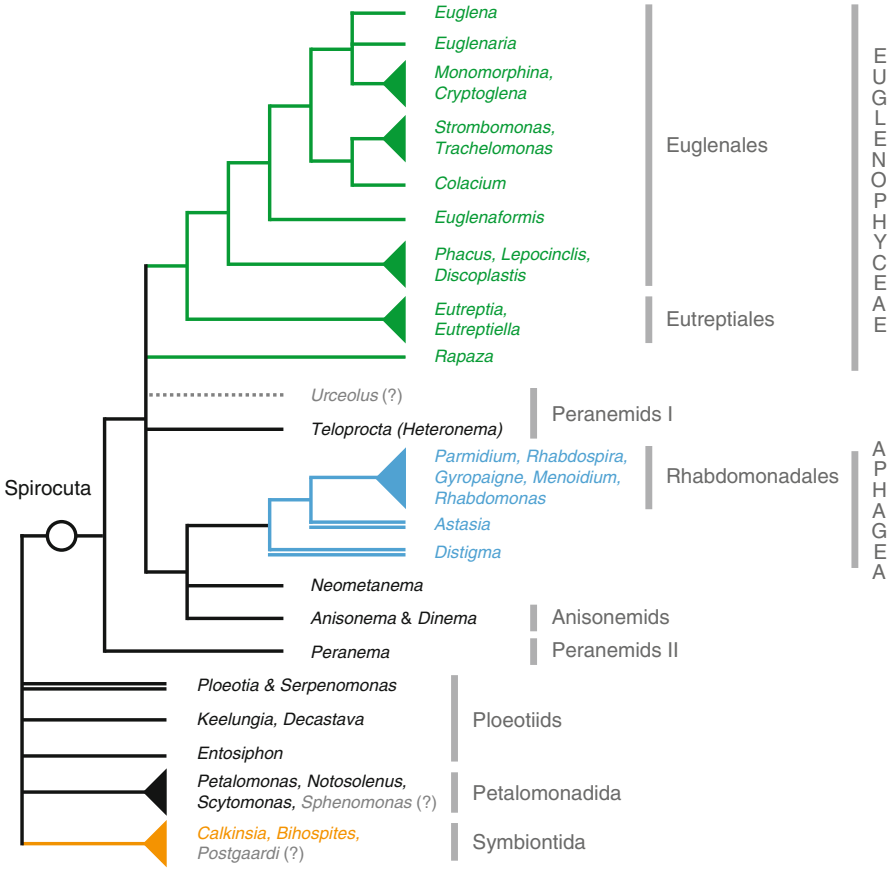

Fig. 12 Current knowledge of the evolutionary tree of euglenids, based primarily on SSU rRNA gene phylogenies. Photoautotrophic taxa are shown in green, primary osmotrophs in blue, "typical" phagotrophic taxa in black, and symbiontids in orange. Selected higher taxa are depicted to the right, though Spirocuta (= "H" or "HP" clade) is marked with a circle on its basal branch. Polytomies indicate regions of the tree that are poorly supported and/or resolved differently in various recent analyses. Genera shown in gray are important taxa whose positions are inferred from morphological information alone, since no molecular data are currently available (genera for which there are relatively limited data are not shown). Double lines on a branch denote paraphyletic groups (note also that both "peranemids" and "ploeotiids" appear to be paraphyletic). *Ploeotia* is probably paraphyletic at present, but it is also unclear whether *Serpenomonas* and *Ploeotia* are phylogenetically distinct (sequence information is awaited from *Ploeotia vitrea*, the type species of *Ploeotia*). The clade containing *Phacus*, *Lepocinclis*, and *Discoplastis* represents the taxon Phacaceae; the clade containing all other genera within Euglenales corresponds to the taxon Euglenaceae (see text)

- *Discoplastis* is the monophyletic sister group to *Phacus* and *Lepocinclis* and shares several morphological features with them (e.g., disc-shaped plastids without pyrenoids and 32 pellicle strips); however, these cells undergo dynamic metaboly.

- The monotypic genus *Euglenaformis* branches at the base of the assemblage of Euglenaceae.
- The loricate taxa *Trachelomonas* and *Strombomonas* are each monophyletic and together form a monophyletic group.
- The nearest sister group to the loricates is *Colacium*, which forms mucilaginous stalks.
- The rigid euglenophytes *Monomorphina* and *Cryptoglena* form a monophyletic group; these lineages have only one plastid and a relatively small number of broad pellicle strips (around 16–20).
- *Euglenaria* is monophyletic and possess morphological features similar to those of some representatives of *Euglena* (lobate plastids with diplopyrenoids), but distinct molecular signatures in nuclear SSU rDNA sequences. The molecular phylogenetic position of that lineage is not well resolved.
- The modern (revised) version of the genus *Euglena* is monophyletic with two known exceptions (see above); *Euglena* species often have 40 pellicle strips, undergo metaboly, and show great diversity in cell shape and plastid morphology (e.g., shield-shaped, stellate, lobed, spherical).
- Photosynthesis was lost several times independently within the euglenophytes (e.g., *Euglena longa* and *Euglena quartana* – previously assigned to "*Astasia*" and "*Khawkinea,*" respectively).
- The nearest sister lineages to euglenophytes are certain eukaryovorous euglenids, possibly *Teloprocta* (formerly *Heteronema*) and/or *Urceolus*.
- Primary osmotrophic euglenids (Aphagea, e.g., *Distigma*, *Rhabdomonas, Astasia*) are monophyletic and diverged from eukaryovorous ancestors independently from euglenophytes.
- Euglenophytes, primary osmotrophs, and eukaryovorous euglenids form a monophyletic group (Spirocuta; formerly the "H" or "HP" clade).
- Eukaryovorous euglenids are paraphyletic because they gave rise, independently, to both primary osmotrophs and euglenophytes – see above.
- Bacterivorous euglenids are probably paraphyletic.
- One clade of bacterivorous euglenids, petalomonads (Petalomonadida), has retained several possibly ancestral characters, such as few pellicle strips (10 or fewer), an MtR pocket, kDNA-like mitochondrial inclusions, and bacterivorous modes of nutrition; however, phylogenetic evidence that petalomonads are a particularly deep branch within euglenids is equivocal at best.
- Other bacterivorous euglenids ("ploeotiids," including *Entosiphon*) have unclear molecular phylogenetic positions vis-à-vis each other and petalomonads and symbiontids. These lineages have rigid pellicles with 12 or fewer strips (usually 10), somewhat similar to petalomonads, but have complex feeding apparatuses, including rods and vanes, similar to eukaryovorous euglenids.
- Symbiontids are a monophyletic group of anaerobes that lack pellicular strips, but usually branch among bacterivorous euglenids in molecular phylogenies, albeit with weak statistical support. They likely descended from "classical" bacterivorous euglenids, and secondarily lost pellicular strips, perhaps as a consequence of entering into symbioses with epibiotic bacteria. However,

transverse sections through the cell surface of *Bihospites* show many S-shaped profiles that are reminsicent of pellicle strips.
- Knowledge about the overall diversity and phylogenetic relationships of bacterivorous and eukaryovorous euglenids is still very poor.

Morphological Evolution, Especially the Pellicle

The euglenid pellicle is very diverse, and comparative analyses have demonstrated a great array of intermediate states for several cytoskeletal characters. This diversity placed in a molecular phylogenetic context demonstrates many large-scale evolutionary trends within the group (Leander et al. 2007).

The evolution of strip number involved at least three mechanisms associated with cytoskeletal replication and cell division: (1) asymmetrical segregation of strips to daughter cells, (2) permanent strip doubling events, and (3) permanent strip halving events (Esson and Leander 2006; Leander 2004; Leander et al. 2001a, b, 2007; Yubuki and Leander 2012). Permanent strip duplication events refer to a cell that duplicates its strips but fails to divide. Permanent strip halving events refer to a cell that divides without first duplicating its strips. The distribution of strip numbers found in euglenids suggests that these mechanisms collectively happened several times during the evolution of the group; there is evidence for the following events: four strips to eight strips (or vice versa) in petalomonads, 10 strips to 20 strips coincident the emergence of Spirocuta (the HP clade), and 20 strips to 40 strips near the origin of the Euglenales (Esson and Leander 2006; Leander et al. 2001a, b, 2007; Leander 2004).

The ancestral state for the number of strips in phototrophic euglenids is between 40 and 50; strip numbers that are significantly higher or lower than 40–50 are inferred to represent derived states. For instance, some relatively enormous species have either doubled or tripled this number of strips (e.g., 80 strips in *Lepocinclis helicoideus* and 120 strips in *Euglena obtusa*) (Esson and Leander 2008; Leander and Farmer 2000b). The phototrophic lineages that have lost metaboly, such as *Phacus* and *Lepocinclis*, tend to have 32 strips, which is the inferred ancestral state for the more inclusive clade consisting of these two genera plus *Discoplastis*. A subgroup of *Phacus* reduced the number of strips even further to about 20; these cells are among the smallest of all known photoautotrophic euglenids (Fig. 6). The strip-halving process (see above) helps explain the reduction of strips during the evolution of the rigid photoautotrophic lineage *Monomorphina* (32 strips to 16 strips; Leander and Farmer 2001b) (Figs. 1 and 6).

Fossil Record

Euglenid fossils are sparse. Aside from the loricas of *Trachelomonas* and *Strombomonas*, euglenids do not secrete hard parts that would promote fossilization.

However, some photoautotrophic euglenids have exceedingly thick proteinaceous strips, which could presumably fossilize. *Moyeria* is an enigmatic fossil with euglenid-like features (e.g., strips and a canal opening) that was discovered in Silurian deposits (Gray and Boucot 1989). The size, shape, and surface morphology of these fossils are reminiscent of some phototrophic euglenids in the genus *Monomorphina*.

Acknowledgments The authors thank Won Je Lee and Bożena Zakryś for extensive use of their unpublished micrographs. BSL and AGBS gratefully acknowledge the support of the Canadian Institute for Advanced Research (CIfAR), program in Integrated Microbial Biodiversity. AK was supported by a grant from the Tula Foundation to the Centre for Microbial Biodiversity and Evolution at UBC.

Kinetoplastea

30

Wendy Gibson

Abstract

The class Kinetoplastea Cavalier-Smith 1981 (previously known as the order Kinetoplastida Honigberg 1963) constitutes an important group of free-living and parasitic flagellates. The group is named after the kinetoplast, a unique cell organelle consisting of the tightly packaged mitochondrial DNA, which forms a stainable structure within the single mitochondrion. The Kinetoplastea includes several important human pathogens that are carried by bloodsucking insect vectors, e.g., *Trypanosoma brucei*, *T. cruzi*, *Leishmania donovani*, *L. major*, and *L. tropica*, as well as vector-borne animal pathogens such as the African tsetse-transmitted trypanosomes that cause nagana. Some kinetoplastids are plant parasites, e.g., *Phytomonas*, transmitted by phytophagous bugs. While these pathogenic kinetoplastids are of major medical, veterinary, and economic importance, many other kinetoplastid species also have a parasitic lifestyle, either in a single host species or alternating between two different hosts. The ubiquitous free-living kinetoplastids such as *Bodo* are of major ecological importance as heterotrophs in marine and freshwater environments. Some kinetoplastid species are popular and significant laboratory model species for biochemical and molecular biology investigations. In particular, *Trypanosoma brucei* is notorious for its ability to undergo antigenic variation, and *Leishmania* infection is a paradigm for T-helper cell type I and type II immune responses.

Introduction

General Characteristics

The class Kinetoplastea Cavalier-Smith 1981 constitutes a group of small colorless flagellates with one or two flagella and massed mitochondrial DNA that forms a stainable structure – the kinetoplast – within the single mitochondrion. The size, shape, and position in the cell of the kinetoplast are of taxonomic and ontogenetic significance. In many genera the kinetoplast is found close to the kinetosomes (basal bodies) of the flagella and consists of a network of interlocked circular DNA

molecules, tightly packaged into a disc-shaped bundle. The kinetoplast DNA may also be dispersed and occupy all or a large part of the mitochondrion. In a few mutants stainable kinetoplast DNA may be absent (dyskinetoplasty).

The kinetoplastids are classified together with the euglenids and diplonemids in the phylum Euglenozoa Cavalier-Smith 1981, which is recovered as a monophyletic group in molecular phylogenetic trees based on ribosomal RNA and protein-coding genes (Keeling et al. 2005). Kinetoplastids can be divided by morphology into two groups: one that is uniflagellate and the other with two heterodynamic flagella – one directed anteriorly and locomotory, the other directed posteriorly and recurrent or trailing (Figs. 1 and 2). These groups were traditionally classified as the suborders Trypanosomatina (family Trypanosomatidae) and Bodonina (families Bodonidae, Cryptobiidae), respectively. However, molecular phylogenetic evidence indicates that while the Trypanosomatina and Trypanosomatidae are both monophyletic, the suborder Bodonina and its constituent families are not (Callahan et al. 2002; Dolezel et al. 2000; Wright et al. 1999). With increasing diversity of kinetoplastids represented in phylogenetic analyses, a more complete picture is now beginning to emerge (Moreira et al. 2004; von der Heyden et al. 2004). There is a core group of

(Pycnomonas) suis* (TPM) from pig blood (After Vickerman and Preston 1976)

kinetoplastids, subclass Metakinetoplastina (Moreira et al. 2004) that comprises the trypanosomatids and bodonids, with a highly divergent sister group, and subclass Prokinetoplastina (Moreira et al. 2004) that includes the fish ectoparasite *Ichthyobodo necator*, a related kinetoplastid symbiont of amoebae and organismal DNA recovered from environmental samples (Callahan et al. 2002; Moreira et al. 2004; von der Heyden et al. 2004).

Molecular phylogenetic studies are adding to the number of kinetoplastid genera through the formal recognition of polyphyletic genera, e.g., the revision of genus *Bodo* (Moreira et al. 2004), and the discovery of new genera, particularly among the trypanosomatids from arthropod hosts (Maslov et al. 2013). Methods of obtaining molecular phylogenetic information from previously unculturable organisms, living, for example, in marine sediments and soil, also add to the number of bodonid genera

and species (von der Heyden and Cavalier-Smith 2005). A general problem for kinetoplastid taxonomy is the lack of discernable morphological differences between sometimes quite different species. Molecular approaches have been widely used to discriminate species and strains of clinically important genera such as *Trypanosoma* and *Leishmania* and are now being employed more widely for species identification.

Many bodonids are free living and as heterotrophs constitute an important part of the community in marine and freshwater environments. The group also includes parasitic forms traditionally grouped into the Cryptobiidae, now subsumed into the parabodonid group (Moreira et al. 2004). Parasitic bodonids occur in fish, either in the bloodstream or gut, and also in other aquatic or terrestrial organisms. The ectoparasite *Ichthyobodo necator* lives on the gills and skins of fish and a few other organisms (see Table 1). Endosymbiotic kinetoplastids have been described in other protists. Bodonids are usually phagotrophic, ingesting food through a cytopharynx with a cytostome bordered by prominent lips often drawn out into a projecting rostrum (Fig. lb, e, g). The bodonid kinetoplast is highly variable in morphology and structure, generally being larger and often more diffuse or dispersed that in the trypanosomatids. The fundamental difference between the kDNAs of bodonids and trypanosomatids appears to be that the kDNA does not form a network in any of the representative bodonid species studied thus far, in contrast to the trypanosomatids where kDNA mini- and maxicircles are interlinked and densely packaged (Lukeš et al. 2002). The diagnostic characteristics of some representative bodonid genera are summarized in Table 1.

Trypanosomatids are invariably parasitic and their host ranges are indicated in Table 2. They have a small, strongly staining kinetoplast – referred to as the eukinetoplastic condition (Vickerman 1990). During their life cycles, the position of the kinetoplast-basal body-flagellar pocket complex may shift in relation to the nucleus and body extremities, and the flagellum may change in length. Thus, the following forms are recognized (Fig. 2): *amastigote*, round to oval body, flagellum short, not emerging from pocket; *promastigote*, kinetoplast close to anterior end of elongate body, flagellum emerging anteriorly and unattached; *opisthomastigote*, similar, but kinetoplast is postnuclear and flagellar pocket forms long canal to anterior end of body; *choanomastigote*, body pyriform, kinetoplast just in front of nucleus, flagellum emerging anteriorly; *epimastigote*, prenuclear kinetoplast, flagellum emerging from pocket along the body and attached to the body along its anterior portion; *trypomastigote*, similar, but kinetoplast and flagellar pocket are postnuclear. The term spheromastigote is sometimes used for a rounded body with an emerging flagellum attached to it. *Endomastigote* has been coined for the condition described in *Wallaceina* where the flagellum is enclosed within the cell. The different genera are characterized according to which of these morphological forms are present in the life cycle and whether the cycle is monogenetic (monoxenous) or digenetic (heteroxenous) (Table 2), i.e., involves one host or alternates between two different animal hosts, usually a vertebrate and an invertebrate. The clinically important genera, *Trypanosoma* and *Leishmania*, are divided into sections and subgenera, summarized in Table 3.

Table 1 Principal bodonid genera of Kinetoplastea

Order	Genus	Diagnostic characters[a]	Feeding	Habitat/life cycle
Eubodonida Vickerman 2004	*Bodo* Ehrenberg 1830 emend. Vickerman 2004	Eukinetoplastic; AF non-tubular hairs; PF free from body; lateral cytostome-cytopharynx lacks PR	Phagotrophic, bacterivorous	Solitary, free living (fresh- or seawater, soil); can colonize fleeting habitats (dew, spittle bug exudate)
Parabodonida Vickerman 2004	*Parabodo* Skuja 1939 emend. Vickerman 2004	Eukinetoplastic in trophozoite; pankinetoplastic in cyst; body flattened; PF free/mainly free from body and used as skid; cytostome-cytopharynx lacks PR	Phagotrophic, bacterivorous	Solitary, free living (commonly coprozoic)
	Procryptobia Vickerman 1979	Eukinetoplastic trophozoite; PF attached to body over greater length, acts as "skid." Cysts sometimes polykinetoplastic	Phagotrophic, bacterivorous	Free living, commonly coprozoic
	Cryptobia[b] Leidy 1846	Eukinetoplastic or pankinetoplastic trophozoites; PF attached along the length of body; cysts unknown	Osmotrophic	Parasitic or endocommensal in gut or reproductive system of invertebrates
	Trypanoplasma[b] Laveran and Mesnil 1901	Eukinetoplastic; PF attached along length of body and forms "undulating membrane"; cysts unknown	Osmotrophic	Parasitic in blood (and gut?) of fish; cyclical transmission of blood trypanoplasms primarily by leeches. Occasionally pathogenic

Neobodonida	*Neobodo* Vickerman 2004	Eukinetoplastic; PF free/mainly free from body and used as skid; apical cytostome-cytopharynx supported by PR	Phagotrophic, bacterivorous	Solitary, free living (fresh- or seawater, soil)
	Rhynchomonas Klebs 1893	Eukinetoplastic trophozoite; PF mostly free from body, acts as "skid"; short AF attached to long proboscis formed from rostrum. Cysts undescribed	Phagotrophic, bacterivorous	Free living (fresh water, marine planktonic, soil); coprozoic
	Dimastigella Sandon 1928	Polykinetoplastic trophozoite and cyst; PF attached along elongate body acts as "skid." Long rostrum alongside AF	Phagotrophic, bacterivorous	Free living in soil and coprozoic
Prokinetoplastida Vickerman 2004	*Ichthyobodo* Pinto 1928 (*Costia* Leclerque 1890)	Polykinetoplastic; trophozoite attached to host by elongate rostrum; free-swimming dispersive stage lacks rostrum; PF free from body. No cysts	Phagotrophic ingesting cytoplasm of host cell (histophagic)	Biphasic life cycle; trophozoite ectoparasitic on fish and urodeles; alternates with free-swimming dispersive phase. Pathogenic in young fish

Notes: [a]Abbreviations *AF* anterior flagellum, *PF* posterior flagellum, *PR* prismatic rod of microtubules
[b]*Trypanoplasma* and *Cryptobia* are treated as separate genera here, although the taxonomy of the fish gut and invertebrate cryptobias is still under debate (Moreira et al. 2004; Woo 1994)

Table 2 Principal trypanosomatid genera of Kinetoplastea

Genus	Diagnostic characters[a]	Hosts and practical significance
Leptomonas[b] Kent 1880	Monogenetic; *promastigotes* and cysts only in life cycle	Mainly insects (Hemiptera, Diptera, Hymenoptera, Blattoidea, Lepidoptera, Siphonaptera, Anoplura), rarely other invertebrates and ciliates. Nonpathogenic
Herpetomonas[b] Kent 1880	Monogenetic; promastigotes and *opisthomastigotes* (not all species) in life cycle	Diptera, Heteroptera, Siphonaptera. Nonpathogenic
Crithidia[b] Léger 1902	Monogenetic; *choanomastigotes* only	Diptera, Hemiptera, Trichoptera; Hymenoptera. Nonpathogenic
Blastocrithidia[b] Laird 1959	Monogenetic; *epimastigotes* and cysts only	Diptera, Hemiptera, Siphonaptera, and ixodid ticks. Possibly pathogenic in some species
Rhynchoidomonas Patton 1910	Monogenetic; *trypomastigote* stage only (but genus poorly known)	Diptera. Nonpathogenic
Wallaceina Podlipaev, Frolov, and Kolesnikov 1999 (*Proteomonas* Podlipaev, Frolov & Kolesnikov 1990)	Monogenetic; *endomastigotes* and promastigotes	Hemiptera
Angomonas Souza and Corte-Real 1991	Monogenetic; defined phylogenetically; endosymbiont bearing	Diptera, Heteroptera
Strigomonas Lwoff and Lwoff 1931	Monogenetic; defined phylogenetically; endosymbiont bearing	Diptera, Heteroptera
Sergeia Svobodová and Votýpka 2007	Monogenetic; defined phylogenetically	Diptera
Phytomonas Donovan 1909	Digenetic; *promastigotes*	Plants (Euphorbiaceae, Asclepiadaceae, Moraceae, Palmae, mainly) *and* phytophagous Hemiptera. Pathogenic species cause hartrot in oil and coconut palms and wilt disease in coffee plant
Leishmania Ross 1903	Digenetic; intracellular *amastigotes* (mammal) and promastigotes (vector)	Mammals (Primates, Rodentia, Edentata, Hyracoidea, Carnivora, Marsupialia) and Diptera (Phlebotominae). Pathogenic species in humans cause dermal, mucocutaneous, and visceral leishmaniasis (see Table 5)
Sauroleishmania Ranque 1973	Digenetic; intracellular *amastigotes* (reptiles) and promastigotes (vector)	Reptiles (lizards and snakes) and Diptera (Phlebotominae). Nonpathogenic

(*continued*)

Table 2 (continued)

Genus	Diagnostic characters[a]	Hosts and practical significance
Endotrypanum Mesnil and Brimont 1908	Digenetic; intra-erythrocytic trypomastigotes and epimastigotes (in mammal); promastigotes and amastigotes (in vector)	Edentata (sloths) and Diptera (Phlebotominae, genus *Lutzomyia*). Nonpathogenic
Trypanosoma Gruby 1843	Digenetic; *trypomastigotes* (and more rarely epimastigotes or intracellular amastigotes) in vertebrate; trypomastigotes, epimastigotes (rarely promastigotes, amastigotes) in vector	Vertebrates (all classes) and Hirudinea or Arthopoda (insects, mites). Pathogenic species cause sleeping sickness and Chagas disease in humans and nagana and related diseases in domestic animals (see Tables 3 and 4)

References: (Maslov et al. 2013; Merzlyak et al. 2001; Wallace 1966, 1979)
Notes: [a]The morphological type characteristic of each genus is given in italics. In *Endotrypanum* the type found in the mammal depends on the species
[b]Genera known to be paraphyletic and currently under revision. The endosymbiont-bearing genera *Strigomonas* and *Angomonas* have been revised, *Leptomonas* split into two clades and *Herpetomonas* redefined; see (Maslov et al. 2013) and references therein

Literature

Accounts of the pathogenic Trypanosomatidae loom large in texts on tropical medicine and veterinary medicine as well as in frequent papers in journals dealing with these subjects. Research into the biochemistry, immunology, and molecular genetics of the pathogenic trypanosomatids, including *T. cruzi*, has been fueled by the need for new drugs and vaccines. As 2005 saw the publication of genome sequences for *T. b. brucei*, *T. cruzi*, and *L. major* – the so-called Tritryps (El-Sayed et al. 2005b) – research on these organisms has now entered the post-genomic era. *Trypanosoma brucei* and *Leishmania* species have proved to be tractable laboratory models, fostering a huge literature of recent work on molecular biology and immunology. Trypanosome antigenic variation is now a standard textbook example for gene rearrangements, while *Leishmania* infection is a paradigm for T-helper cell type I and type II immune responses in the mouse. Molecular phylogenetic studies have refocused attention on some of the more obscure kinetoplastids, as these have proved important in constructing accurate evolutionary trees. The great diversity of insect trypanosomatids has also come under scrutiny, following the introduction of molecular taxonomic methods (Maslov et al. 2013; Podlipaev 2001).

Practical Importance

Several kinetoplastids are of medical, veterinary, or agricultural importance on account of their pathogenicity to humans, livestock, and even crop plants.

Table 3 Subgenera of *Trypanosoma* from mammals: distinguishing features and representative species

Subgenus	Mammalian trypomastigote distinguishing features	Representative species	Behavior in mammal
Section: *Stercoraria*			
Megatrypanum[a] Hoare 1964	Large TPM(40–100 μm); long pointed PE; medium, nonterminal kinetoplast; long FF	*T. (M.) theileri*	Division in BS as EPM; ND TPM
Herpetosoma[a] Doflein 1901	Medium TPM (21–36 μm); long pointed PE; large rodlike nonterminal kinetoplast; long FF	*T. (H.) lewisi*	Multiple fission in visceral capillaries as EPM; ND TPM
Schizotrypanum Chagas 1909	Small TPM(15–24 μm); short pointed PE; large subterminal kinetoplast; long FF	*T. (S.) cruzi*	Division as intracellular AM in muscle or MNP; ND TPM in blood
Tejeraia[a,b] Anez 1982	Medium TPM (25–35 μm); long pointed PE; medium nonterminal kinetoplast; long FF	*T. (T.) rangeli*	ND TPM only, known in mammal
Section: *Salivaria*			
Duttonella Chalmers 1908	Medium TPM (21–26 μm); blunt, small (14–17 μm) to rounded PE; large terminal kinetoplast; long FF	*T. (D.) vivax*	Division in BS as medium TPM; wholly intravascular
Nannomonas Hoare 1964	Small TPM (12–18 μm); blunt PE; medium, subterminal marginal kinetoplast; no or short FF	*T. (N.) congolense* Savannah, forest, and Kilifi (Kenya coast) subgroups	Division in BS as TPM attached to endothelia
		T. (N.) simiae	As *T. congolense*, but long and short forms occur (pleiomorphic)
		T. (N.) godfreyi	As *T. congolense*
Pycnomonas[c] Hoare 1964	Small TPM (8.5–19 μm); very short pointed PE; small subterminal kinetoplast; short FF	*T. (P.) suis*	Division in BS as TPM
Trypanozoon Lühe 1906	Pleomorphic TPM; long slender forms (mean 30 μm) with long FF and short stumpy forms (mean 18 μm) with no FF; small subterminal kinetoplast	*T. (T.) brucei* Subspecies *T. (T.) b. brucei*, *T. (T.) b. gambiense*, *T. (T.) b. rhodesiense*	Dividing slender TPM in blood, lymph, CT; nondividing stumpy TPM in blood and lymph

Notes: [a]There is no phylogenetic support for subgenera *Megatrypanum*, *Herpetosoma*, or *Tejeraia* (Hamilton et al. 2004; Stevens et al. 1999b)
[b]Originally included by (Hoare 1972) in subgenus *Herpetosoma*, removed to subgenus *Tejeraia* by (Anez 1982) on account of anomalous life cycle
[c]Rarely reported. New subgenus created to reflect unique developmental cycle in tsetse: development in midgut, salivary glands, and proboscis (Hoare 1972; Peel and Chardome 1954)

Kinetoplastids were first recognized as pathogens when Evans in 1880 discovered the trypanosome (*Trypanosoma evansi*) that causes the disease surra of horses and camels in India. In Africa, the threat of trypanosomiasis (nagana) to livestock has had a profound effect on the agricultural economies of the tsetse-infested countries south of the Sahara, as this disease has prevented the exploitation of livestock for transport and traction as well as for human food production. Three approaches are used in the control of diseases caused by the kinetoplastids: chemotherapy, vaccination, and vector control, as these diseases are usually insect-borne. The lack of safe and effective drugs for chemotherapy, investment in development of new drugs, and the withdrawal of some existing drugs have kindled interest in the indirect control of disease by tackling the insect vectors. This strategy has proved very successful in halting transmission of Chagas disease in the so-called Southern Cone countries of South America. While vaccination against leishmaniasis is a realistic possibility (Kedzierski et al. 2006), this is ruled out for the African trypanosomes by their renowned ability for antigenic variation and for *T. cruzi* by strain variation.

The trypanosomes responsible for human and animal trypanosomiasis in Africa (see Table 4) are transmitted by tsetse flies (*Glossina* spp.) in which the parasites undergo a complex cycle of development before they reach the infective metacyclic stage in the fly's mouthparts (cyclical transmission, Fig. 5, Table 4, and *Life Cycles*). In tsetse-infected areas, susceptible animals die from severe anemia and other pathogenic consequences of trypanosome infection, while general production losses (decreased rate of weight gain, sterility, abortion) debilitate infected livestock. Human African trypanosomiasis (HAT), colloquially known as sleeping sickness, is a severe and fatal disease if untreated and is caused by two subspecies of *T. brucei*. The chronic form of HAT in West and Central Africa is caused by *T. b. gambiense* and is typically transmitted by riverine tsetse such as *Glossina palpalis*, while *T. b. rhodesiense* causes the acute East African form of the disease and is transmitted by a number of different tsetse species, e.g., *G. morsitans*, *G. pallidipes*, and *G. fuscipes*. Both forms of the disease are zoonoses, with known reservoirs in domestic pigs for

Table 4 Trypanosomes of mammals: hosts, transmission, and relation to disease of man and domestic animals

Species	Main hosts/ reservoirs	Vectors/ transmission	Disease	Geographical distribution
T. (Megatrypanum) theileri	Cattle	Tabanid flies (C; PS)	Nonpathogenic	Cosmopolitan
T. (Herpetosoma) lewisi	Rats	Rat fleas (C; PS)	Nonpathogenic	Cosmopolitan
T. (Schizotrypanum) cruzi[a]	Humans, opossums, armadillos, raccoons, cats, dogs, rodents	Triatomine bugs (C; PS)	Chagas disease	C. and S. America
T. (Tejeraia) rangeli	Humans, dogs, cats, opossums, monkeys	Triatomine bugs (C; AS; SG)	None (pathogenic in vector only)	S. America
T. (Duttonella) vivax	Ruminants	Tsetse flies (C; AS; P); outside Africa tabanid flies (M)	Nagana	Sub-Saharan Africa, S. America, W. Indies, Mauritius
T. (Nannomonas) congolense	Ruminants, equines, pigs, carnivores, rarely camels	Tsetse flies (C; AS; P)	Nagana	Sub-Saharan Africa
T. (N.) simiae	Pigs, camels, monkeys	Tsetse flies (C; AS; P)	Acute in pigs	Sub-Saharan Africa
T. (N.) godfreyi	Pigs	Tsetse flies (C; AS; P)	Mild disease in pigs	Sub-Saharan Africa
T. (Pycnomonas) suis[b]	Pigs, warthog	Tsetse flies (C; AS; P)	Acute in piglets	Sub-Saharan Africa
T. (Trypanozoon) brucei brucei	Ruminants, equines, camels, pigs, carnivores	Tsetse flies (C; AS; SG)	Nagana	Sub-Saharan Africa
T. (T.) brucei rhodesiense	Humans, ruminants, antelopes, carnivores	Tsetse flies (C; AS; SG)	Acute sleeping sickness	E. Africa
T. (T.) brucei gambiense	Humans, domestic pig, dog	Tsetse flies (C; AS; SG)	Chronic sleeping sickness	W. and C. Africa
T. (T.) evansi	Camels, equines, ruminants, Indian elephant, carnivores, vampire bat	Tabanid flies (M); vampire bats	Surra, Mal de caderas	N. Africa, Middle East, S. Asia, E. Indies, Mauritius, C. and S. America

(*continued*)

Table 4 (continued)

Species	Main hosts/ reservoirs	Vectors/ transmission	Disease	Geographical distribution
T. (T.) equiperdum	Equines	Venereal contact	Dourine	Cosmopolitan

References: (Hoare 1972); (McNamara et al. 1994)
Abbreviations: Transmission *C* cyclical, *M* mechanical. Metacyclics formed in *AS* anterior station (mouth parts of vector, for injection with saliva); *P* in proboscis, *SG* salivary glands, *PS* posterior station (hindgut of vector for deposit with feces)
Notes: [a]A consensus was reached among researchers on Chagas disease that *T. cruzi* strains should be referred to by six discrete typing units (*T. cruzi* I–VI) characterized by multilocus genotype (Zingales et al. 2009, 2012). *T. cruzi* I–VI vary in geographical distribution, ecotope, reservoir hosts and vectors, and the severity of human disease. *T. cruzi* V and VI are believed to be natural hybrids of *T. cruzi* II and III
[b]Rarely reported. Metacyclics in tsetse proboscis, but trypanosomes also develop in salivary glands

the Gambian disease and in cattle or wild animals such as bushbuck for the rhodesian parasite; however, the animal reservoir assumes greater importance in the epidemiology of the rhodesian disease. According to the World Health Organization, annual incidence has fallen over the past decade, with numbers of reported cases falling below 10,000 in 2009; the true incidence is likely to be higher, as many cases go unreported. Thirty-six African countries are currently listed as at risk from HAT, although many of these reported few or no cases during the decade 2000–2009 (WHO 2013b). Gambian HAT is more prevalent and widespread than rhodesian HAT, which is a more sporadic disease. In the recent past, epidemic resurgence of HAT has been blamed on the breakdown of disease surveillance and control measures by civil disturbance and diversion of resources to more pressing health priorities such as malaria and AIDS.

Outside the tsetse belt of Africa, *Trypanosoma evansi*, a monomorphic descendant of *T. brucei* (see Tables 3 and 4 and Evolutionary History), and *T. vivax* may be spread by biting flies (especially tabanids) without a cycle of parasite development in the vector. The principal victims of such mechanical transmission are the draft animals of the unmechanized farming world, horses and camels in particular (Table 4). Vampire bats (*Desmodus* spp.) may act as mechanical vectors of *T. evansi*, with the trypanosomes moving from blood of the ungulate to that of the bat and vice versa via the bat's saliva. The now rare equine disease dourine is due to *T. equiperdum*, which, like *T. evansi*, is another monomorphic descendant of *T. brucei* now transmitted venereally between horses. Carnivores (e.g., lions, leopards, dogs) can acquire infection with the salivarian trypanosomes by eating the carcasses of infected ungulates (Hoare 1972), and this has been demonstrated experimentally by feeding infected goat meat to cats and dogs (Moloo et al. 1973).

Chagas disease caused by *T. cruzi* currently affects an estimated 7–8 million people worldwide, predominantly in South and Central America, where it is an important etiological agent of cardiac disease (WHO 2013a). The trypanosome multiplies intracellularly in the heart and other muscles, emerging into the blood as a trypomastigote to invade other cells or to be taken up by the bloodsucking triatomine

bug vector for cyclical transmission. The disease is transmitted through the bug's feces, which are contaminated with metacyclic trypomastigotes and ejected by the bug after feeding. The metacyclics penetrate the vertebrate host through skin lesions or normal eye mucous membranes. In rural areas these bugs readily invade dilapidated housing where they hide in crevices in wall and thatch, emerging at night to feed. Besides transmission by live bugs, outbreaks of infection have also occurred as a consequence of the contamination of food or drink by dead bugs or their feces. Blood transfusion and organ transplants account for direct transmission in urban areas, and vertical transmission is also possible via perinatal infection or breast milk. The disease is a zoonosis with a reservoir in several mammals (Table 4). It has an acute phase (1–2 months) during which trypanosomes are found in the blood, followed by the apparent disappearance of the parasite during the chronic phase that may last for years. Most people do not show further symptoms, but a minority (estimated 30%) progress to chronic inflammatory disease of the heart or digestive tract – the so-called mega-syndromes. An autoimmune reaction is suspected in pathogenesis of Chagas disease, but this is controversial (Tarleton and Zhang 1999; Urbina 2010). Chagas disease is increasingly reported far beyond its traditional area of distribution in Latin America, as a consequence of the increased mobility of the human population.

The leishmaniases in humans are caused by a complex of 11 principal species of *Leishmania* (Ashford and Crewe 2003; Bates 2007) and have a wide distribution including Southern Europe, Africa, the Middle East, the Indian subcontinent, Asia, and Central and South America (Piscopo and Mallia 2006; WHO 2013c). All leishmanias are transmitted by sand flies (Phlebotominae), the ingested amastigotes transforming to promastigotes in the insect gut (Table 5). Infective forms develop in a plug of proteinaceous material secreted by the parasite, which blocks the pharynx; in order to feed the fly regurgitates this plug of infectious material into the bite wound and substances within the plug exacerbate infection. As the morphology of these parasites in their macrophage host cell is similar, species recognition depends on the clinical features of the disease caused and on molecular identification of the parasites in the laboratory (see *Classification Schemes*). Clinical manifestations of leishmaniasis include both cutaneous and visceral forms of the disease as summarized in Table 5. The most serious disease, kala-azar (visceral), involves the macrophages of the liver, spleen, and bone marrow, causing a fatal anemia that, left untreated, has a high mortality rate. The danger these diseases represent for the health of children should be especially emphasized, as infants are more vulnerable and risk of failure of diagnosis is high. Leishmanial infections in humans induce both humoral and cellular immune responses, but the balance of their expression varies with the type of disease. In visceral leishmaniasis, the cell-mediated immune response is deficient, and although antibody levels are high, infected macrophages disseminate widely, producing disease in various organs. In cutaneous leishmaniasis, a cutaneous delayed hypersensitivity reaction develops early, controlling proliferation and spread of the parasite; however, in patients lacking immune responsiveness to the parasite, diffuse cutaneous leishmaniasis can develop (Evering and Weiss 2006).

Other kinetoplastids of practical importance are the fish-parasitizing bodonids (Woo 1994) and species of *Phytomonas* that parasitize palm trees and coffee plants

Table 5 Principal species of *Leishmania* causing human disease

Species	Disease/lesion	Distribution	Reservoir hosts
Old World species[a]			
L. tropica[b]	Dry cutaneous; chronic; urban OS; (LR)	Central and W. Asia, N. Africa	Rock hyrax, dog (rare)
L. major	Wet cutaneous; acute; rural OS	Asia, Africa	Rodents
L. aethiopica	Dry cutaneous rural OS; (mucocutaneous, DCL)	Ethiopia, Kenya	Hyrax
L. donovani[b]	Visceral kala-azar (PKDL)	Africa, Asia	Rodents in Africa
L. infantum	Infantile visceral	Mediterranean, Central and W. Asia	Dogs
New World species[c]			
L. mexicana	Cutaneous (Chiclero's ulcer); sylvatic	Central America	Forest rodents
L. amazonensis	Cutaneous (DCL); sylvatic	S. America	Forest rodents
L. braziliensis	Mucocutaneous (espundia); metastasizing; sylvatic	Central and S. America (exc. Argentina, Chile)	Forest rodents
L. guyanensis	Cutaneous (pian bois); metastasizing; sylvatic	Guyana, N. Brazil	Sloth, anteater
L. panamensis	Cutaneous; metastasizing; sylvatic	Panama	Sloth
L. peruviana	Cutaneous (uta)	Peruvian Andes	Dogs
L. infantum	Infantile visceral	Central and South America	Dogs, foxes

References: (Ashford and Crewe 2003; Bates 2007)
Abbreviations: *OS* Oriental sore, *(DCL)* disseminative cutaneous leishmaniasis in some individuals in the absence of cell-mediated immunity, *(LR)* Leishmaniasis recidivans, chronic, nonhealing lesion not responding to treatment, *(PKDL)* post-kala-azar dermal leishmaniasis, skin lesions occurring after apparent cure of visceral leishmaniasis. Abbreviations in brackets represent occasional complications
Notes: [a]Vectors, species of *Phlebotomus*
[b]Humans and other hosts required (anthroponotic). Humans are considered incidental hosts for the other species
[c]Vectors, species of *Lutzomyia*

(Dollet 1984; Wallace et al. 1992) (see Tables 1 and 2 and "Habitats and Ecology"). The kinetoplastids have assumed importance in molecular biology by virtue of the unusual structure of kinetoplast DNA and the phenomenon of RNA editing (kDNA, see "The Kinetoplast") and as a result of detailed studies on the genetic basis of antigenic variation – the process whereby trypanosomes evade their host's immune response (see "The Surface Membrane") – and of flagellar structure and function (see "Cytoskeleton and Motility").

Habitats and Ecology

Completely free-living kinetoplastids are all phagotrophic bodonids (Table 1), and many are common in infusions. Most feed on bacteria while creeping along surfaces, using the anterior flagellum for locomotion and for propelling food particles toward the cytostome, while the posterior flagellum functions as a "skid" that permits contact of the kinetoplastid with the substratum. These organisms are most abundant in organic-rich environments, but many species have strict oxygen requirements and tend to accumulate at a characteristic distance from the air/water interface. Common as coprozoic organisms, they have often been mistaken for parasites in stools or urine samples from a variety of patients (Vickerman 1978). Since bodonids do not survive body temperature, these instances must result from contamination of the samples with free-living organisms. Most free-living bodonids can form thin-walled cysts (Fig. 1d) and thus can pass through the gut of vertebrates to hatch out in the voided feces. One of the most ubiquitous bodonids, *Bodo saltans*, however, appears to be unable to form a cyst.

Epizoic bodonids include *Cephalothamnium cyclopum* (Fig. 1h), which forms colonies attached to its copepod host. Many bodonids live on the gills and skin of fish where they adopt a variety of lifestyles. *Cryptobia branchialis* and *C.* (*Bodomonas*) *concava*, which attach by their recurrent flagella, are claimed to feed on bacteria and dead cells in the gill mucus and so should be transferred to the genus *Procryptobia. Ichthyobodo necator* (*Costia necatrix*), an important parasite of freshwater fish and especially of alevins in fish hatcheries (Woo 1994), attaches to epithelial cells by an anterior rostrum and ingests cell cytoplasm (Fig. 1f). A dispersive free-living phase (Fig. 1g) lacks the rostrum and probably does not feed.

The bloodstream trypanoplasms of fish are transmitted primarily by aquatic bloodsucking leeches but can also be transmitted directly between fish (Woo 1994). Several species of *Cryptobia* have been described from the foregut of marine teleosts, the esophagus or stomach sometimes being thickly carpeted with these bodonids (Becker 1977; Woo 1994). Gut cryptobias are common, too, in freshwater planarians (e.g., *C. dendrocoeli* in *Dendrocoelum lacteum*). *C. iubilans* of the gut of cichlid fishes (Nohýnkovà 1984) can spread to other organs (the gall bladder, spleen, ovary, liver) where it appears to multiply inside macrophages within a parasitophorous vacuole (cf. *Leishmania* spp., see below). Transmission of these gut cryptobias is probably via a free-swimming aquatic phase (Woo 1994), but the cryptobias reported from the gut of terrestrial gecko lizards (Bovee and Telford 1962) may have an encysted stage that ensures transmission. Copulation seems the most likely means of transmission of the cryptobias (e.g., *C. vaginalis*: Fig. 1i, j) found in the female reproductive tract of invertebrates. *Cryptobia helicis* of terrestrial and aquatic gastropods attaches to the microvillar surface of its host organ by tentacle-like outgrowths of its anterior flagellum (Current 1980). All true cryptobias feed by pinocytosis through a cytostome-cytopharynx. A trypanoplasm-like organism, *Jarrellia atramenti*, was described from mucus recovered from the blow hole of a stranded pygmy whale, an unusual report of a bodonid from a warm-blooded vertebrate (Poynton et al. 2001).

While some bodonids have blatantly parasitic lifestyles, the nature of the relationship between other endo- or ectosymbiotic bodonids and their hosts is doubtful. Perhaps the most curious endosymbiotic kinetoplastids are those living in other protists. Kinetoplastids related to *Ichthyobodo necator* (*Perkinsela*, previously referred to as *Perkinsiella* and "*Perkinsela*-related" forms) appear to be obligate symbionts of paramoebid amoebae, such as *Paramoeba*/*Neoparamoeba pemaquidensis*, which causes amoebic gill disease in sea-farmed salmonids (Caraguel et al. 2007). The trypanosomatids, *Leptomonas karyophilus* and *L. ciliatorum*, were described from the macronuclei of ciliates (Gillies and Hanson 1963; Gortz and Dieckmann 1987).

Most of the monogenetic trypanosomatids of arthropods (Wallace 1979) are strictly localized in the guts of their larval or adult hosts. *Crithidia* species tend to be found in the hindgut, where they attach to the chitinized lining by their shortened flagella (Fig. 2e). Such attached or "haptomonad" stages (Molyneux 1983) are also found in *Leptomonas*, *Herpetomonas*, and *Blastocrithidia.* More often species of these genera are found as free-swimming "nectomonads" in the gut lumen, either within or outside the peritrophic membrane. Occasionally the Malpighian tubules are invaded (e.g., *Rhynchoidomonas* spp.) or the hemocoel and salivary glands. The developmental stages of digenetic trypanosomatids occupy similar sites. Those trypanosomes (Stercoraria, see Table 3) that produce the infective metacyclic stage in the hindgut have no reason to leave the alimentary tract. Although *Phytomonas* spp. (Table 2) and *Trypanosoma rangeli* (Table 4) invade the hemipteran's salivary glands from the gut via the hemocoel, the evidence that *Trypanosoma brucei* follows the same route in *Glossina* is poor, and it is generally accepted that migration to the glands is via the foregut and proboscis (Fig. 5) (Lewis and Langridge 1947; Van den Abbeele et al. 1999; Vickerman 1985). Attached stages in the trypanosomatid life cycle may densely carpet the body surface to which they attach. Although the environment of these organisms is aerobic, anaerobic conditions may exist locally, especially in the parasite-packed insect hindgut.

A remarkable interaction of *Leishmania* with the sand fly vector facilitates transmission of the parasite to the vertebrate host. Parasites in the anterior gut secrete a proteinaceous gel, which blocks the pharynx causing flies to regurgitate the plug of flagellates and gel in order to feed, thereby depositing it in the skin of the host. Components of the gel exacerbate disease in the host (Bates 2007; Rogers et al. 2004). Sand fly saliva itself has notable pharmacological effects in the host, such as vasodilation, and also plays a role in disease exacerbation (Bates 2007; Titus and Ribeiro 1988).

Transmission of the monogenetic trypanosomatids is apparently through the nectomonad form in the aqueous environment and more rarely via an encysted stage (see *Life Cycles*) contaminating food. These trypanosomatids survive the diapause in some endopterygote insects, but their location in the pupa is uncertain. Transovarian transmission to offspring of *Leptomonas jaculum* and *Blastocrithidia euryophthalmi* has been reported (McGhee and Cosgrove 1980). Predatory Hemiptera may "adopt" the trypanosomatids of their prey insects, and the so-called *Leishmania* spp. found as promastigotes in the hindgut and rectum of chameleons and other lizards may be similarly acquired (Telford 1995).

Phytomonas spp. inhabit the latex or phloem vessels of their plant hosts, and *P. serpens* is also found in fruit (e.g., tomatoes), but not in the leaves, stems, or unripe fruit of the plant (Dollet 1984; Wallace et al. 1992). Phytomonads are transmitted by various bugs that suck plant juices, but must be distinguished from other trypanosomatids carried by these insects. The nonpathogenic species from lactiferous plants are probably transmitted cyclically by phytophagous hemiptera of the families Lygaeidae and Coreidae (Wallace et al. 1992), but details of the transmission of the pathogenic phytomonads found in the phloem of coffee bushes and palms are limited; the phytomonad of palm trees is transmitted by genus *Lincus* (Wallace et al. 1992).

The digenetic trypanosomes and trypanoplasms of the blood of aquatic poikilotherms share transmission by marine or freshwater leeches. After ingestion in the blood meal of the annelid, trypanosomes undergo a cycle of morphological changes culminating in the production of infective metacyclics in the proboscis sheath (Lom 1979), ready to infect the vertebrate host; multiplication without a developmental cycle has been described for trypanoplasms in the leech crop and proboscis (Woo 1994).

The trypanosomes are best known as free-swimming flagellates in vertebrate blood. However, they may become sequestered in the capillaries of certain organs, especially during the multiplicative phase (e.g., *T. lewisi*), attach to peripheral capillary endothelia (e.g., *T. congolense*), or leave the vascular system and invade the lymphatics and connective tissue fluid (e.g., *T. brucei*, *T. evansi*; see Table 3) (Losos and Ikede 1972). *Trypanosoma cruzi* invades and multiplies as amastigotes inside many different host cell types including muscle cells, macrophages, and fibroblasts (Andrade and Andrews 2005). Like *Leishmania* parasites in macrophages, *T. cruzi* must avoid killing and digestion by the host cell's lysosomal enzymes. *T. cruzi* surmounts this problem by escaping from the parasitophorous vacuole in which it was engulfed into the cytosol, using a hemolysin related to the C9 component of complement to punch holes in the lysosomal membrane (Andrade and Andrews 2005). In contrast, *Leishmania* parasites survive and proliferate as amastigotes inside the phagolysosome of the host macrophage, somehow resisting destruction while benefiting from the nutritionally rich environment (Naderer and McConville 2008). *Endotrypanum* species, which like leishmanias are also transmitted by phlebotomine sand flies, avoid the lysosome threat in the mammal by inhabiting erythrocytes (Table 2).

Characterization and Recognition

Summary Description of Class Kinetoplastea

Flagellates with one or two flagella, each typically possessing a paraflagellar rod in addition to the axoneme and arising from a flagellar pocket or pit. They contain a single mitochondrion, typically extending the length of the body – linear, branched, or reticulate – that contains a prominent DNA kinetoplast usually

located close to the flagellar kinetosomes that insert on (or close to) the mitochondrial outer membrane. Mitochondrial cristae are discoid or tubular. Primary enzymes of the glycolytic pathway are housed in glycosomes – microbody-like organelles characteristic of the taxon. The cytoskeleton is composed of supporting pellicular microtubules (microtubular arrays associated with the plasma membrane). A microtubule-surrounded cytopharynx is present in many species, presumably secondarily lost by many osmotrophic forms. Pseudopodia are absent. There is a single vesicular nucleus with a prominent nucleolus. Nuclear division with intranuclear spindle, lacking polar structures. Condensed chromosomes are not visible. No plastids or storage carbohydrate bodies are present, but lipid globules commonly are present. The Golgi apparatus is typically in the region of the flagellar pocket, but is not connected to kinetosomes. Contractile vacuoles, if present, empty into the flagellar pocket. Reproduction typically is by binary fission; genetic exchange has been described in a handful of species, but likely occurs widely throughout the group, since genes for meiosis-specific proteins have been identified in the genome sequences obtained thus far – see "Sex and Genetics". Kinetoplastids are free living or parasitic. Encystation is common among free-living forms, rare in parasitic forms.

The ultrastructure of representative bodonids and trypanosomatids is depicted in Figs. 3 and 4.

The Kinetoplast and RNA Editing

The kinetoplast stains with basic dyes, the Feulgen reaction, and other DNA-specific stains. The kinetoplast divides before the nucleus, although the DNA replication periods (S phase) of the two organelles partially overlap (Matthews and Gull 1994). In transmission electron micrographs of sections, kDNA is seen as a disc, sphere, or rod composed of 2.5–3.0 nm thick fibrils. In trypanosomatids these are oriented anisotropically and are orthogonal to the face of the disc. In bodonids the structure of the kDNA is more variable: kDNA may be arranged in bundles of anisotropic fibrils as several distinct kinetoplasts (polykinetoplasty; Fig. 1e, f, g) or as bundles isotropically distributed through part or all of the mitochondrial lumen (pankinetoplasty; Fig. 1i) (Lukeš et al. 2002; Vickerman and Preston 1976). The terms eu-, poly-, and pankinetoplasty were coined by Vickerman (1990) to describe the appearance of the kinetoplast, with pro-kDNA and mega-kDNA added more recently (Lukeš et al. 2002). These various structures can also be understood according to the arrangement of the minicircle component of the kDNA and have been interpreted as an evolutionary progression from free minicircles to either an intercalated network (in the trypanosomatids) or giant circles (mega-kDNA found in *Trypanoplasma borreli*) composed of many minicircles joined together in tandem (Lukeš et al. 2002). The key difference between the kDNA of trypanosomatids and bodonids lies in the presence or absence, respectively, of a network structure, rather than in the degree of compaction and mitochondrial distribution of the kDNA as seen by microscopy.

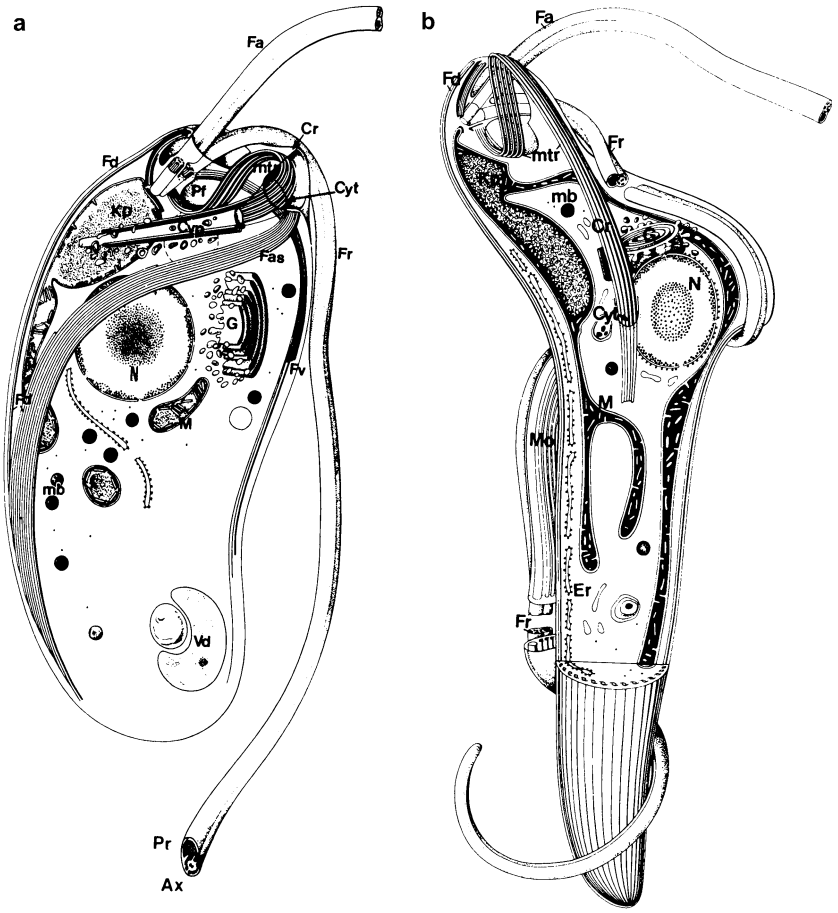

Fig. 3 Ultrastructure of bodonid flagellates. (**a**) Schematic dissection of trophozoite of *Parabodo caudatus* seen in right lateral view. The two flagella (*Fa*, anterior flagellum; *Fr*, posterior (recurrent) flagellum) arise from a flagellar pocket (*Pf*); each has a paraflagellar rod (*Pr*) in addition to an axoneme (*Ax*) in its shaft. Their kinetosomes are separated from the kinetoplast (*Kp*) region of the mitochondrion by a dense plate; the single mitochondrion (seen as several profiles *M*) forms a figure eight in the cell. The cytoskeleton consists of three microtubular bands: *Fd*, the dorsal fiber arising from the dorsal *Pf* wall and connected to the kinetosome of *Fa* by three microtubules; *Fv*, the ventral fiber, connected to the kinetosome of *Fr* and passing along the left side of the *Pf* wall; *mtr*, a band of microtubules from the same kinetosome reinforcing the preoral crest (*Cr*) and deflected inward at the cytostome (*Cyt*) to support the cytopharynx (*Cyp*). A band of microtubules *Fas*, associated with the cytostome, passes along the right side to become incorporated into a sheet of microtubules along with the dorsal fiber. The contractile vacuole (which empties into *Pf*) is seen behind *Cyp* and *Fas*. *N* nucleus, *Er* endoplasmic reticulum, *G* Golgi apparatus, *Vd* digestive vacuole, *mb* microbody (probably a glycosome) (From Brugerolle et al. 1979). (**b**) Schematic dissection of *Trypanoplasma borreli* from blood of goldfish *(Carassius auratus).* Although similar in structure to *Parabodo,* the posterior (recurrent) flagellum (*Fr*) adheres to the body and in beating draws up its surface into an "undulating membrane" (*Mo*). The body is enclosed in an incomplete corset of microtubules corresponding to the *Fd* and *Fv* of *Bodo.* The preoral crest (*Cr*) is extremely long and supported by a microtubule band (*Mtr*) which plunges in the cytostome/cytopharynx about one third of the way along the body. Label abbreviations as in a (From Brugerolle et al. 1979)

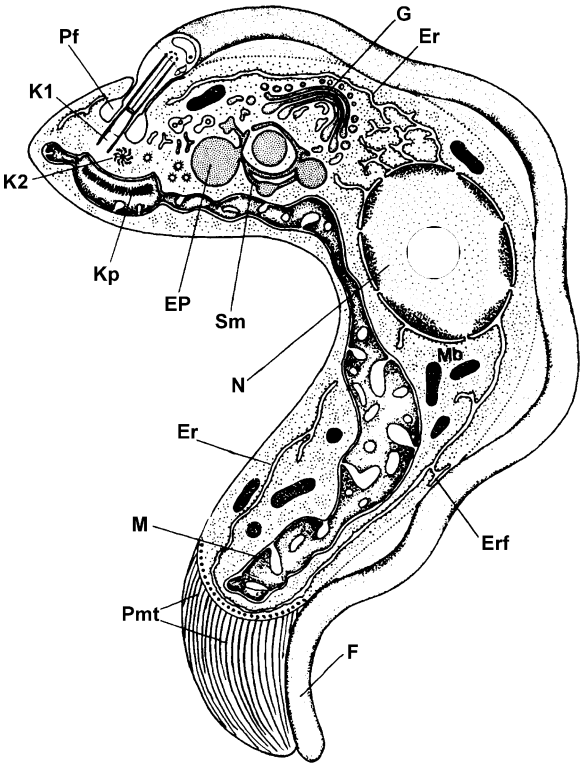

Fig. 4 Ultrastructure of a trypanosomatid, *Trypanosoma congolense*, from the blood of its mammalian host. The single flagellum (*F*) arises from a flagellar pocket (*Pf*) and corresponds to the posterior/recurrent flagellum of bodonids; in *Trypanosoma* it adheres to the body to form an undulating membrane. Close to its kinetosome (*Kl*) lies a barren kinetosome (*K2*), which is all that remains of the anterior flagellum. The kinetoplast (*Kp*) lies in an expansion of the single mitochondrion (*M*), which has tubular cristae. Pellicular microtubules (*Pmt*) form a corset encasing the entire body. Granular endoplasmic reticulum (*Er*) is abundant in the cytoplasm, as are glycosomes (microbodies, *Mb*); a specialized cisterna of ER (*Erf*) runs along the entire length of the undulating membrane. Between the nucleus (*N*) and flagellar pocket, the cytoplasm contains a smooth-membraned reticulum (*Sm*) with saclike dilations; this probably forms a sequestering and digestive system for protein (*EP*) endocytosed from the flagellar pocket. *G*, Golgi apparatus (After Vickerman 1969)

The kDNA of trypanosomatids is the only DNA known which is in the form of a network consisting of thousands of interlocked circles (Shapiro and Englund 1995). The network structure causes the DNA to band rapidly in CsCl density gradients when deproteinized cell lysates are centrifuged. Spread networks are seen by EM to consist usually of two classes of circle, with, depending on species, 25–50 maxicircles each 20–40 kb and 5,000–10,000 minicircles each 0.5–10 kb. Maxicircles, which are equivalent to the mitochondrial DNAs of other eukaryotes, contain genes essential for mitochondrial biogenesis and code for mitochondrial ribosomal RNA and subunits of some proteins involved in electron transport and

ATP synthesis. Transcripts from some of these genes require extensive editing by insertion or deletion of uridine residues before they can be translated correctly; the precise position of each RNA edit is directed by a guide RNA molecule, typically transcribed from one of the minicircles but also encoded by maxicircles in some species (Benne et al. 1986; Shaw et al. 1988; Stuart et al. 2005). Phylogenomic evidence supports the view that RNA editing evolved early in kinetoplastids and is an ancient feature of the group (Deschamps et al. 2011). The whole sequence of the maxicircle genome is known for *T. brucei*, *T. cruzi*, and *Leishmania tarentolae* (Sloof et al. 1992; Westenberger et al. 2006) and also for the partially deleted maxicircle of *T. equiperdum* (Lai et al. 2008). Maxicircles can be removed from the network by restriction enzyme digestion without affecting network integrity, as it is fundamentally a structure of intercalated minicircles. Indeed, this structural role was the only function assumed for minicircles until their key role in RNA editing was discovered. Minicircles are heterogeneous in nucleotide sequence, except in mutants, such as *T. evansi* and *T. equiperdum*, in which they have become homogeneous, presumably as a result of an active mitochondrial system no longer being required.

Why trypanosomatids alone among eukaryotes should have their mitochondrial DNA organized in a network is not known, neither is the purpose of RNA editing, which has been found to varying extent in all kinetoplastids studied and thus is presumed to have evolved before the divergence of the group (Deschamps et al. 2011; Maslov et al. 1994; Simpson et al. 2000). The gene transcripts requiring editing and the extent of edits vary between species, and it has been postulated that retroposition events have gradually corrected the genomic sequences. Transfer RNAs have to be imported into the kinetoplastid mitochondrion, as there are no tRNA genes in the maxicircle, and a second RNA editing process targeting the tRNA anticodon converts the tryptophan tRNA to read the stop codon UGA (Simpson et al. 2000).

The structure of kDNA has been studied in relatively few bodonids. In *Parabodo caudatus* (formerly *Bodo caudatus*), the kinetoplast appears as a single structure at the base of the flagellum – eukinetoplasty (Vickerman 1990) – but becomes fragmented and dispersed during encystment; the kDNA fraction from gradients contained free circular DNAs identified as minicircles of 10 and 12 kb, and 19 kb maxicircles (Hajduk et al. 1986). A similar nonnetwork organization of the kDNA was found in *Bodo saltans* with 70 kb maxicircles and 1.4 kb minicircles, abundant and free circles for the most part with a few catanenes (Blom et al. 1998); in the EM image shown, the kinetoplast sits at the base of the flagellum as a disc-shaped mass and resembles that of trypanosomatids, i.e., eukinetoplastic condition, although subsequently described as pro-kDNA (Lukeš et al. 2002). In *Cryptobia helicis*, a parasite of snails, the kDNA is seen as multiple foci within the mitochondrion (pankinetoplasty) and consists of ~43 kb maxicircles and 4.2 kb minicircles, which, unusually for minicircles, are supercoiled; again there is no network structure (Lukeš et al. 1998). In *Trypanoplasma borreli* the minicircles are joined in tandem to make 180 kb circular DNAs (mega-kDNA), with 80 kb maxicircles (Maslov and Simpson 1994). Despite the fact that the kDNA of genus *Dimastigella* appears as

multiple distinct nucleoids in the mitochondrial lumen – polykinetoplasty (Vickerman 1990) – no network structure was revealed in the analysis of kDNA and only free minicircles recovered (Stolba et al. 2001). Thus, albeit on a limited sample of bodonids, kDNA network structure is absent and bodonid mini- and maxicircles are more variable in size than those of trypanosomatids.

Replication of the kinetoplast in trypanosomatids raises problems not found with any other DNAs, owing to the network structure (Liu et al. 2005). This complex and intricate process has been intensively studied in *Crithidia fasciculata* and *Trypanosoma brucei* (Jensen and Englund 2012). Minicircles are released from the kDNA network by a topoisomerase and replicated daughter minicircles then reattach to the periphery of the network at opposite sides. At the end of replication, the network has doubled in size and is composed entirely of replicated minicircles, each of which has a nick in one DNA strand; the network then divides in two. In *C. fasciculata* the kDNA network rotates so that as replicated minicircles are attached at the two poles, they become evenly distributed on the periphery of the network; in *T. brucei* the same problem is solved in a different way – the network oscillates from side to side (Liu and Englund 2007). Less is known about the replication of maxicircles: like minicircles, they replicate only once per generation, but do not detach from the network; replication is via a theta intermediate structure and initiates in the variable region of the maxicircle (Carpenter and Englund 1995; Liu et al. 2005). The kinetoplast replicates during the division cycle after kinetosome (basal body) reproduction is complete. The kinetoplast is connected to the kinetosome by filaments – the tripartite attachment complex (TAC) – ensuring linkage between the replication of both structures (Jensen and Englund 2012).

The maxicircle gene products are essential for activation of the mitochondrion. Some mutants of *T. brucei* that cannot transform to the procyclic stage (i.e., undergo development in the insect) have maxicircle deletions or even complete absence of maxicircles. Some such mutants – the so-called dyskinetoplastic trypanosome lines – arise through disruption of network structure and dispersion of kDNA throughout the mitochondrion (Schnaufer et al. 2002). They lack a stainable kinetoplast and typical maxicircles and minicircles cannot be isolated from them (Cuthbertson 1981). Dyskinetoplasty can be induced by certain trypanocidal drugs (acridines, phenanthridines, diamidines). Dyskinetoplastic lines of *T. brucei* and its evolutionary derivatives, *T. evansi* and *T. equiperdum* (see Evolutionary History), can live indefinitely in the mammalian host – presumably because the mitochondrion is repressed in that phase of the life cycle and maxicircle gene products are not required. Other dyskinetoplastic kinetoplastids have not been described in nature (Schnaufer et al. 2002).

The Glycosome and Basic Metabolism

All kinetoplastids contain glycosomes – microbody (peroxisome)-like organelles – in their cytoplasm, diameter 0.02–1.0 μm, with a finely granular matrix and a bounding membrane similar in thickness to that of the endoplasmic reticulum

(Fig. 3). In some cases crystalline bodies are present in the matrix. Glycosomes were thought to be unique to kinetoplastids, being absent in *Euglena* (Michels and Hannaert 1994; Opperdoes et al. 1988), but evidence of glycosomes in *Diplonema papillatum* now suggests that these organelles evolved in the common ancestor of diplonemids and kinetoplastids (Gualdron-Lopez et al. 2012). Glycosomes play a key role in energy metabolism in that they harbor seven primary enzymes of the glycolytic pathway as well as two enzymes involved in the metabolism of glycerol-glycerol kinase and NAD^+-linked glycerol-3-phosphate dehydrogenase. Together, these enzymes account for the conversion of glucose and glycerol to 3-phosphoglycerate (Hannaert et al. 2003; Opperdoes 1985). A major peculiarity of *T. brucei* and related species is that reoxidation of NADH generated in glycolysis is via a dihydroxyacetone phosphate/glycerol-3-phosphate shunt operating in conjunction with a terminal glycerophosphate oxidase. The oxidase is cyanide/azide insensitive and is located in the mitochondrial membrane. It reacts with oxygen directly and lacks coupling to ATP synthesis. The high activity of this glycerophosphate oxidase accounts for the high oxygen demands of bloodstream trypanosomes; the enzyme is inhibited by aromatic hydroxamic acids. A similar oxidase is found in many other organisms but not mammals (Chaudhuri et al. 2006).

Glycosomes also contain adenylate kinase, two enzymes of de novo pyrimidine synthesis, and, in insect stages of the life cycle, malate dehydrogenase and phosphoenolpyruvate carboxykinase, which participate in the glycolytic reoxidation of NADH and CO_2 fixation, respectively. Glycosomes also have an important role in the synthesis of ether lipids as do mammalian peroxisomes (Hannaert et al. 2003; Opperdoes 1985). Microbodies are believed to be derived from the ER (endoplasmic reticulum) rather than having an endosymbiotic origin, like mitochondria and chloroplasts; indeed, phylogenetic analysis of glycolytic enzymes indicates a eukaryote rather than prokaryote origin (Michels and Hannaert 1994). The compartmentalization of glycolysis in the glycosome concentrates enzymes and substrates, making glycolysis more efficient; however, among extant kinetoplastids, only some trypanosomes and phytomonads benefit from the ability to maintain a high glycolytic flux, and therefore the evolutionary advantage of the glycosome requires alternative explanations (Michels and Hannaert 1994).

Glycosomes undergo a morphological change in the life cycle of *T. brucei*; the spherical structures of the metacyclic and bloodstream forms become bacilliform and more electron dense in the uncoated vector stages (Fig. 5), paralleling the repression of glycolysis in the insect host (Vickerman 1985). The glycosome, being essential to kinetoplastids, may be an appropriate target for rational chemotherapy of diseases caused by these organisms.

Trypanosomatids show flexibility in their basic metabolism, which may end in oxidative phosphorylation or proceed only as far as aerobic fermentation, according to the extent of mitochondrial suppression and corresponding dependence on glycolysis for energy production (Bringaud et al. 2006; Chaumont et al. 1994). As parasites, they rely on available carbon sources in their hosts; for example, glucose is the preferred carbon source for mammal stages of *Trypanosoma brucei* and *T. cruzi*, which dwell in the bloodstream or cytoplasm of the host, whereas for insect stages

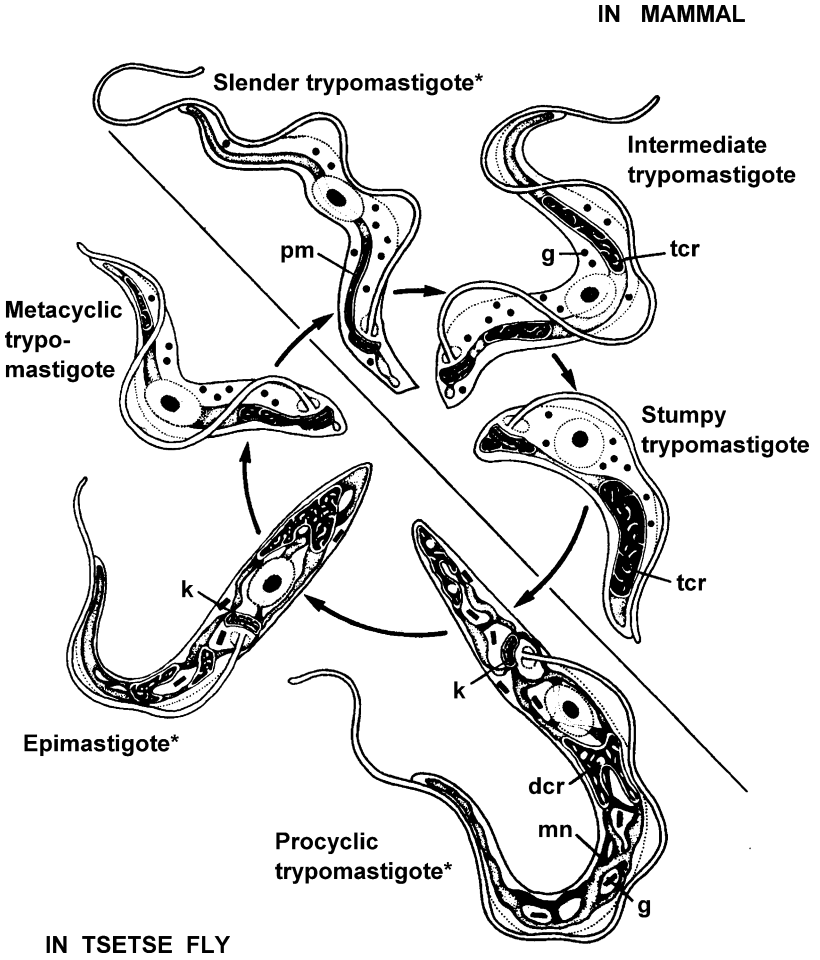

Fig. 5 Life cycle of *Trypanosoma brucei* showing changes in position of kinetoplast and in the form of the mitochondrion and glycosomes (*g*). The mitochondrion is shown cut open to display its interior. Stages in which division occurs are marked with an asterisk. *In mammalian host:* Long slender trypomastigotes divide in blood and tissue fluids giving rise to nondividing intermediate and short stumpy trypomastigotes. Slender forms have a simple promitochondrion (*pm*) with few or no internal cristae; a functional respiratory chain is missing and the parasite depends entirely on glycolysis for energy production. Glycolytically reduced NADH is reoxidized by a dihydroxyacetone phosphate/glycerol 3-phosphate oxidase shuttle in combination with a cyanide- and azide-insensitive glycerophosphate oxidase, located in the mitochondrial membrane, which reacts with O_2 without the intervention of cytochromes and without coupling to ATP synthesis. Transformation to the stumpy form is accompanied by acquisition of proline and α-ketoglutarate oxidase activities as the mitochondrion swells and develops tubular cristae (*tcr*). *In the insect host:* On entering the tsetse midgut, the mitochondrion expands into a network (*mn*) as the post-kinetoplast and prenuclear regions of the trypomastigote increase in size. Succinoxidase activity appears and proline and α-ketoglutarate oxidases are augmented as the trypanosome switches from a glucose-based energy metabolism to one based on proline. Later, in the midgut, discoid cristae (*dcr*) replace the tubular type and a complete cytochrome chain appears; the chain may be branched at cytochrome

only amino acids are readily available; similarly *Leishmania* promastigotes in the insect use amino acids, whereas amastigotes in the phagolysosome of the mammalian macrophage use fatty acids as their energy source (Bringaud et al. 2006). *Phytomonas* spp. from fruit or the phloem or latex of plants use glucose and the other simple sugars present in plant sap or produced by enzymatic digestion of complex carbohydrates to fuel glycolysis, meanwhile suppressing mitochondrial activity (Fernandez Becerra et al. 1997; Sanchez-Moreno et al. 1992).

Many aspects of basic metabolism in the so-called Tritryps (*Trypanosoma brucei*, *T. cruzi*, and *Leishmania major*) are now plain to see from the genome data, if the constituent enzymes of a particular biochemical pathway are present (Berriman et al. 2005). In addition, analysis of all the small metabolites present in the cell (metabolomics) provides a global picture of cell metabolism (Creek et al. 2012). In contrast, little is yet known about the metabolism of bodonids due to the difficulties of growing these organisms in axenic culture, but the availability of a draft genome sequence of *Bodo saltans* will speed up further investigation (Jackson et al. 2008). Presumably the free-living bodonids such as *Bodo* are able to obtain and utilize the wide variety of organic compounds from their prey, while parasitic bodonids such as *Trypanoplasma* and *Cryptobia* are dependent on available carbon sources in their hosts. Glycosomes, glycosomal enzymes, and genes have been studied in *Trypanoplasma borreli* (Adje et al. 1998; Opperdoes et al. 1988; Wiemer et al. 1995). The free-living bodonids tolerate a wide range of conditions, including extremes of salinity or temperature and anoxic environments, and have even been found in deep-sea vent communities (Atkins et al. 2000). This indicates great adaptability in their metabolic and physiological requirements, but to what extent individual species are capable of these feats of adaptation is open to debate. For example, superimposing the salt tolerance of various isolates of *Neobodo (=Bodo) designis* onto their phylogenetic tree has revealed a high degree of cryptic speciation (Koch and Ekelund 2005).

Trypanosomatids such as *Trypanosoma brucei*, *T. cruzi*, and *Leishmania* spp. lack catalase, although this enzyme has been detected in the glycosomes of *Crithidia luciliae*, *Leptomonas samueli*, and possibly *Phytomonas* spp., as well as the bodonid, *Trypanoplasma borreli* (Fernandez Becerra et al. 1997; Opperdoes et al. 1988; Sanchez-Moreno et al. 1992). The antioxidant defense system of

Fig. 5 (continued) b allowing flow of electrons to oxygen either via cytochromes a-a_3 (cytochrome oxidase). Procyclics migrate anteriorly to the proventriculus (cardia) of the fly, where the nucleus elongates and the cell undergoes an asymmetric division resulting in one short and one long epimastigote (not shown). All these stages are found among the migratory stages in the foregut, but it is believed to be the short epimastigote that becomes an attached, multiplicative epimastigote, with prenuclear kinetoplast (*k*) and tubular mitochondrial cristae, on reaching the salivary glands. On transformation to the metacyclic trypomastigote, the mitochondrion becomes a linear structure again; as yet nothing is known about the respiration of the salivary gland stages in the life cycle. The surface of the mammal stages and metacyclics is covered with variant surface glycoprotein; note change in form of glycosomes (*g*) from spherical to bacilliform structures and vice versa (Based on Lewis and Langridge 1947; Opperdoes 1985; Vickerman 1985)

Trypanosoma and *Leishmania* species instead relies on a unique dithiol, trypanothione (Fairlamb et al. 1985); trypanothione reductase and other enzymes involved in the biosynthesis and metabolism of trypanothione are prime candidates for the development of new drugs against trypanosomiasis (Fairlamb and Cerami 1992). Trypanothione metabolism has also been studied in *Crithidia luciliae*, but whether this is a system unique to trypanosomatids, or kinetoplastids in general, is unknown.

Before leaving metabolic pathways, the distinctive nucleotide biosynthesis of kinetoplastids deserves mention. While kinetoplastids have to scavenge purines, they have both synthesis and salvage pathways for pyrimidines. In *Trypanosoma cruzi* one of the key enzymes in this biosynthetic pathway, dihydroorotate dehydrogenase (DHOD), is cytosolic rather than being located in the mitochondrial membrane and uses fumarate as electron acceptor rather than ubiquinone; the same type of DHOD was also found in two free-living bodonids – *Neobodo saliens* and *Parabodo caudatus* (formerly *Bodo saliens* and *Bodo caudatus*) – but not in *Euglena gracilis* and is hypothesized to have entered the kinetoplastid lineage by horizontal gene transfer from prokaryotes (Annoura et al. 2005).

The Surface Membrane and Antigenic Variation

Most probably all kinetoplastids have a plasma membrane that is divided into several functional domains – minimally, main cell body, flagellum, flagellar pocket, cytostome – but, as ever, there is little information on bodonids, the bulk of research being on the pathogenic trypanosomatids. Each stage in the kinetoplastid life cycle may have a variety of glycoproteins and glycoconjugates exposed on its surface, some of which are stage specific and may also show inter- or intrastrain variation. Much current research focuses on the structure and function of exposed macromolecules as ligands binding to host cells during invasion, as antigens playing a part in the induction of immunity and evasion of the host's immune response or as receptors for the uptake of molecules from the environment. In addition, small glycolipid molecules – glycosylinositolphospholipids or GIPLs – cover the surface of *T. cruzi*, *Leishmania*, and other trypanosomatids, providing a protective physical barrier between the parasite and the harsh environment of the host.

The chronic infection and fluctuating parasitemia of African trypanosomiasis are due to evasion of the host's immune response through antigenic variation on the part of the parasite. As trypanosomes multiply by fission in the rising parasitemia, a small number of variable antigen types (VATs) are present in the trypanosome population and these are the focus of the host antibody (IgM) response. The parasitemia goes into remission as trypanosomes of these VATs are killed off, leaving trypanosomes that have switched to other VATs to form the next wave of parasitemia. VAT switching does not require host antibody to induce it and is a stochastic mutational process (Borst and Cross 1982). The molecular basis for antigenic variation in the African tsetse-transmitted trypanosomes has attracted much attention and is now a textbook example of developmental gene rearrangements in eukaryotes (reviewed

by Borst and Cross 1982; Pays et al. 2004; Taylor and Rudenko 2006). Most studied is *Trypanosoma brucei*, with relatively little known about antigenic variation in the other salivarian trypanosomes such as *T. congolense* or *T. vivax.*

The variant surface glycoprotein (VSG) can be seen as a 12–15 nm thick coat covering the entire trypanosome plasma membrane, except the flagellar pocket where it is recycled (Engstler et al. 2004); the coat is composed of a monomolecular layer of VSG dimers. The various VSGs differ in the amino acid sequence of the N-terminus and hence in their antigenic specificity; the N-terminal portion of the VSG is exposed, while the C-terminus is conserved (Blum et al. 1993) and attached to the membrane proper (lipid bilayer) via a glycosyl phosphate inositol (GPI) anchor (Ferguson 1994). Each VSG is the product of a single *VSG* gene, which is expressed in a telomeric expression site. Antigenic variation comes about by replacement of the expressed *VSG* gene with the whole or part of another *VSG* gene. Only one *VSG* gene is expressed at a time, which was thought to result from there being only a single expression site; however, this hypothesis fell by the wayside when it was realized that a single trypanosome had about 20 different expression sites and could switch between them. Instead it turns out that *VSG* is transcribed in a special compartment in the nucleus – called the expression site body or ESB (Navarro and Gull 2001) – which is unique to trypanosomes.

The number of *VSG* genes in the antigenic repertoire of a single trypanosome was estimated at 1000 (Borst and Cross 1982), a ballpark figure confirmed by the results of the *T. brucei* genome sequencing project (Berriman et al. 2005); silent VSG genes were found clustered in subtelomeric arrays on the 11 pairs of large chromosomes, but surprisingly most were found to be either pseudogenes or part genes, which would require recombination with another VSG gene to produce a functional protein. Besides devoting an estimated 10% of its genes to encode VSG (Berriman et al. 2005), *T. brucei* also transcribes these genes at high rate using RNA polymerase I, making VSG mRNA one of the most abundant mRNAs in a bloodstream form cell. *VSG* gene transcription appears to be tightly bound to cell division, as cells undergo pre-cytokinesis cell cycle arrest when *VSG* gene transcription is disrupted (Sheader et al. 2005). The VSG protein is continuously recycled via the flagellar pocket, the whole coat being turned over in an astonishing 12 min (Engstler et al. 2004). While antigenic variation is clearly a successful immune evasion strategy, it comes at a huge metabolic cost to the trypanosome.

When the trypanosome embarks on cyclical development in the tsetse fly, the VSG coat is discarded and replaced by a less dense covering of other stage-specific, GPI-anchored glycoproteins, such as the acidic procyclins of *T. brucei* and *T. congolense*, which are characterized by repetitive amino acid sequences (Roditi et al. 1987; Utz et al. 2006). The VSG coat is reacquired by the metacyclic trypanosomes in the vector's salivary glands (*T. brucei*) or hypopharynx (*T. vivax*, *T. congolense*). The metacyclic VAT repertoire is limited and these *VSG* genes are expressed in a special set of expression sites (Barry et al. 1998). The metacyclic VATs are the first to appear in the mammal following a bite by an infected tsetse fly

and are succeeded by bloodstream form VATs expressed from the usual telomeric expression sites. The seemingly inexhaustible series of antigenic variants that a single trypanosome can produce makes vaccination a hopeless proposition.

The cell surface of *Trypanosoma cruzi* is covered with a dense layer of mucins, protruding above a GIPL layer (Guha-Niyogi et al. 2001). Mucins serve key roles in host cell invasion and protection of the parasite surface and show stage-specific expression, with several different mucin gene families recognized. Many hundreds of mucin genes occur in the *T. cruzi* genome and they are found clustered with genes for the aptly named mucin-associated surface proteins (MASPs, function unknown), proteases (GP63), and trans-sialidases (El-Sayed et al. 2005a). Why so many genes are required, how they are regulated during development, and what role they play in evasion of host immune responses are major unanswered questions (Buscaglia et al. 2006). Trypanosomes cannot synthesize sialic acid de novo, so trans-sialidases serve to transfer sialic acid residues from host to parasite molecules, including mucins; such modifications can be crucial for host cell recognition and invasion (Schenkman et al. 1991). *Trypanosoma cruzi* epimastigotes are characterized by abundant lipopeptidophosphoglycan (LPPG) on their surface (Singh et al. 1994).

Cell-surface molecules of *Leishmania* also show stage-specific expression and have key roles in host cell invasion and protection of the parasite against host defenses (Olivier et al. 2005). Promastigotes in the sand fly vector are protected by a thick glycocalyx consisting of a heterogeneous mix of GPI-anchored glycoproteins, GIPLs, and lipophosphoglycans (LPGs). Some *Leishmania* species use LPG to attach to the gut epithelium of their particular sand fly vector (Bates 2007), while the glycocalyx on the surface of the mammal-infective metacyclics includes branched LPG molecules, capable of resisting complement attack on transfer to the mammalian host (Olivier et al. 2005). Invasion of host macrophages involves a complex interplay of parasite surface molecules and macrophage receptors, facilitating attachment and uptake of the parasite, while deactivating and delaying macrophage defenses; once inside, the parasite continues to subvert its host cell by manipulation of signaling pathways, thereby modulating the host immune response – of key relevance to the very different clinical pictures produced by different *Leishmania* species (Olivier et al. 2005).

A thick, protective glycocalyx seems to be a feature of the trypanosomatid cell surface, whether produced by GIPLs and LPG in *Leishmania* or the bulky carbohydrate side chains of the GPI anchors for surface proteins in trypanosomes (Ferguson 1994). GIPLs, LPG, and LPPG share a core structural motif with GPI anchors – the mannose-glucosamine-phosphatidylinositol linkage to the phospholipid bilayer; further carbohydrate and lipid groups are then linked to this "anchor" group (Ferguson 1994). GIPLs have been found in *Leishmania* spp. and *T. cruzi* as well as some insect trypanosomatids (Guha-Niyogi et al. 2001). Mucins may also be a general feature of the trypanosome surface, having been found in both *T. cruzi* and in the fish trypanosome, *T. carassii*, although lost in the Salivaria (Overath et al. 2001).

Nutrition and Symbionts

Knowledge of nutritional requirements is fragmentary, with the focus of research as always on the pathogenic trypanosomatids, and feeding mechanisms remain a mystery in the majority of kinetoplastid species. In bodonids, a cytostome-cytopharynx is invariably present, and through it bacteria and macromolecules are phagocytosed for digestion in food vacuoles, which subsequently empty into the flagellar pocket (Vickerman and Preston 1976). The preoral crest (Fig. 3a) and wall of the flagellar pocket form seizing lips for prey and these lips may be drawn out to form a prehensile rostrum (Fig. 1). In trypanosomatids, a cytostome-cytopharynx has been reported in *Crithidia* and certain invertebrate stages of the life cycle of some trypanosome species (e.g., *T. cruzi*, *T. cyclops*). The cytostome has been shown to be active in protein uptake in *T. cruzi* epimastigotes and empties into the reservosome – see below (Porto-Carreiro et al. 2000). However, the flagellar pocket seems to be the main site for endo- and exocytosis in most trypanosomatids (Field and Carrington 2009). The cytostome and flagellar pocket are the only two regions without pellicular microtubules and a protective glycocalyx or protein coat and are therefore available for vesicular traffic. Endocytic pathways and cellular machinery have been well characterized in *T. brucei* and other pathogenic trypanosomatids (Morgan et al. 2002a, b).

Few trypanosomatids have been grown in defined media but these include representatives of the major genera; actual nutritional requirements, however, have been determined for very few. Metabolomic analysis is now being used to provide a global view of metabolic flux, facilitating the rational design of new culture media, as well as improving understanding of cellular metabolism (Creek et al. 2013). Trypanosomatids studied to date require minimally the following nutrients: at least ten but often more amino acids, depending on other constituents of the medium; hemin; purine (hemomastigotes can synthesize their own pyrimidines); thiamine, riboflavin, pantothenic acid, nicotinamide pyridoxamine, biotin, folic acid, and biopterin; and a mixture of inorganic nutrients and possibly specific lipids (Trager 1974). Since they have no storage carbohydrates, kinetoplastids are primarily dependent upon exogenous substrates, such as carbohydrates or amino acids, for their energy supplies. However, *T. cruzi* epimastigotes store proteins and lipids in reservosomes – large membrane-bound organelles found at the posterior end of the cell (Figueiredo et al. 2004) – these in association with the cytostome may be adaptations for survival in a vector prone to prolonged bouts of starvation, interrupted by periods of plenty after a blood meal. Storage lipid occurs in several kinetoplastids and fatty acids are used as an energy source by *Leishmania* amastigotes (Bringaud et al. 2006).

Parasitic kinetoplastids exploit the nutrients available in their particular host environment, so their biosynthetic capabilities vary according to life cycle stage. Blood-dwelling parasites such as *Trypanosoma brucei* are bathed in nutrient-rich serum, allowing uptake to replace de novo synthesis. Thus, in the vertebrate host, the trypanosome's requirement for sterols is met by extraction of cholesterol from low-density lipoprotein (LDL) particles taken up from serum by receptor-mediated

endocytosis; in addition, procyclic insect forms maintain the capacity to synthesize ergosterol from scratch (Coppens and Courtoy 2000). Trypanosomatids require exogenous heme and, indeed, the first two enzymes of the heme biosynthetic pathway are missing in the genome sequences of *T. brucei*, *T. cruzi*, and *Leishmania major* (Berriman et al. 2005). In *T. brucei*, heme is obtained by uptake of hemoglobin coupled to haptoglobin by a specific receptor in the flagellar pocket; this seems to be an Achilles heel of the parasite as the same receptor also internalizes apolipoprotein L1, which is the trypanolytic factor in human serum (Vanhollebeke et al. 2008). Apolipoprotein L1 ends up in the lysosomes, where it creates holes in the membrane, leading to swelling and eventual cell lysis (Perez-Morga et al. 2005). The human pathogenic subspecies, *T. b. rhodesiense*, uses its own serum resistance-associated (SRA) protein to deactivate apolipoprotein L1, thereby escaping lysis (Vanhamme et al. 2003). The essential nutrient iron is bound to transferrin in host serum and taken up by receptor-mediated endocytosis; in bloodstream form *T. brucei*, the transferrin receptors are located in the flagellar pocket, while in *T. cruzi* epimastigotes, transferrin enters via the cytostome and is routed to the reservosome; the location of *Leishmania* amastigotes within the lysosome of the host macrophage has the interesting consequence that nutrients are delivered via the endocytic system of the host cell (Morgan et al. 2002a).

Symbiotic prokaryotes are common in the cytoplasm of bodonids and occur in some insect trypanosomatids; those of *Crithidia oncopelti*, *C. deanei*, *C. desouzai*, *Blastocrithidia culicis*, and *Herpetomonas roitmani* have been studied in some detail. Antibiotic treatment has produced aposymbiotic (symbiont-free) strains of most of these species, enabling detailed examination of the role of the endosymbiont in supplying essential nutrients (de Souza and Motta 1999). Symbionts relieve *C. deanei* and *C. oncopelti* of their heme requirements and also synthesize several metabolites essential for growth. Cells generally host one or two endosymbionts, but their large size (1.3–2.3 μm in length and 0.3–1.0 μm in width) leads to some distortion of cell structure (de Souza and Motta 1999). A phylogenetic comparison of the three trypanosomatid genera with endosymbionts demonstrated that the endosymbiont-containing trypanosomatids are a monophyletic group, separate from naturally occurring, symbiont-free species of the same genera (Hollar et al. 1998). This implies that a single endosymbiosis event occurred in this lineage, and in agreement with this, phylogenetic analyses show that the bacterial symbionts of *Crithidia* and *Blastocrithidia* are very closely related within the β division of the Proteobacteria (de Souza and Motta 1999). The endosymbionts of bodonids appear to be intact encapsulated gram-negative bacteria (Eyden 1977; Vickerman 1977).

Cytoskeleton and Motility

Microtubules are the only known element of the kinetoplastid cytoskeleton. Axonemal microtubules are involved in locomotion, pellicular microtubules (PMT) in the maintenance of cell shape, and nuclear spindle microtubules in cell division. In the bodonids the PMT array is usually incomplete (Brugerolle et al. 1979) and composed

of a series of microtubule bands ("fibers") as depicted for *Parabodo caudatus* in Fig. 3a. In trypanosomatids, evenly spaced PMT form a corset enveloping the entire body (Fig. 4), the spindle shape of the cell being accommodated by variation in the length of individual microtubules; only in certain aposymbiotic insect trypanosomatids is the corset interrupted by PMT-aligned branches of the mitochondrion. The PMT are cross-linked to each other and to the plasma membrane, thus holding the trypanosomatid cell in shape; during cell division, the old PMT array is maintained and used as the framework for addition of the new microtubules of the daughter cell (Gull 1999).

Microtubule assembly and disassembly play an important role in kinetoplastid morphogenesis and differentiation. The major structural units of trypanosomatid microtubules, α- and β-tubulin, are subject to a range of protein modifications, although of uncertain significance to the living cell, some of these modifications have proved to be valuable markers for the analysis of microtubule assembly, e.g., the removal and addition of tyrosine (Gull 1999). Other minor tubulin types have been detected and have discrete roles: as well as being associated with the microtubule-organizing centers (MTOCs) of *Trypanosoma brucei* (Scott et al. 1997), γ-tubulin is essential for building a normal flagellar axoneme, since the central two microtubules were missing in cells lacking this protein (McKean et al. 2003).

The axoneme of kinetoplastids has a characteristic "9 + 0" transition zone between it and the kinetosome, the two central axonemal microtubules arising beyond the second of two transverse plates delimiting the zone (Fig. 4). No arms are present on the doublets of the transition zone, and a fine "collarette" of unknown composition surrounds the zone outside its bounding membrane. A latticelike chord, the paraflagellar rod (PFR), running alongside and linked to the axoneme is a second characteristic of the kinetoplastid (and euglenid) flagellum. Other names for the PFR include "paraxonemal rod" and "paraxial rod." The PFR is composed largely of two similar proteins; loss of either has been shown to severely reduce motility in *Trypanosoma brucei* and *Leishmania* (Bastin et al. 1998; Santrich et al. 1997). Striated rootlets are undeveloped in the kinetoplastids; the kinetosomes, which serve as microtubule-organizing centers (Vickerman 1976), are associated with the kinetoplast (mitochondrial) capsule membrane. Nontubular mastigonemes are found on the anterior flagellum of certain bodonids (e.g., *Bodo saltans*, *Cephalothamnium cyclopum)*.

All kinetoplastids have two kinetosomes. Both bear flagella in the anisokont bodonids (Fig. 3). In the trypanosomatids the single axoneme-bearing kinetosome (Fig. 4) corresponds to the posterior flagellum of the bodonids. Attachment of the recurrent flagellum to the body occurs in several bodonids (Table 1) and in some trypanosomatid genera epimastigote and trypomastigote stages (Table 2). A linear series of desmosome-like attachments binds the flagellum to the body in trypanosomatids, but similar structures are rare in bodonids. Detailed analysis of the flagellar attachment zone (FAZ) in *Trypanosoma brucei* reveals a complex structure consisting of a longitudinal bundle of cytoplasmic filaments attached to four specialized PMTs, which arise near the kinetosomes (Gull 1999). Molecular

dissection of flagellar attachment has demonstrated essential roles for the surface membrane glycoprotein, FLA1 (Cooper et al. 1993; LaCount et al. 2002), and the FAZ protein, FAZ1 (Vaughan et al. 2008), as mutant trypanosomes lacking expression of these genes had defects in attachment and cytokinesis. In dividing trypanosomes, the new flagellum arises alongside the old flagellum and, as it lengthens, remains attached by its tip to the old flagellum by a structure called the flagellar connector (Moreira-Leite et al. 2001); the flagellar connector thus guides the growth of the new flagellum and thereby directs the correct configuration of other associated cell structures. The flagellum is therefore central to cell pattern control, and it is therefore no surprise that disruption of flagellar structure impacts on cell division as well as motility (Broadhead et al. 2006).

No detailed studies of movement in bodonids are available, but trypanosomatids have found a use in studies on hydrodynamic aspects of flagellar movement. A notable feature of these flagella is that they propagate waves from tip to base as well as from base to tip (Holwill 1980). Indeed, bends can be initiated at any point along the flagellum, whereas in most other flagella, bending is dependent upon activation in an adjacent region. The ability to dissect flagellar function at the molecular level has renewed interest in the control of flagellum beating (Branche et al. 2006).

A final peculiarity of the kinetoplastid flagellum is its ability to act as an attachment organelle in parasitic species, securing the "haptomonad" to its substratum or to the flagellum of an adjacent kinetoplastid. The flagellum may develop extensive cortical outgrowths to aid attachment (Molyneux 1983; Tetley and Vickerman 1985). Such attached stages play an important part in the life cycles of trypanosomatids. The physical nature of the attachment is unknown, but hemidesmosome-like plaques are present on the axonemal membrane in attachments to a foreign substratum and desmosomes are present in attachments to other flagella (Molyneux 1983; Vickerman 1973).

Nucleus and Transcription: Sex and Genetics

All kinetoplastids have a vesicular nucleus with large central nucleolus. Perinuclear chromatin is visible in electron micrographs, but no chromosomal condensation cycle is apparent. Nuclear division takes place without dissolution of the nuclear envelope; an intranuclear microtubular spindle structure is present but lacks polar structures; a few kinetochore-like plaques which split into hemiplaques that migrate to the poles have been demonstrated (Solari 1983).

There is detailed knowledge about the chromosomal complement and genetics of the pathogenic trypanosomatids. All are fundamentally diploid, although aneuploidy has been reported in *Leishmania* and *T. cruzi*, and cloned isolates of *T. cruzi* were shown to have a wide range of DNA contents (Dvorak et al. 1982). *Trypanosoma brucei* has 11 pairs of large chromosomes, a few small chromosomes, and an estimated 100 minichromosomes (Melville et al. 1998). In contrast, *T. cruzi* and *Leishmania* spp. have large numbers of chromosomes – the genome strains of *T. cruzi* and *L. major* have ~28 and 36 pairs of chromosomes, respectively

(El-Sayed et al. 2005b; Ivens et al. 2005). Notwithstanding these differences in chromosome number, the Tritryp genome sequences reveal large-scale conservation of gene order (synteny) when chromosomes are aligned (El-Sayed et al. 2005b; Ivens et al. 2005).

Present in the Tritryp genome sequences are six meiosis-specific genes, indicating that these kinetoplastids have the machinery for a meiotic division and production of haploid gametes (El-Sayed et al. 2005a). Genetic exchange has now been demonstrated in laboratory crosses of *T. brucei* (Jenni et al. 1986), *T. cruzi* (Gaunt et al. 2003), and *Leishmania major* (Akopyants et al. 2009), as well as in the bumblebee parasite *Crithidia bombi* (Schmid-Hempel et al. 2011). In *T. brucei* genetic exchange occurs during co-transmission of different strains via the tsetse fly and takes place in the insect's salivary glands (Gibson et al. 2008). Analysis of allelic inheritance indicates that the mechanism includes conventional meiosis (MacLeod et al. 2005), meiosis-specific proteins are expressed by epimastigotes in the salivary glands (Peacock et al. 2011), and haploid gametes have been demonstrated (Peacock et al. 2014). As in *T. brucei*, the process of genetic exchange in *Leishmania* occurs in the insect vector and appears to involve meiosis (Akopyants et al. 2009). In contrast, genetic exchange in *T. cruzi* was demonstrated in mammalian cell culture and the process appears to be parasexual; the parental trypanosome genomes fuse with subsequent chromosome loss (Gaunt et al. 2003). Naturally occurring hybrids have been described in *T. cruzi* and *Leishmania* spp. (Kelly et al. 1991; Miles et al. 2009; Ravel et al. 2006), and there is evidence that *T. b. brucei* and *T. b. rhodesiense* are genetically intermixed in East Africa (Balmer et al. 2011).

Studies of gene expression in trypanosomes and *Leishmania* have revealed several features in these trypanosomatids that are unusual in eukaryotes. Transcription of protein-coding genes is polycistronic as in prokaryotes, with posttranscriptional regulation of individual messenger RNAs (mRNAs); the genes lack introns. During processing of the transcript, the usual 3′ poly A tail is added, but in addition a conserved 39-nucleotide leader sequence or mini-exon is spliced onto the 5′ end of each mRNA; as the spliced leader is transcribed from a separate array of tandemly linked repeats, transcription is referred to as discontinuous (Borst 1986). Spliced leader genes have been widely found in kinetoplastids and also in *Diplonema* and *Euglena gracilis* (Sturm et al. 2001). The presence of the molecular machinery for RNA interference (RNAi) in some trypanosomatids (*Trypanosoma brucei*, *Leishmania braziliensis*) has enabled targeted knockdown of particular genes, facilitating investigation of gene expression (Ngo et al. 1998; Subramaniam et al. 2006). An unusual base – β-D-glucosyl-hydroxymethyluracil or J – initially discovered in *T. brucei* appears to be characteristic of the Euglenozoa in general (Dooijes et al. 2000). Base J was thought to be involved in DNA silencing or suppression of recombination, but recent results from *Leishmania* show that it controls the correct termination of transcription (van Luenen et al. 2012).

The development of methods for genetic transformation of trypanosomatids (Beverley and Clayton 1993) was a major advance and opened up the many avenues of investigation predicated on genetic manipulation. Coupled with the

publication of several genome sequences (Berriman et al. 2005; El-Sayed et al. 2005b; Ivens et al. 2005; Jackson et al. 2010, 2012; Peacock et al. 2007), with more to follow, the pathogenic trypanosomatids are one of the best-studied groups of protists.

The thorniest taxonomic problems lie in species recognition, especially among the trypanosomatids of practical importance. Here, exact identification is necessary for epidemiological studies, but as morphology is of no help, there is increasing reliance on molecular approaches. For population genetics analysis, initial characterization studies based on isoenzyme variation have been largely superseded by DNA analyses, such as microsatellite genotyping. Identification of individual species, subspecies, or strains was accomplished initially using DNA probes and subsequently by PCR. A range of different target genes have been chosen for PCR: kDNA minicircles offer ease of purification and limited complexity and have proved useful for identification of *T. evansi* (Masiga and Gibson 1990) and *Leishmania* spp. (Lambson et al. 2000); the spliced leader gene is easily amplified from a wide variety of trypanosomatid species by virtue of the conserved 39-nucleotide spliced leader sequence (Maslov et al. 2007); single-gene PCRs have been developed for specific identification of the human pathogens, *T. b. gambiense* and *T. b. rhodesiense* (Radwanska et al. 2002a, b). Similarly, application of DNA-based approaches should prove very helpful for bodonid identification.

Maintenance and Cultivation

The introduction of cryopreservation to maintain stocks of kinetoplastid organisms in the 1960s, using glycerol or dimethyl sulfoxide (DMSO) as cryoprotectants, removed the need for routine maintenance of cell lines and greatly facilitated research. Similarly, the development of semi-defined media for in vitro cultivation of parasitic trypanosomatids in the 1970s reduced reliance on animals to maintain cell lines; recipes for media in routine laboratory use and detailed protocols may be found in Taylor and Baker (1978). Complex biphasic blood agar media such as NNN or the simpler "Sloppy Evans," which is a mixture of blood and agar, are useful for initial isolation into culture, but thereafter organisms are more easily cultivated by adapting to monophasic media. Widely used complex monophasic media are FYTS (Roitman et al. 1972) for *Leishmania* spp., LIT medium (Camargo 1964) for *T. cruzi*, and SDM (Brun and Schonenberger 1979) or Cunningham's medium (Cunningham 1977) for *T. brucei* and related trypanosomes. Bacterial contamination may be controlled with broad-spectrum antibiotics such as gentamycin (10–100 μg ml^{-1}). Yeast or other fungal contamination may be controlled by 5-fluorocytosine in primary cultures (Maser et al. 2002). Insect hosts in particular are liable to be infected with several species, or even genera, of trypanosomatids, so once a culture is isolated and growing vigorously, cloning should be attempted. Cloning can be achieved by plating on culture medium solidified with agar or agarose or by serial dilution in microtiter plates.

The salivarian trypanosomes (except *T. vivax*, which lacks a vector midgut stage in the life cycle) are readily grown in culture as the vector midgut procyclic form. Other insect developmental stages are more difficult to culture in vitro, but a recent breakthrough was the discovery that overexpression of the RNA-binding protein RPB6 triggers mass metacyclogenesis of *T. brucei* procyclics in culture (Kolev et al. 2012). The blood and extravascular tissue forms of *T. brucei* and related species were first cultivated by Hirumi and co-workers using bovine fibroblast cultures as feeder layers, but semi-defined liquid media containing various additives such as bathocuproine, cysteine, and mercaptoethanol are now used routinely in many labs to support continuous growth of bloodstream forms (Hirumi et al. 1997). Metabolomic analysis holds potential for further refinement of culture methods (Creek et al. 2013).

Bloodstream forms of the salivarian trypanosome species *T. brucei*, *T. evansi*, *T. equiperdum*, and *T. congolense* can be readily grown in laboratory rodents and rabbits, but bloodstream forms of other species usually fail to grow in these small laboratory animals and require experimental calves, goats, or pigs. Intracellular stages of *Leishmania* species and *T. cruzi* may be grown in mammalian tissue culture cells. Various cell types can be used to grow the intracellular trophic amastigote stage, e.g., chick embryo, bovine embryo muscle, HeLa, Vero, and myocardial cells; nondividing trypomastigotes are released into the medium and can be collected to infect fresh cultures.

The phagotrophic free-living bodonids may be isolated in monoprotist culture from rich infusions of soil, feces, or vegetable matter by serial dilution with soil extract (SE) diluted 1:10 with distilled water (or seawater in the case of marine species). Monoxenic cultures can sometimes be obtained by migration: packed, washed cells are layered on the surface of diluted SE medium in a long Pasteur pipette, with the sealed fine end repeatedly bent to give a zigzag path; flagellates migrate toward the sealed tip leaving behind their accompanying bacteria, so that axenic specimens can be recovered from the tip and placed in 0.05% liver infusion with a suitable food bacterium (e.g., *Enterobacter aerogenes)*; however, axenic cultures of these organisms have not been achieved. Media formulae for cultures provided by the American Type Culture Collection (ATCC) are in (Nerad 1991).

Of the parasitic bodonids, only trypanoplasms of freshwater fish have been cultivated to date, with various blood agar media, such as NNN and SNB9, giving good results for both bloodstream and vector stages (Woo 1994). Blood forms of *Trypanoplasma salmositica* (previously *Cryptobia salmositica*) and *T. bullocki* were successfully cultivated in MEM liquid medium supplemented with 20–25% inactivated fetal calf serum, subculturing every 15 days; culture forms were infective to fish (Woo 1994). Other parasitic bodonids have been obtained in bulk from their hosts, e.g., large numbers of *Ichthyobodo necator* were obtained directly from parasitized fish (Callahan et al. 2002) and *Cryptobia helicis* was recovered from dissected snails (Lukeš et al. 1998).

Population doubling times vary from 6 to 18 h in trypanosomatid cultures, and yields of up to 10^7 organisms per ml can be obtained under optimum growth conditions.

Evolutionary History

There are few fossil kinetoplastids, although trypanosomatids, including putative digenetic parasites, have been recovered from insects preserved in amber (Poinar and Poinar 2004). Therefore, the evolutionary history of the group must largely be reconstructed from comparative morphology, cell biology, and gene sequences. The euglenids, which have more morphological features in common with kinetoplastids than any other major extant group (basically two flagella with paraxonemal rods and flagellar pocket, peripheral microtubular cytoskeleton, mitochondrial network with discoid cristae, nuclear division with persistent nucleolus), and the diplonemids are grouped together with kinetoplastids in the Euglenozoa Cavalier-Smith 1981. Molecular phylogenies indicate that diplonemids are more closely related to kinetoplastids than euglenids are (Kamikawa et al. 2014; Simpson and Roger 2004), and consistent with this they have similar spliced leader RNA sequences (Sturm et al. 2001) and appear to have glycosomes (Makiuchi et al. 2011). Massive development of the mitochondrial DNA to form the kinetoplast sets kinetoplastids apart, although it is noteworthy that the diplonemid *Hemistasia* has a kinetoplast-like structure identified by EM (see Elbrachter et al. 1996; Simpson and Roger 2004; Yabuki and Tame 2015).

Molecular phylogenies have confirmed the long-held assumption that the mainly free-living and biflagellate bodonids evolved earlier than the exclusively parasitic and uniflagellate trypanosomatids (e.g., Callahan et al. 2002; Deschamps et al. 2011; Moreira et al. 2004; Simpson et al. 2004). Most bodonids fall into three distinct clades: Neobodonida, Parabodonida, and Eubodonida (Moreira et al. 2004; Simpson et al. 2002; von der Heyden et al. 2004). Neobodonida mostly includes free-living taxa with moderately to highly elongate rostra that extend beyond the flagellar pocket and contain the ingestion apparatus, e.g., *Neobodo*, *Dimastigella*, and *Rhynchobodo*. In the most extreme case, the rostrum of *Rhynchomonas* has evolved as a proportionately huge bulbous-ended structure that is attached to the short anterior flagellum (invisible by light microscopy) and sweeps from side to side as the flagellum beats. Parabodonida includes the free-living *Procryptobia* and *Parabodo* (such as the well-known *Parabodo caudatus*, formerly known as *Bodo caudatus*) but also the parasitic/commensal *Cryptobia* spp. and the digenetic trypanoplasms (*Trypanoplasma*), which are therefore very likely to have evolved from free-living ancestors independently of trypanosomatids. Eubodonida currently contains the free-living taxon *Bodo* only, but is of great evolutionary importance as the sister group to the trypanosomatids (Deschamps et al. 2011). Curiously, the deepest confirmed branch within the kinetoplastid phylogenetic tree, Prokinetoplastina, contains no known free-living forms, just the ectoparasitic *Ichthyobodo* and the *Perkinsela*(-like) permanent symbionts of paramoebid amoebae (Callahan et al. 2002; Moreira et al. 2004; von der Heyden et al. 2004).

Loss of the anterior flagellum, leaving only the posterior (recurrent) as the organ of propulsion, and the adoption of obligate parasitism occurred early in the history of the trypanosomatid lineage. Catenation of the circular kDNA molecules to form a network may have occurred at the same time. A widely favored hypothesis has been

that trypanosomatids were ancestrally monogenetic parasites of insects, and this hypothesis received additional support with the recent discovery that a presumably monogenetic parasite of mosquitos, *Paratrypanosoma confusum*, represents the deepest branch within trypanosomatids (Flegentov et al. 2013). Among the other monogenetic trypanosomatids, the promastigote *Leptomonas* genus may represent the simplest form, with *Crithidia* and *Herpetomonas* possibly representing later developments in one-host parasitism (although note that these genera are not monophyletic). *Phytomonas* and *Leishmania* retain the simple promastigote form while becoming two-host parasites. The genus *Trypanosoma* is a separate, monophyletic lineage of two-host parasites. The hematozoic habit (living in animal blood) thus evolved in at least two separate lineages in kinetoplastids, in the trypanoplasms when the blood-gills-skin contact route of transmission was improved by leech transmission and in the trypanosomatids when the insect host became hematophagous. In this scenario, the leech-transmitted trypanosomes of fish arose secondarily from insect-transmitted forms, with amphibia forming the bridge between terrestrial and aquatic transmission cycles (Hamilton et al. 2004; Maslov et al. 1996).

In trypanosome phylogenies, the African tsetse-transmitted trypanosomes – the Salivaria – form a divergent group, with large evolutionary distances separating this clade from the rest of the genus (Hamilton et al. 2004; Stevens et al. 1999a). The two human pathogens, *T. brucei* and *T. cruzi*, thus had separate origins, borne out by their distinctive life cycles in their respective vertebrate and invertebrate hosts. The date of divergence of the *T. brucei* and *T. cruzi* clades has been inferred to coincide with the separation of South America and Africa 100 mya (Stevens et al. 1999a), but *T. cruzi* may have evolved more recently from bat trypanosomes, considering the potential for long-range dispersal offered to parasites of these highly mobile, flying mammals (Hamilton et al. 2012).

In historical time, *T. evansi* is believed to have evolved from the cyclically transmitted *T. brucei* of the African tsetse belt by transportation across the Sahara in camel trains (Hoare 1972). Tabanid flies served to transmit the blood infection mechanically with concomitant loss of trypanosome pleomorphism, kinetoplast DNA maxicircles, and mitochondrial function. From North Africa, *T. evansi* spread in horses east across Southern Asia to the East Indies and Taiwan and West to South America. In the latter case, vampire bats as well as biting flies have become responsible for transmission. Similarly, *T. vivax* was imported into the New World in infected cattle from West Africa in the seventeenth century, and *Leishmania infantum* (known as *L. chagasi* in South America) was carried by people and dogs from the Mediterranean region. The origin of the venereally transmitted, equine parasite *T. equiperdum* is unclear, although it resembles *T. evansi* in loss of pleomorphism and in the homogeneity of the kinetoplast DNA minicircles; however, few bona fide lab isolates remain, and these have either lost maxicircles completely like *T. evansi* or have a deleted maxicircle (Lai et al. 2008). The distinctive pathology and mode of transmission of *T. equiperdum*, clearly described in ancient texts and evident to modern scholars when dourine was a common equine disease (Hoare 1972), mark it out as a distinct species. Although both *T. evansi* and *T. equiperdum* are now viewed as mutants of *T. brucei* and, from an evolutionary perspective,

should be renamed as subspecies of *T. brucei*, the rules of taxonomic precedence do not allow this, because *T. evansi* was described first. The pragmatic solution is for use of the species names to prevail, in recognition of the distinct pathology of these two parasites and the fact that they are now genetically isolated from *T. brucei*, because they cannot develop in tsetse flies where sexual reproduction occurs.

Preaxostyla

31

Vladimir Hampl

Abstract

Preaxostyla comprises Oxymonadida, containing 14 genera of gut endosymbionts plus two genera of free-living bacterivorous flagellates from low oxygen sediments (*Trimastix* and *Paratrimastix*). The group was recognized on the basis of 18S rRNA phylogenies, and ultrastructural investigations have revealed a synapomorphy in the organization of the "I" fiber that supports microtubular root R2. *Trimastix* and *Paratrimastix* are typical excavates with three anterior/lateral flagella and the recurrent flagellum passing through a conspicuous ventral feeding groove. The cellular structure of oxymonads is more derived, and a particularly striking diversity of large cellular forms is observed in genera inhabiting guts of lower termites and wood-eating cockroaches. Here the large oxymonad species and their bacterial ecto- and endosymbionts are probably involved in the cellulose digestion, similarly to the large species of parabasalids. All Preaxostyla live in low oxygen environments, and this has affected their metabolism and organelle complement. Glycolysis is apparently the main source of cellular ATP and mitochondria are either reduced to hydrogenosome-like compartments (in *Trimastix* and *Paratrimastix*) or lost completely (in oxymonads). Peroxisomes are absent in the whole group. Stacked Golgi bodies are unknown in oxymonads; however, genes encoding proteins functional in Golgi are present, indicating the existence of a cryptic Golgi. Phylogenomic analyses have shown that Preaxostyla represent one of the three main lineages of Metamonada (within Excavata). Because oxymonads are the only known eukaryotes that have completely lost the mitochondrial organelle, they may serve as models for studies of amitochondriality and mitochondrial evolution.

Introduction

General Characteristics

Preaxostyla are heterotrophic protists, typically bearing four flagella. *Trimastix* and *Paratrimastix* have a typical excavate morphology, with a hunched appearance and conspicuous excavate ventral groove. Flagella originate subapically, and the posterior flagellum trails through the cytostome and bears two vanes. Oxymonadida Grassé 1952 are morphologically diverse group, and they never form cytostomes. In oxymonads, flagella are arranged in two separated pairs, and their number can multiply to eight in *Pyrsonympha* and to eight or 12 in *Saccinobaculus* or increase to many in, e.g., *Microrhopalodina* and *Sauromonas*. Nuclei or whole karyomastigonts (nucleus, flagella, basal bodies, preaxostyle, axostyle, and microtubular roots) are multiplied in the oxymonad genera *Microrhopalodina* and *Barroella*. Cells of *Trimastix* and *Paratrimastix* contain hydrogenosome-like derivates of mitochondria and, usually, stacked Golgi bodies. Neither mitochondria nor peroxisomes nor Golgi bodies were reported in oxymonads with the potential exception of *Saccinobaculus doroaxostylus*. Several oxymonad species have developed a microfibrillar organelle for attachment to the intestinal wall (holdfast) often situated on an anterior extension of the cell (rostellum). Preaxostyla divide by binary fission and have either open mitosis (*Paratrimastix*) or mitosis of a closed type with an intranuclear spindle (Oxymonadida). Trophozoites are the dominant life stages of the cell cycle; formation of gametes and cysts has been demonstrated in only a few species.

Occurrence

Trimastix and *Paratrimastix* are free-living inhabitants of hypoxic sediments in marine or freshwater habitats, respectively. The typical habitat of oxymonads is the gut of insects; the exceptions are several species of *Monocercomonoides* that inhabit intestines of vertebrates. The largest diversity of oxymonads, in terms of both species count and morphology, is found in the hindgut of lower termites and the cockroach genus *Cryptocercus*.

Literature and History of Knowledge

Light microscopy of *Trimastix* and *Paratrimastix* was studied by Saville Kent (1880), Grasse (1952), and Bernard et al. (2000). Light microscopy and ultrastructure was studied by Brugerolle and Patterson (1997), O'Kelly et al. (1999), Simpson et al. (2000), and, most recently, Zhang et al. (2015), who also revised the taxonomy and created genus *Paratrimastix* for two species originally classified as *Trimastix*.

Transcriptomic and cell biological studies, all on *Paratrimastix pyriformis*, were performed by Stechmann et al. (2006), and Zubáčová et al. (2013). The evolutionary history of the group has been investigated by Dacks et al. (2001), Hampl et al. (2009), and Zhang et al. (2015).

Oxymonads (*Pyrsonympha vertens* and *Dinenympha gracilis*) were first observed by Leidy (1877). During the first half of the twentieth century, all genera and most species were described using light microscopy. Between 1960 and 1990, the ultrastructure of the most important genera was reconstructed using electron microscopy, with a particular focus on the structure of the axostyle and the mechanism of its movement (e.g., McIntosh et al. 1973; Brugerolle and Joyon 1973; Bloodgood et al. 1974). The first papers that employed molecular methods to study the diversity and evolutionary history of oxymonads and their bacterial symbionts were published at the very end of the twentieth century (Moriya et al. 1998; Iida et al. 2000; Tokura et al. 2000; Dacks et al. 2001). Fragmentary information on oxymonad biochemistry, molecular genetics, and cellular biology became available from 2003 onward (e.g., Keeling and Leander 2003; Liapounova et al. 2006). The genome project of *Monocercomonoides* sp. was finished in 2016 (Karnkowska et al. 2016).

The earliest light microscopic observations of oxymonads were performed by Porter (1897), Kofoid and Swezy (1919, 1926), Kidder (1929), Powell (1928), Kirby (1928), Jírovec (1929), Georgevitch (1932), Cleveland et al. (1934), Cross (1939, 1946), Kirby and Honigberg (1949), Nie (1950), Cleveland (1950a, b, c, 1966), Moskowitz (1951), Gabel (1954), and Jensen and Hammond (1964). The most comprehensive light microscopic tract is in Grassé (1952). The fossils of oxymonads have been studied by Poinar (2009a, b). Oxymonad ultrastructure was studied with electron microscopy by Grimstone and Cleveland (1965), Hollande and Carruette-Valentin (1970a, b), Brugerolle (1970), Smith and Arnott (1973a), Mcintosh et al. (1973), Lavette (1973), Brugerolle and Joyon (1973), Bloodgood et al. (1974), Kulda and Nohýnková (1978), Cochrane et al. (1979), Brugerolle (1981), Radek (1994), Brugerolle and König (1997), Rother et al. (1999), Simpson et al. (2002), Brugerolle et al. (2003), Leander and Keeling (2004), Maass and Radek (2006), Carpenter et al. (2008), and Tamschick and Radek (2013). Physiological and electron microscopic studies regarding axostyle motility were performed by Mcintosh et al. (1973), Mcintosh (1973, 1974), Bloodgood and Fitzharris (1978), Heuser (1986), and Jensen and Smaill (1986). The symbiotic bacteria of oxymonads were studied by Smith and Arnott (1974b), Iida et al. (2000), Tokura et al. (2000), Noda et al. (2003, 2006), Stingl et al. (2005), Yang et al. (2005), and Hongoh et al. (2007). The cell biology and biochemistry of oxymonads have been studied by Keeling and Leander (2003), Slamovits and Keeling (2006a, b), Liapounova et al. (2006), de Koning et al. (2008), and Dacks et al. (2008). The first genomic project was carried out by Karnkowska et al. (2016). The evolutionary history of oxymonads has been studied by Moriya et al. (1998, 2001, 2003), Dacks et al. (2001), Hampl et al. (2005, 2009), Heiss and Keeling (2006), Carpenter et al. (2008), and Radek et al. (2014).

Practical Importance

Oxymonads are of indirect practical importance because of their obligate association with their wood-destroying hosts, the dry wood and subterranean lower termites, and the closely related wood-feeding cockroach *Cryptocercus* (Lo et al. 2000; Inward et al. 2007). Because of their large microtubular axostyles, pyrsonymphids, and saccinobaculids have been useful subjects for research into microtubule function. Oxymonads represent the only known group of eukaryotes containing amitochondriate representatives (Karnkowska et al. 2016).

Habitats and Ecology

Trimastix and *Paratrimastix* are small free-living bacterivorous flagellates inhabiting marine and freshwater sediments that are low in oxygen, where they presumably play a role in grazing bacteria, creating a food-web link between the bacterial biomass and larger organisms.

All oxymonads are endobiotic, and most representatives inhabit the hindgut of lower termites and the intestine of the wood-feeding cockroaches. Several species live in the intestine of larvae of the crane fly and Scarabaeoidea beetles, myriapods, and the intestine of vertebrates. The list of oxymonad species and their hosts is given in Table 1. There are no known pathogenic species.

Oxymonads are often involved in symbiotic relationships. Oxymonads of termites and wood-feeding cockroaches are members of large communities of bacteria, archaea, and anaerobic protists (especially parabasalids) in the hindgut of the host (Brune and Ohkuma 2011; Ohkuma and Brune 2011). The community is essential for cellulose digestion, and if the microorganisms are killed, the insect dies within a few weeks (Cleveland 1924). The exact role of the flagellates (oxymonads and parabasalids) in cellulose digestion is not clear (for review, see Radek (1999), Li et al. (2006), Brugerolle and Radek (2006), Brune and Ohkuma (2011)). Microscopic observations clearly show that large oxymonads (*Pyrsonympha*, *Oxymonas*, *Microrhopalodina*), similarly to large parabasalids (e.g., *Trichonympha*), internalize and digest large pieces of wood. High-resolution imaging mass spectrometry (NanoSIMS) gave direct evidence for the flow of organic carbon from ^{13}C-enriched cellulose to the cell interior of *Oxymonas dimorpha* (Carpenter et al. 2013). The smaller species are probably not involved in cellulose digestion (Cleveland 1925; Radek 1999). Production of cellulolytic enzymes has been reported in several parabasalid species (Yamin 1981; Nakashima et al. 2002; Zhou et al. 2007) but not, so far, in any oxymonad. The association of oxymonads with termites and roaches was observed in 97–110 mya old Cretaceous fossils (Poinar 2009a, b).

The surface and cytoplasm of most oxymonads are colonized by prokaryotic symbionts. The surface bacteria belong to the groups *Spirochaetes* (Iida et al. 2000; Noda et al. 2003) and *Bacteroidales* (Noda et al. 2006; Hongoh et al. 2007). Protists and/or bacteria often form special attachment structures (Bloodgood et al. 1974; Smith

and Arnott 1974b; Rother et al. 1999; Brugerolle 1981; Leander and Keeling 2004). Ectobiotic bacteria are occasionally phagocytosed by the host (Brugerolle 1981; Leander and Keeling 2004; Noda et al. 2006). The prokaryotes in the cytoplasm of oxymonads belong to the groups *Endomicrobia* (TG-1), which are specific to this environment (Stingl et al. 2005; Yang et al. 2005), methanogens (Tokura et al. 2000), and mycoplasmas (Yang et al. 2005). Verrucomicrobial symbionts have been reported from the nuclei (Sato et al. 2014). The essence of the oxymonad-bacterial relationship is unclear, although some metabolite transfers have been proposed between parabasalid protists and their endosymbionts living in the same environment (Hongoh 2010). The association of protists with prokaryotes is not strictly one-to-one specific, i.e., unrelated protists are associated with closely related bacteria and several types of bacteria are associated with a single oxymonad.

Characterization and Recognition

Organization of Cytoskeleton

The organization of the *Trimastix* and *Paratrimastix* cytoskeleton closely follows the basic scheme known from other typical excavates (Simpson 2003; Yubuki et al. 2013), and it likely represents the ancestral organization of the group. Four basal bodies are arranged in a cruciate pattern. Left (R1) and right (R2) microtubular roots are connected to a recurrent basal body B1 and support the margins of the cytostome. The right root (R2) is associated with a thick I fiber with a lattice-work substructure (see below). From the anterior basal body B2 originates the anterior root (R3), which is associated with the dorsal fan of microtubules (F) supporting the dorsal side of the cell. Differences between *Trimastix* and *Paratrimastix* are subtle. Common features of both, which distinguish them from other typical excavates, can be found in the organization of the supportive fibers B, C, and I (Zhang et al. 2015). In particular, the I fiber forms one thin sheet connected to R2 by lattice-like structure, which resembles the structure of the paracrystalline part of the preaxostyle in oxymonads. These two cytoskeletal components are regarded as homologous, and similarity of their fine structure is the defining synapomorphy of Preaxostyla (Simpson 2003).

The structure of the oxymonad cytoskeleton has diverged from the canonical excavate form. Here it will be described using the genus *Monocercomonoides*, which probably resembles the ancestral state in oxymonads, employing terminology according to Radek (1994) (Figs. 1 and 2). Each oxymonad cell contains one karyomastigont (as in the case of *Monocercomonoides*) or sometimes more than one. Each karyomastigont consists of a nucleus, four basal bodies with flagella that are organized in two pairs, and a preaxostyle that connects the pairs of basal bodies. The preaxostyle (="primary row" in older works) is made of two layers. The layer facing the nucleus consists of a single row of microtubules (homologous to R2 in excavates), and this attaches to a second layer made of non-microtubular material (homologous to the I fiber in excavates). The preaxostylar region is rich in polysaccharide granules. The cell's anterior-posterior axis is formed by an axostyle that consists of parallel rows of microtubules that are interconnected by bridges. In the nuclear region, the axostyle is associated with the preaxostyle by the single row of microtubules that is continuous between both structures. The axostyle is contractile in Pyrsonymphidae, Saccinobaculidae, and Oxymonadidae, where it serves as the organelle for locomotion. Microtubular root R1 or funis (fully developed in *Monocercomonoides*) is connected to the basal body of the recurrent flagellum (basal body 1) and underlies this flagellum. In *Monocercomonoides*, the most

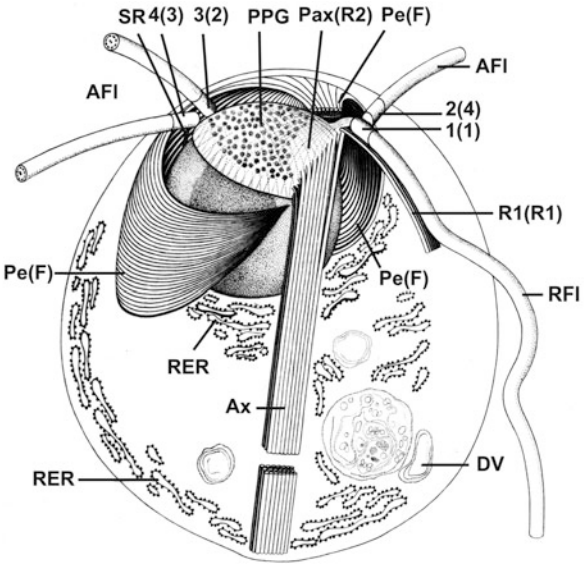

Fig. 2 Ultrastructure of *Monocercomonoides*. Terminology follows Radek (1994); terminology according to Yubuki and Leander (2013) is given in brackets. *1, 2, 3, 4* basal bodies 1–4, *AFl* anterior flagella, *Ax* axostyle, *DV* digestive vacuole, *F* fan, *Pax* preaxostyle, *Pe* pelta, *PPG* perinuclear polysaccharide granules, *R1* microtubular root R1, *R2* microtubular root R2, *RFl* recurrent flagellum, *RER* rough endoplasmic reticulum, *SR* striated root. The axostyle in its distal part is artificially interrupted to show the organization of microtubules (Courtesy of Eva Nohýnková, adapted)

anterior basal body (4) is associated with a microtubular root (not shown in Figures), which underlies the pelta. This pelta is a microtubular sheet that covers the nucleus and that is homologous to the dorsal fan of typical excavates. Simpson et al. (2002) suggested homologies between the oxymonad cytoskeleton and cytoskeleton of typical excavates; the excavate terminology for cytoskeletal structures according to Yubuki and Leander (2013) is given in Fig. 2 in brackets.

Sex and Reproduction

Preaxostyla reproduce by binary fission. *Paratrimastix* use an open mitosis, while mitosis is of a closed type in oxymonads. A characteristic migration of nuclei through the cell is typical for family Oxymonadidae and will be described in more detail below. Sexual processes comprising gametogenesis, fertilization, and meiosis were reported in the oxymonads of the wood-feeding cockroach *Cryptocercus*, namely, *Notila*, *Saccinobaculus*, and *Paranotila* (Cleveland 1950b, c; Cleveland 1966). Cleveland also described sexual processes in two *Oxymonas* species from *Cryptocercus* (*O. doroaxostylus* and *O. nana*) (Cleveland 1950a); however, these species are currently regarded as members of the genus *Saccinobaculus*

(*S. doroaxostylus*, *S. minor*; Heiss and Keeling 2006). Synaptonemal complexes characteristic for meiosis were reported from *Pyrsonympha flagellata* (Hollande and Carruette-Valentin 1970a). Encystation has been reported in *Monocercomonoides*, *Saccinobaculus*, and *Sauromonas*, as well as in *Paratrimastix* (Cleveland 1950a; Grassé 1952; O'Kelly et al. 1999). The developmental cycles of flagellates and the sexual cycles (where present) are synchronized with the molting cycle of the insect host and are governed by the molting hormone ecdysone (May 1941; Grassé 1952; Cleveland 1956; Cleveland et al. 1960). Termites lose all intestinal protozoa during nymphal molt; both young termites, and post-molt adult termites must establish their protozoan biota by proctodeal feeding from adults (Brugerolle and Radek 2006; Brune and Ohkuma 2011).

Molecular Genetics and Biochemistry

Due to the impossibility of axenic cultivation, our knowledge on molecular genetics and biochemistry is very fragmentary, and the studies are restricted to transcriptomic and genomic surveys and gene fishing from genomic DNA and cDNA. The only sequenced genome of the group (*Monocercomonoides* sp.) is ~75 MB in size and 36.8 GC and contains 16,629 predicted protein coding genes (Karnkowska et al. 2016).

The cytoplasm of *Trimastix* and *Paratrimastix* contains electron-dense mitochondrion-like organelles with poorly known biochemistry. In *Paratrimastix pyriformis*, the only protein experimentally localized into these organelles is an enzyme of the glycine cleavage system, part of amino acid metabolism. Transcriptome studies in *P. pyriformis* indicate the presence of pyruvate:ferredoxin oxidoreductase and [FeFe]hydrogenase, suggesting an extended glycolysis in this organism (Zubacova et al. 2013). Peroxisomes have not been reported in *Trimastix* and *Paratrimastix*.

Energetic metabolism of oxymonads seems to be broadly similar to other studied anaerobes such as *Trichomonas*, *Giardia*, or *Entamoeba* (Reeves et al. 1977; Upcroft and Upcroft 1998; Müller 1992). Among the glycolytic enzymes of *Monocercomonoides*, several were acquired by lateral gene transfer from prokaryotes, including the ATP-efficient alternatives pyrophosphate fructose-6-phosphate phosphotransferase and pyruvate orthophosphate dikinase (Liapounova et al. 2006; Slamovits and Keeling 2006b). Pyruvate is probably oxidatively decarboxylated by pyruvate:ferredoxin oxidoreductase (PFO) in the cytosol, and the resulting acetyl-CoA is further fermented to ethanol (Karnkowska et al. 2016). Transcripts of [FeFe]hydrogenase are abundant (Karnkowska et al. 2016), but the production of hydrogen has not been established. Dacks et al. (2008) found that the expression of cathepsin B cysteine proteases in *Monocercomonoides* is relatively high and comparable to housekeeping genes. Unlike other metamonads (*Giardia*, *Trichomonas*), the oxymonad genome is relatively intron rich (1.1 and 1.9 introns per gene in *Streblomastix* and *Monocercomonoides*, respectively) (Slamovits and Keeling 2006a; Karnkowska et al. 2016). Some oxymonads (*Streblomastix*, some *Monocercomonoides*) use a noncanonical genetic code, in which the codons TAA and TAG encode the amino acid glutamine (Keeling and Leander 2003; de Koning et al. 2008).

Mitochondria, stacked Golgi, and peroxisomes have not been clearly demonstrated in oxymonads. Electron-dense organelles of uncertain nature, but resembling mitochondria, were reported from *Saccinobaculus doroaxostylus* however (Carpenter et al. 2008). In the case of *Monocercomonoides* sp. strain from chinchilla, no genes for mitochondrion-specific proteins have been detected in the fully sequenced genome, confirming the absence of any mitochondrion suggested by electron microscopy (Karnkowska et al. 2016). The same applies to peroxisomes, but in the case of the Golgi apparatus, a full set of genes coding for "Golgi-associated" proteins was found. The cellular localization of their protein products is unknown.

Taxonomy

Preaxostyla are classified within the phylum Metamonada (Cavalier-Smith 2003), a subgroup of the taxon Excavata (Cavalier-Smith 2002; Simpson 2003; Adl et al. 2005; Hampl et al. 2009; Adl et al. 2012). Preaxostyla contains three described species of Trimastigidae, two of Paratrimastigidae (Zhang et al. 2015), and approximately 140 described species of oxymonads, divided into five families – Polymastigidae, Saccinobaculidae, Pyrsonymphidae, Streblomastigidae, and Oxymonadidae (Brugerolle and Lee 2000), plus the isolated genus *Opisthomitus* (Fig. 3). List of described species is given in Table 1.

Trimastigidae

The family contains a single genus *Trimastix* Saville Kent. Cells bear four flagella stretched roughly in the anterior, right, left, and posterior directions. The posterior flagellum passes through a suspension-feeding groove and bears two vanes. Vane margins are not thickened. The genus contains two marine species *T. marina* and *T. inaequalis* and one freshwater species *T. elaverinus* with uncertain status. Light microscopy of *Trimastix* was studied by Saville Kent (1880), Dumas (1930), Grasse (1952), and Bernard et al. (2000). Light microscopy and ultrastructural observations were reported by Zhang et al. (2015).

Paratrimastigidae

The family contains a single genus *Paratrimastix* Zhang, Taborsky, Silberman, Panek, Čepička, and Simpson. Cells bear four flagella directed anteriorly, to the right and left, and posteriorly. The posterior flagellum passes through a suspension-feeding groove and bears two vanes with thickened margins. The genus contains two species *P. pyriformis* (syn. *convexa*) and *P. eleionoma* from freshwater habitats around the globe (Fig. 3). Light microscopy and ultrastructure of *Paratrimastix* was studied by Brugerolle and Patterson (1997), O'Kelly et al. (1999), and Simpson

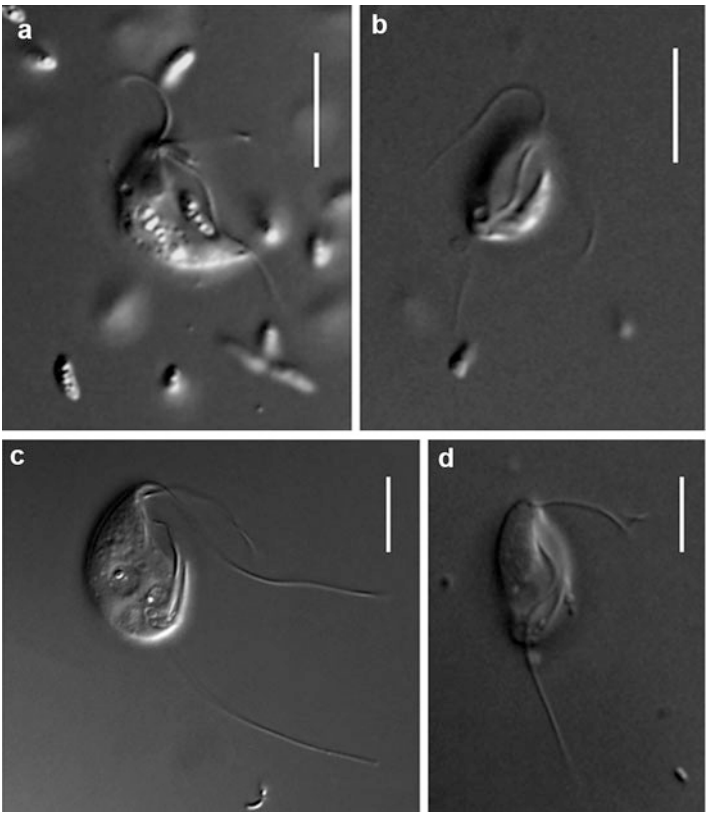

Fig. 3 **DIC images of *Paratrimastix.*** *P. pyriformis* (**a**, **b**) and *P. eleionoma* (**c**, **d**); bars 10 μm

et al. (2000). In the literature between years 1997 and 2013, these two species are referred to as *Trimastix pyriformis* and *Trimastix marina*, respectively.

Oxymonadida

More than 140 described species of oxymonads (Table 1 and Fig. 4) are all gut endobionts. They are classified into five families (Polymastigidae, Streblomastigidae, Pyrsonymphidae, Saccinobaculidae, and Oxymonadidae) and a genus *Opisthomitus*.

Polymastigidae

There are four described genera of small tetraflagellates with pelta and slender noncontractile axostyle and without attachment organelles.

(**d**) was kindly provided by Guy Brugerolle; (**m**–**o**) were kindly provided by Patrick Keeling and Kevin Carpenter

Monocercomonoides Travis

Monocercomonoides Travis has a small oval to pyriform body (5–15 μm in length) and four flagella arranged in two pairs, with one which is recurrent and attached to the body (Fig. 4a–c). The organization of the *Monocercomonoides* cytoskeleton was described above and is depicted in Fig. 2. Over 40 species have been described (Table 1), but the validity of some of them is uncertain. About half of the species inhabit the posterior part of the digestive tract of wood-eating insect imagoes (the cockroaches *Cryptocercus* and *Parasphaeria* and lower termites), insect larvae (*Tipula*, Coleoptera), or millipedes, while the rest live in the gut of vertebrates (rodents, bovids, reptiles, and amphibians). The ultrastructure was studied by Brugerolle and Joyon (1973), Kulda and Nohýnková (1978), Radek (1994), Simpson et al. (2002), and Brugerolle et al. (2003).

Tubulimonoides Krishnamurthy and Sultana

The genus *Tubulimonoides* described from the gut of *Gryllotalpa africana* (African mole cricket) is very similar to *Monocercomonoides* but differs from it by its tubular axostyle. In the type species (*Tubulimonoides gryllotalpae*) the flagella are reportedly organized into groups of three and one, unlike all other oxymonads. The other two species have the flagella organized in a typical 2:2 fashion. Because of these discrepancies and in the absence of electron microscopic study, the validity of this genus is questionable. Light microscopy was carried out by Krishnamurthy and Sultana (1976), Mali and Sultana (1993), and Mali et al. (2003).

Polymastix Bütschli

Spindle-shaped tetramastigotes (5–22 μm in length) differ from *Monocercomonoides* by the absence of a recurrent (cell-adhering) flagellum, very short or no fiber R1, the presence of a microfibrillar bundle connecting the nucleus to the first pair of basal bodies, a narrow and grooved preaxostyle, a slender axostyle composed of about 10 microtubules, a small pelta, and, most strikingly, the presence of long symbiotic *Fusiformis* bacteria on the surface (Fig. 4d, e). Up to 11 species are currently recognized (Table 1); another as-yet undescribed species has been observed in the cockroach *Parasphaeria* (Brugerolle et al. 2003). *Polymastix* was found in the gut of larvae of Scarabaeoidea beetles and crane flies, myriapods (*Glomeris* and *Rhizocrinus*), cockroaches, and termites. EM studies were conducted by Brugerolle (1981) and Brugerolle et al. (2003).

Paranotila Cleveland

A single species *P. lata* was described from the gut of *Cryptocercus punctulatus*. On the basis of morphology, Brugerolle and Lee (2000) classified *Paranotila* among polymastigids. The uninuclear cell is larger than *Monocercomonoides* (15–25 μm) and has four flagella only slightly adhering to the cell and directed laterally and a single axostyle that does not protrude from the cell. Under the influence of molting hormone ecdysone, *Paranotila* undergoes a sexual cycle that involves automixis. During the nuclear division without cytokinesis, the cell transforms to a gametocyte containing eight male and eight female gametic nuclei.

The nuclei fuse to form an eight-nuclear zygote that breaks gradually into eight uninuclear cells. A single morphological study was conducted by Cleveland (1966); no EM study has been published.

Streblomastigidae

The family contains a single genus with one described species, *Streblomastix strix* Kofoid and Swezy 1919, that inhabits the hindgut of termopsid termites, e.g., *Zootermopsis angusticollis* (Fig. 4f, j). Noda et al. (2006) report undescribed *Streblomastix* sp. from *Archotermopsis* sp. The relatively rigid spindle-shaped cells of *S. strix* are typically 15–50 μm long, but rare giant forms can be as long as 300 μm. Four flagella are inserted subapically and do not adhere to the cell. The anterior tip of the cell forms a thin rostellum with a cup-like holdfast. This structure can be lengthened and retracted, and it serves for attachment to the gut epithelium. In many individuals (probably recently divided cells), the rostellum is small or absent. The surface of the cell (besides the very anterior tip) is covered by 100–200 long rod-shaped epibiotic bacteria of at least three morphotypes, and the sequencing of 16S rRNA revealed three closely related phylotypes related to *Bacteroides* (Leander and Keeling 2004; Noda et al. 2006). In transverse section, *Streblomastix* shows a stellate organization with the cytoplasm reduced to a dense central core from which radiate 6–7 thin vanes. The ridges between vanes are apparent in the light microscope and typically show torsion from left to right starting at the anterior end. The ragged cell shape is probably an adaptation to accommodate bacterial epibionts and naked cells, produced by antibiotic treatment, shift to a teardrop shape (Leander and Keeling 2004). The nucleus is a dense thin spiral rod. The microtubular cytoskeleton consists of axostyle, pelta, and preaxostyle. In the prenuclear region, the microtubules of the axostyle are organized in several parallel rows (syn. "rhizoplast" in Kidder (1929)); in the nuclear region, microtubules form a single row that envelops the nucleus, and in the post-nuclear region, the axostyle consists of a loose bundle of microtubules. The pelta helically encircles the prenuclear axostyle and covers the anterior part of the nucleus. The cell divides by binary fission, and the cell cycle is probably affected by the molting cycle of the termite. No cysts have been reported. Morphology was studied by Kofoid and Swezy (1919) and Kidder (1929). Electron microscopy was conducted by Hollande and Carruette-Valentin (1970b) and Leander and Keeling (2004).

Pyrsonymphidae

All 25 described species in two genera are hindgut symbionts of the lower termite genus *Reticulitermes* (Table 1). The nucleus is situated anteriorly. Four or eight flagella are organized in two or four pairs separated by preaxostyle(s). Flagella emerge at the anterior end of the cell, bend posteriorly, insert into grooves on the cell surface, wind around the cell in left-handed spirals, and trail posteriorly. The

contractile axostyle is the main motile organelle. It extends the entire length of the organism and consists of thousands of microtubules arranged in many parallel rows connected by bridges. Most, if not all, pyrsonymphids contain endobiotic bacteria in the cytosol, and many species also harbor epibiotic bacteria on the surface (Smith and Arnott 1974b; Iida et al. 2000; Tokura et al. 2000; Stingl et al. 2005; Yang et al. 2005; Hongoh et al. 2007). The bacteria are often attached to the cell by specialized structures developed by both bacteria and protists (Smith and Arnott 1974b). Two extant and two fossil genera are currently recognized (Poinar 2009a, b).

Pyrsonympha Leidy

Representatives of this genus (13 described species; Table 1) are relatively large cells (up to 150 μm) and show a pyriform, sack-like appearance (Fig. 4h, i). The broader posterior end of the cell is filled with phagocytic vesicles containing wood pieces. *Pyrsonympha* often develops an attachment organelle (holdfast) at the anterior pole of the cell (Cochrane et al. 1979). Many individuals of *Pyrsonympha vertens* have eight flagella and two preaxostylar fibers (Bloodgood et al. 1974). These individuals likely represent a prolonged stage in the life cycle prior to cell division. The axostyle of *Pyrsonympha* can be isolated and movement reactivated in vitro (Bloodgood et al. 1974). In *P. vertens*, a loose bundle of microtubules (paraxostyle) runs parallel to the axostyle from the basal bodies region (Brugerolle 1970). The pelta is reduced to several microtubules (= solénolemme in Hollande and Carruette-Valentin (1970b)). The surface of *Pyrsonympha* is covered by fine scales of unknown function and composition (Smith and Arnott 1973). Ring-like structures were reported on the surface of an undetermined pyrsonymphid from the gut of *Neotermes cubanus* (Maass and Radek 2006). Hollande and Carruette-Valentin (1970a) reported synaptonemal complexes in *P. flagellata*, suggesting the existence of meiosis.

Dinenympha Leidy

Dinenympha Leidy are smaller (tens of μm) freely motile cells with four flagella, which are characterized by a screw-like shape. If not associated with epibiotic bacteria like *D. fimbriata*, the cells exhibit distinctive wiggly movement (*D. gracilis*). Twelve species have been described (Fig. 4g, k, l and Table 1).

The long-lasting debate as to whether *Pyrsonympha* and *Dinenympha* represent separate genera or life-cycle stages of the same genus was apparently resolved by molecular studies (Moriya et al. 2003; Stingl and Brune 2003) showing that the sequences of *Dinenympha* and *Pyrsonympha* form separate groups and, importantly, that specific DNA probes hybridize exclusively to one genus but not the other and vice versa (see Fig. 1 in Moriya et al. (2003)). Light microscopic observations of pyrsonymphids were carried out by Porter (1897), Powell (1928), Jírovec (1929), Georgevitch (1932), and Grassé (1952) and electron microscopy by Brugerolle (1970), Hollande and Carruette-Valentin (1970a, b), Smith and Arnott (1973, 1974a, b), Smith et al. (1975), Bloodgood et al. (1974), Cochrane et al. (1979), and Maass and Radek (2006). Two fossil species of Pyrsonymphidae – *Dinenymphites spiris* and *Pyrsonymphites cordylinis* – have been described from

Cretaceous amber from Burma. The age of the amber was dated between 97 and 110 mya (Poinar 2009a, b). The protists were found in association with a fossil termite, *Kalotermes burmensis*.

Saccinobaculidae

Saccinobaculidae are hindgut symbionts of the wood-feeding cockroaches *Cryptocercus punctulatus* and *C. relictus*. The four, eight, or 12 flagella do not adhere to the body except, in some cases, in the proximal part (Fig. 4m). No attachment organelle has been observed. The large axostyle is contractile and is responsible for cell locomotion. It undulates vigorously inside the cell, like "a snake in a bag," causing rapid and dramatic changes in the cell shape (Cleveland et al. 1934). The waves originate at the anterior end and propagate posteriorly in a single plane – they are sinusoidal rather than helical (Mcintosh 1973; Mcintosh et al. 1973). As in *Pyrsonympha*, the movement of the isolated axostyle can be reactivated in vitro (Mooseker and Tilney, 1973). A sexual process was reported in this family (Cleveland 1950a, b, c). The family contains two morphologically very similar genera.

Saccinobaculus Cleveland

As in other oxymonads, the basic unit of the mastigont consists of two pairs of basal bodies associated with a preaxostyle, and multiplication of flagella is accompanied by the multiplication of preaxostyles. The microtubules of the preaxostyle continue to form the first row of axostylar microtubules facing away from the nucleus. In the prenuclear region, similar but shorter rows of microtubules gradually attach to this primary row, forming the axostyle that contains more than 8000 microtubules in the largest sections. The axostyle forms an arch anteriorly to the nucleus and then runs posteriorly, twisting and forming a crescent that almost closes to a circle or spiral to the distal end, where it protrudes from the cell. The number of microtubules decreases significantly toward the posterior end. The nucleus is tightly associated with the axostyle by its dorsal side. The region of the nucleus and preaxostyle is wrapped from the posterior and ventral side in a thin single layer of microtubular sheet, the pelta (= thin lamina in Mcintosh et al. (1973)). Conspicuous electron-dense granules were reported from the cytoplasm of *Saccinobaculus* (Mcintosh et al. 1973; Carpenter et al. 2008), which may represent peroxisomes or a modified mitochondrion (Carpenter et al. 2008). The surface of the cell is covered by circular concavities that sometimes show circular pits in the center (Carpenter et al. 2008). These are similar to those reported from pyrsonymphids (Maass and Radek 2006). Their function is unknown, but the presence of what appears to be clathrin coating in these pits suggests they may play a role in endocytosis. Epibiotic bacteria are present only rarely. Seven species of *Saccinobaculus* are currently recognized (Table 1). They differ in size and presence of granules in the axostyle or cytoplasm (Cleveland et al. 1934; Heiss and Keeling 2006). Cleveland (1950b) transferred *S. doroaxostylus* and *S. minor* into the genus *Oxymonas* as *O. doroaxostylus* and *O. nana*, but the

molecular phylogenetic study by Heiss and Keeling (2006) showed that they should be classified as *Saccinobaculus*. Light microscopy studies were performed by Cleveland et al. (1934), Cleveland (1950b, c), and Heiss and Keeling (2006), with electron microscopy by Grimstone and Cleveland (1965), Mcintosh et al. (1973), Mcintosh (1973), and Carpenter et al. (2008).

Notila Cleveland

Cleveland (1950c) distinguished *Notila* from *Saccinobaculus* on the basis of differences in their sexual cycles. The major difference is that both trophozoites and "gametes" of *Notila* are diploid. As late as after fusion of two diploid "gametic" cells, their nuclei undergo single-step meiosis to form four haploid gametic nuclei. The gametic nuclei fuse to form a double zygote that soon undergoes cytokinesis. Morphologically, *Notila* differs from *Saccinobaculus* by its axostyle that does not protrude, has no terminal sheath, and contains granules. The validity of the genus has yet to be confirmed. A single species, *Notila proteus*, was studied using light microscopy by Cleveland (1950c), Grassé (1952), and Bobyleva (1973); no EM study has been done.

Oxymonadidae

All described species are hindgut symbionts of termites, specifically Kalotermitidae. They can either take the form of free-swimming flagellates or attach to the intestinal wall by a microfibrillar holdfast situated at the tip of a cellular extension – the rostellum. In some cases the rostellum may be several times longer than the cell (Fig. 4o). It is probably able to contract or extend by a slow passive movement. The stout axostyle is contractile, but does not undulate as violently as in *Saccinobaculus*. Locomotion probably results from the combined activity of the axostyle and flagella. Oxymonadidae may have single or multiple nuclei. Nuclei migrate posteriorly during mitosis and travel back after telophase. The surface of the cell (including the rostellum of most species) is densely covered by epibiotic rod-shaped bacteria, oriented perpendicularly to the cell. Four extant and three fossil genera of Oxymonadidae are currently recognized (Table 1).

Oxymonas Janicki

Oxymonas Janicki are club-shaped cells, usually containing a single nucleus, two pairs of flagella, and a single axostyle (Fig. 4n, o). Amoeboid forms have been also reported (Tamschick and Radek 2013). Over 30 species have been described (Table 1), including two fossil species. The length of the reported species varies between 5 and 240 μm and the width between 4 and 165 μm. The rostellum of *Oxymonas* is supported by a paraxostyle (homology to the paraxostyle of *Pyrsonympha* is unclear) and a bundle of free microtubules. The paraxostyle originates at the dense microtubule-organizing center at the tip of the rostellum and extends posteriorly to the cell body. It consists of microtubules organized in convoluted ribbons. Free microtubules originate at various positions in the trunk of the

rostellum, extend posteriorly, and continue to the axostyle. The stout axostyle consists of parallel, stacked rows containing thousands of microtubules. It originates at the base of the rostellum by inserting new microtubules among the free microtubules continuing from the rostellum. The microtubules in the axostyle are interconnected by cross-bridges. The axostyle is tightly adpressed to the nucleus, continues posteriorly, splits into smaller bundles, and often enrolls at the posterior end. In some cells, the axostyle protrudes posteriorly. The preaxostyle that connects the pairs of basal bodies is situated close to the origin of the axostyle, but studies do not show any connection between the two structures. A dense plate adjacent to the preaxostyle underlies a region in the flagellar area where long spirochetes attach (Cross 1946; Brugerolle and König 1997; Rother et al. 1999).

The surface of *Oxymonas*, under the epibiotic bacteria, is densely covered by external surface structures that form a honeycomb-like pattern. They are formed by a cylindrical base and are covered by a lid. Pits with a coat resembling clathrin are formed from the bottom. The surface structures are composed of carbohydrates and likely function in pinocytosis. The lid also serves as an attachment place for bacteria (Rother et al. 1999). Light microscopic observations of *Oxymonas* were conducted by Kofoid and Swezy (1926) and Cross (1939, 1946). Fossils were studied by Poinar (2009a, b). Studies using EM were conducted by Brugerolle and König (1997), Rother et al. (1999), Tamschick and Radek (2013), and Radek et al. (2014).

Microrhopalodina (syn. *Proboscidiella*) Grassi and Foa

Four species are described (Table 1). Cell dimensions range from 23 to 165 μm in length and 11–113 μm in width and contain multiple karyomastigonts. The number of karyomastigonts varies from four to 50, but the common numbers are four, eight, and 12. The karyomastigonts are arranged in a collar at the base of the rostellum. Every karyomastigont associates to its own axostyle. Posterior to the nuclei, axostyles extend independently as bands composed of parallel microtubular rows connected by electron-dense bridges. The bands are strongly curved at the posterior end. In the region of the nucleus, at least one row of axostylar microtubules splits from the band and laterally encircles the nucleus, forming a calyx. In the anterior direction, the microtubules lose the periodic organization, and microtubules from all axostyles join into a single loose bundle that extends into the rostellum. One lamella of microtubules encircles this loose bundle. Similarly to *Oxymonas*, the rostellum contains microtubules of the paraxostyle that originate in the holdfast and extend into the cell as convoluted ribbons. These ribbons are less developed than in *Oxymonas*. The cell body contains numerous vesicles filled with digested material. The surface of the cell is covered by external surface structures and bacteria, as in *Oxymonas* (Rother et al. 1999). Light microscopy was carried out by Kofoid and Swezy (1926), Kirby (1928), Cross (1946), and Rother et al. (1999) and EM by Lavette (1973) and Rother et al. (1999).

Barroella (syn. *Kirbyella*) Zeliff

Only two species are described (Table 1), with cell dimensions ranging between 27 and 224 μm in length and 11–80 μm in width (Cross 1946). The mature cell has a

club-like shape, no flagella, and multiple nuclei (2–114), which are scattered throughout the body. Slender axostyles are tortuously curved and much longer than the body. Axostyles and nuclei are rarely equal in number. Immature cells are similar to *Microrhopalodina*, with a collar of flagella and shorter axostyles. They originate by budding from larger cells that are distinguished by formation of multiple karyomastigont coronas (Cross 1946). No EM study has been done.

Sauromonas Grassé and Hollande

The single species, *Sauromonas m'baikiensis*, is a symbiont of the termite *Glyptotermes boukoko*. In the attached form, the cell is organized like *Oxymonas* and possesses a single nucleus, four flagella, and a single axostyle. The rostellum of *Sauromonas* contains a recurvent fibrillar bundle, which may in fact correspond to the paraxostyle of *Oxymonas* and *Microrhopalodina*. When the termite molts, the organism detaches from the intestinal wall and undergoes series of transformations resulting in a polyflagellated cell, which then loses the flagella and encysts. Light microscopy was carried out by Grassé (1952). No EM study has been done. Three fossil species of Oxymonadidae – *Oxymonites gerus*, *Microrhopalodites polynucleatis*, and *Sauromonites katatonis* – have been described in association with a fossil termite species *Kalotermes burmensis* from Cretaceous amber from Burma, 97–110 mya (Poinar 2009a, b).

Opisthomitus Duboscq & Grassé

Opisthomitus Duboscq and Grassé 1934 are small oxymonads bearing four flagella. The anterior end of the cell is pointed and forms a conspicuous lappet that may be homologous to a rostellum; however, the attachment of the cells to the gut wall has never been observed. The organization of the cytoskeleton resembles *Monocercomonoides*, including the presence of a pelta supported by a microtubular root associated with anterior basal body 4. The surface of the body is covered by numerous ring-like bulges resembling the concavities in *Saccinobacullus*. Light microscopy was studied by Duboscq and Grassé (1934), De Mello (1953), Hollande and Carruette-Valentin (1970b), and Radek et al. (2014). An EM study was performed by Radek et al. (2014). Two valid species, *Opisthomitus avicularis* and *O. longiflagellatus*, and two species with uncertain status, *O. brasiliensis* and *O. flagellae*, have been described. The genus is not classified into any oxymonad family, and the phylogeny based on 18S rRNA suggests its affiliation to Pyrsonymphidae (Radek et al. 2014).

Maintenance and Cultivation

Stable cultures have been established so far only for representatives of *Trimastix*, *Paratrimastix*, and *Monocercomonoides*. The cultures are monoeukaryotic but polyxenic (with admixed bacteria). *Trimastix* grows on ATCC 1525 medium that

should, for some strains, be supplemented by 1 ml of simplified ATCC 1034 medium (without folic acid and yeast nucleic acid added; Zhang et al. 2015). *Paratrimastix* grows well on bacterized ATCC 802 (Sonneborn's *Paramecium* medium). *Monocercomonoides* grows on TYSGM (Diamond 1982) or Dobell-Laidlaw two-phase medium (Dobell and Laidlaw 1926; Hampl et al. 2005). Cultures are maintained in 22 °C, or 37 °C if from a mammalian host, and are transferred every 4–7 days. Insect oxymonads can be maintained in the lab in their hosts.

Phylogeny and Evolution

The close relationship between endobiotic oxymonads and free-living *Paratrimastix* was first realized through phylogenetic analyses of 18S rRNA genes (Dacks et al. 2001). Based on this finding and on ultrastructural comparisons, the taxon Preaxostyla was established and defined by ultrastructural synapomorphy – a characteristic appearance of the I fiber in *Paratrimastix* and its homologue, the paracrystalline part of preaxostyle, in oxymonads (Simpson 2003). The name Anaeromonada has also been used for this grouping (Cavalier-Smith 2003). The "typical excavate" morphology of *Paratrimastix* justified inclusion of Preaxostyla into the supergroup Excavata (Cavalier-Smith 2002; Simpson 2003). Within Excavata, Preaxostyla are regarded as members of Metamonada – a commonly recognized group containing most of the other anaerobic Excavata (i.e., parabasalids and fornicates) (Cavalier-Smith 2003; Hampl et al. 2009). Both Metamonada and Excavata represent reasonable taxonomic hypotheses based on data available today, but the statistical support specifically for Excavata is never strong in molecular phylogenetic/phylogenomic analyses (Hampl et al. 2005, 2009; Simpson et al. 2006; Rodriguez-Ezpeleta et al. 2007a, b; Parfrey et al. 2010; Grant and Katz 2014; Kamikawa et al. 2014). The validity of all Excavata as a clade has been strongly challenged by a potential rooting of eukaryotes "within" Excavata, with *Malawimonas* on one side of the root and other examined Excavata on the other (Derelle et al. 2015); however, these analyses have not included Metamonada. The position of Metamonada relative to this proposed root therefore remains to be established.

The internal phylogeny of Preaxostyla recovered using 18S rRNA genes by Zhang et al. (2015) is schematically depicted in Fig. 5. It suggests that the common ancestor of Preaxostyla was a typical excavate with four flagella resembling the extant genera *Trimastix* and *Paratrimastix*. The morphology of oxymonads is derived and probably affected by their endobiotic way of life. A striking evolutionary explosion of morphological diversity is apparent in oxymonads from cockroach and termite guts. Fossils resembling some current genera of oxymonads have been reported in association with *Kalotermes burmensis* and a blattellid cockroach found in early Cretaceous amber (97–110 mya) from a mine in the Hukawng Valley, southwest of Maingkhwan, Burma (Table 1, Poinar 2009a, b). Sequence data have been obtained from the oxymonad genera *Pyrsonympha*, *Dinenympha*, *Oxymonas*, *Streblomastix*, *Monocercomonoides*, *Saccinobaculus*, and *Opisthomitus*

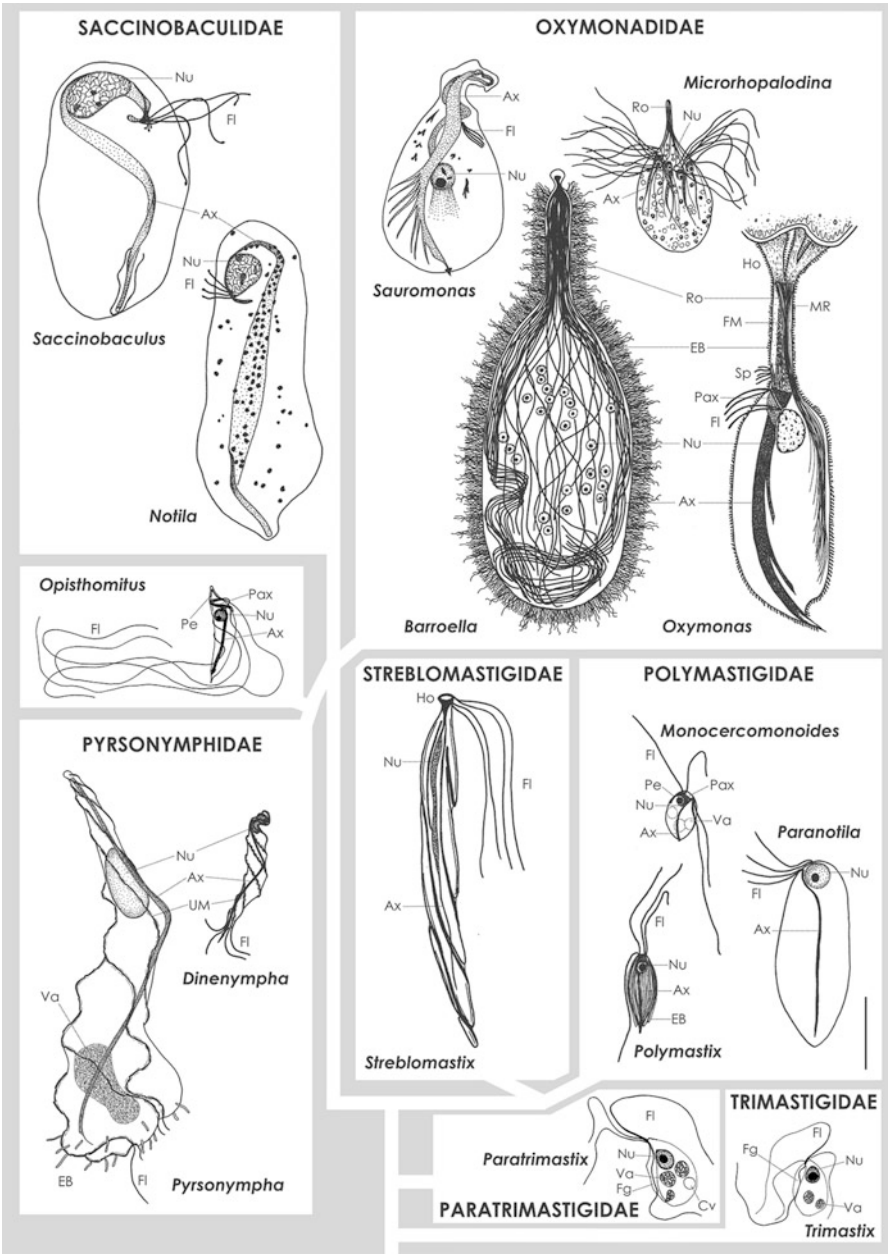

Fig. 5 Genera of oxymonads, their division into families, and probable relationships between the families. *Ax* axostyle, *Cv* contractile vacuole, *EB* ectosymbiotic bacteria, *Fg* feeding groove, *Fl* flagellum, *FM* free microtubules, *Ho* holdfast, *Nu* nucleus, *MR* microtubular ribbons, *Pe* pelta, *Pax* preaxostyle, *Ro* rostellum, *Sp* spirochaetes, *UM* undulating membrane, *Va* vacuole. bar: 10 μm for Polymastigidae and Streblomastigidae; 20 μm for Pyrsonymphidae,

representing all five families. The relationships within oxymonads are not well resolved, but all recent analyses generally agree on the relatively robust clade of Polymastigidae + Streblomastigidae and a weakly supported clade of the remaining oxymonads (Hampl et al. 2005; Heiss and Keeling 2006; de Koning et al. 2008; Radek et al. 2014).

Acknowledgments The author would like to thank Guy Brugerolle, Patrick Keeling, Kevin Carpenter, and Eva Nohýnková for kindly providing figures; Joel B Dacks, Jaroslav Kulda, Naoji Yubuki, Alastair Simpson, and an anonymous reviewer for proofreading the manuscript and helpful comments; Ivan Čepička for providing protargol preparations; and Ivan Hrdý for providing termites. Support for the author's salary came from the project of the Ministry of Education, Youth, and Sports of CR within the National Sustainability Program II (Project BIOCEV-FAR) LQ1604 and by the project "BIOCEV" (CZ.1.05/1.1.00/02.0109).

Parabasalia

32

Ivan Čepička, Michael F. Dolan, and Gillian H. Gile

Abstract

The Parabasalia are a clade of single-celled, anaerobic flagellates that are mainly obligate symbionts or parasites of insects and vertebrates. The group includes the common and widespread human sexually transmitted species *Trichomonas vaginalis*. Many species are found exclusively in the guts of termites and the wood-feeding roach *Cryptocercus*, where they contribute to wood digestion as part of a complex microbial community that sustains the insects. These insect symbionts often harbor an extensive and diverse assortment of ecto- and endosymbionts. The Parabasalia are characterized by a parabasal body (Golgi complex supported by a parabasal fiber), which is associated with the flagellar apparatus. Their mitochondria have evolved into hydrogenosomes, double-membrane-bounded organelles that derive energy from the breakdown of pyruvate to acetate, CO_2, and H_2. They vary in size from the minute *Tricercomitus*, which is only a few microns long, to the half-a-millimeter-long *Mastotermes* gut symbiont *Mixotricha paradoxa*. Historically, the Parabasalia have been treated as two groups: the smaller, simpler "trichomonads" which bear up to six flagella and the typically much larger, multiflagellate "hypermastigotes." Ultrastructural and molecular evidence have shown that together these groups form a monophyletic Parabasalia, and though neither "trichomonads" nor "hypermastigotes" are monophyletic, they continue to be useful as descriptive terms.

Introduction

General Characteristics

Parabasalia is a clade of anaerobic protists, almost all of which are flagellates. Parabasalians are characterized by the presence of a parabasal body (a densely packed Golgi complex that is associated with striated fibers connected to the basal bodies), hydrogenosomes (anaerobic derivatives of mitochondria), closed pleuromitosis with an extranuclear mitotic spindle, and a particular arrangement of microtubular and non-microtubular elements of the mastigont, notably the axostyle and pelta (see below). Although belonging to the Excavata, parabasalians have lost the typical excavate features, particularly the ventral feeding groove and cytostome. Many species possess a characteristic undulating membrane formed by a recurrent flagellum and cytoplasmic projection. Most parabasalians are uninucleate, but multinucleate cells have evolved in some lineages. Although the parabasalians are not particularly species rich, including approximately 450 described species in 100 genera, they display immense variability in cell complexity and in the number of flagella, which ranges from zero to several thousands. Accordingly, Parabasalia has been historically divided into two assemblages, the trichomonads with up to six flagella per mastigont and usually simpler cells, and the hypermastigotes, which can possess thousands of flagella and extraordinarily complex cells. However, it has been shown that an increase in the number of flagella has evolved several times independently from the trichomonad-like cells. The current taxonomy of the Parabasalia consists of six classes that better reflect the evolution of this group. Nonetheless, "trichomonad" and "hypermastigote" are still routinely used as terms of convenience to differentiate simpler cell types from multiflagellate forms.

Occurrence

Almost all parabasalians are symbionts of the digestive tracts of animals, both invertebrates and vertebrates, including humans. Much of the known diversity of Parabasalia occurs in the guts of termites and their sister lineage, the wood-feeding

roach *Cryptocercus*. Parabasalians belonging to the orders Trichonymphida, Spirotrichonymphida, and Cristamonadida are found nowhere else. These parabasalians form obligate, vertically inherited symbioses with the insect families Archotermopsidae, Hodotermitidae, Kalotermitidae, Mastotermitidae, Rhinotermitidae, Serritermitidae, Stolotermitidae, and Stylotermitidae of the infraorder Isoptera, collectively referred to as the lower termites, and *Cryptocercus*, the sole extant genus of infraorder Cryptocercoidea (Krishna et al. 2013). By contrast, termites from the most speciose family, Termitidae, only sporadically harbor small parabasalians such as *Trichomonas* and *Monocercomonas* and never hypermastigotes (Kirby 1937). While the lower termites are found on all continents except Antarctica, *Cryptocercus* has only been reported from the northern hemisphere, in certain mountainous regions of China, Korea, Russia, and the USA.

Besides termites, a number of trichomonad species have been described from other insects, such as cockroaches, crane flies, beetles, and true bugs, and some other invertebrates such as horse leeches and snails (Alexeieff 1911; Mackinnon 1913; Grassé 1926; Bishop 1932; Kozloff 1945; Brugerolle et al. 2003; Zhang 2003; Smejkalová et al. 2014), though nothing is known about their importance for their hosts. Trichomonads of vertebrates are mostly harmless intestinal commensals and can be found in diverse birds, fish, amphibians, reptiles, and mammals (e.g., Alexeieff 1910; Honigberg 1978; Čepička et al. 2005, 2006; Smejkalová et al. 2012). The best-known parabasalians are the few human and livestock parasites that have escaped the lower intestinal tract and live in the genitourinary, upper digestive, or respiratory tracts: *Trichomonas vaginalis*, *Trichomonas gallinae*, *Tritrichomonas foetus*, and *Histomonas meleagridis*.

Although most parabasalian species are host-associated, a few free-living ones have been described as well, for example, *Monotrichomonas carabina*, *Ditrichomonas honigbergii*, *Pseudotrichomonas keilini*, and *Lacusteria cypriaca* (Bishop 1935, 1939; Farmer 1993; Bernard et al. 2000; Yubuki et al. 2010). They inhabit freshwater, brackish, and marine anoxic/microoxic sediments and have been found worldwide.

Literature and History of Knowledge

The first parabasalians to be described were trichomonads associated with humans and animals. The first was *Trichomonas vaginalis* from a human vaginal tract (Donné 1836), followed by three more species of *Trichomonas*, each now known by different names: *Tetratrichomonas limacis* from slugs (Dujardin 1841), *Tritrichomonas suis* from pig intestines (Gruby and Delafond 1843), and *Trichomitus batrachorum* from frogs (Perty 1852). Another early description was of *Pentatrichomonas hominis* from human intestines, originally named *Cercomonas hominis* (Davaine 1854, 1860). The first multiflagellated species (hypermastigotes) were described not long after: *Lophomonas blattarum* (Stein 1860), from the hindgut of a common cockroach, and *Trichonympha agilis* (Leidy 1877) from the hindgut of a termite. Leidy wrote that the multiflagellate swimming cell he called *Trichonympha*

reminded him of "nymphs in a recent spectacular drama, in which they appeared with their nakedness barely concealed by long cords suspended from the shoulders" (Leidy 1877), hence the origin of the *-nympha* suffix that proliferated through the nomenclature of hypermastigotes. Toward the end of the nineteenth century, more researchers began to study the protist hindgut community of termites, using only light microscopy and relatively unsophisticated staining techniques. The parabasalians, like the ciliates, proved accessible to iron hematoxylin and then protargol staining, however, revealing a wealth of taxonomically useful morphological characters. Many new genera of parabasalians from various hosts, both trichomonads and hypermastigotes, were described, and a classification system with elements recognizable in our current classification was in place by the early twentieth century (Grassi and Foà 1911).

The order Trichomonadida (corresponding roughly to the "trichomonad" assemblage) was created by Kirby (1947). His system of families and genera was revised by Honigberg (1963). Honigberg's view on the evolution of the trichomonads was largely supported by electron microscopy (Brugerolle 1976), and his version of the trichomonad system survived to the beginning of the twenty-first century with some minor modifications. Then, it was gradually replaced by the contemporary system present in this chapter (see below), which is based both on morphology, including ultrastructure, and results of molecular phylogenetic studies.

The concept of hypermastigotes is even older than that of trichomonads. An affinity between the multiflagellate *Lophomonas* and *Trichonympha* was first proposed after the discovery of *Joenia*, another termite hindgut protozoan that appeared morphologically intermediate between *Lophomonas* and *Trichonympha* (Grassi 1885). This led to the creation of the order Hypermastigida for multiflagellate forms (Grassi and Foà 1911). Although much of the diversity of both trichomonads and hypermastigotes was described early in the twentieth century, it was still many years before their relatedness was understood. Hypermastigotes were initially thought to be ciliates, or intermediate between ciliates and gregarines (Leidy 1881; Kent 1882). Similarities between hypermastigotes and flagellates were soon recognized, however, and support for this view grew (Stein 1878; Kofoid and Swezy 1919; Cleveland 1923; Kirby 1947; Grassé 1952). With the advent of electron microscopy, ultrastructural studies began to reveal strong evidence that trichomonads and hypermastigotes were specifically related (Hollande and Valentin 1969a; Hollande and Carruette-Valentin 1971; Hollande and Carruette-Valentin 1972; Tamm and Tamm 1973). The superorder Parabasalia was proposed in 1973 to formally unite these two groups (Honigberg 1973). Molecular phylogenetic studies have confirmed the monophyly of Parabasalia but have also shown that neither trichomonads nor hypermastigotes are monophyletic, and at times their results have conflicted directly with morphology-based scenarios of parabasalian evolution (see "Evolutionary History").

No treatise of the Parabasalia exists, and even the economically important species have not been reviewed in depth for nearly 20 years. The most recent books reviewing these species are *Trichomonads Parasitic in Humans* (Honigberg 1990) and *Parasitic Protozoa* (Kreier 1991). An excellent genus-level descriptive key of

the group by Brugerolle and Lee (2000) can be found in *An Illustrated Guide to the Protozoa* (Lee et al. 2000). Several chapters describing the biology and evolution of termite hindgut parabasalians can be found in the *Intestinal Microorganisms of Termites and Other Invertebrates* (König and Varma 2006) and *Biology of Termites: A Modern Synthesis* (Bignell et al. 2011). The American Museum of Natural History houses the extensive microscope slide collections of Harold Kirby and Lemuel Roscoe Cleveland, two of the most prolific investigators of termite and *Cryptocercus* hindgut parabasalians. A set of 35 mm films made by Cleveland is also housed there.

Practical Importance

Parabasalians have evolved as symbionts of the animal digestive tract. Intestinal parabasalids generally cause little or no harm to their hosts (BonDurant and Honigberg 1994), with some pertinent possible exceptions (see examples below). A few species have moved to other areas of the body, where they are parasites. Humans are infected by several species, for example, *Trichomonas vaginalis* in the urogenital tract, *Trichomonas tenax* in the oral cavity, and *Pentatrichomonas hominis* and *Dientamoeba fragilis* in the large intestine (Honigberg 1978; McDougald and Reid 1978). *Trichomonas vaginalis* is the most important by far, infecting 180 million people worldwide annually. It is the most common of the sexually transmitted urogenital infections in humans. The pathogenicity of *Dientamoeba fragilis* for humans is not well understood, but it seems that certain bowel disorders can be attributed to this species (Barratt et al. 2011). A single report of *Dientamoeba* being pathogenic for gorillas was published (Lankester et al. 2010). *Pentatrichomonas hominis* is considered nonpathogenic (Honigberg and Burgess 1994). Several parabasalian species have been found in the respiratory tract of humans, for example, *Trichomonas tenax*, *Trichomonas vaginalis*, *Tritrichomonas foetus*, *Pentatrichomonas hominis*, *Tetratrichomonas gallinarum*, and *Tetratrichomonas empyemagena* (Jongwutiwes et al. 2000; Čepička et al. 2005; Kutisova et al. 2005; Duboucher et al. 2006, 2007; Carter and Whithaus 2008; Leterrier et al. 2012); their pathogenic potential is usually unclear. Although *Lophomonas blattarum*, a hypermastigote from cockroaches, has been repeatedly reported from the respiratory tract of humans, it was possibly confused with epithelial cells (see Li and Gao 2016).

Histomonas meleagridis causes histomoniasis or "blackhead" disease that affects the ceca and liver of turkeys, chicken, quail, and peafowl. It has been effectively treated with dimetridazole and nifursol in the feed, but these drugs are now banned in the European Union. Symptoms in turkeys are listlessness, anorexia, droopy wings, and yellow, sulfur-colored feces. *Histomonas* interacts with cecal worms, earthworms, coccidia, and other intestinal microbiota (AbdulRahman and Hafez 2009). It can be transmitted between birds by the nematode *Heterakis gallinarum*, and earthworms may serve as paratenic hosts (McDougald and Reid 1978).

Another parabasalian affecting birds is *Trichomonas gallinae*, which lives in the upper digestive tract of birds where it can cause disease. It infects turkeys, raptors,

and gulls, but its primary host is the domestic pigeon. In pigeons it is transferred in the "milk" from the crop of an affected bird to the offspring. Virulent strains cause ulcers of the mouth, pharynx, esophagus, and crop, from which the organism enters the blood stream and passes to the liver. From this site it can kill a bird in two weeks (BonDurant and Honigberg 1994). A large outbreak of *T. gallinae* recently led to population declines in two finch species in the UK (Lawson et al. 2011).

Cattle are the primary hosts of *Tritrichomonas foetus*, which is transmitted exclusively as a venereal infection. In infected females, fertilization of the ovum occurs but the embryo may die and be expelled or absorbed. Besides cattle, *T. foetus* is found also in the large intestine and nasal cavity of pigs, where it is considered a harmless commensal, and in the intestine of cats, where it causes diarrhea (Yao and Köster 2015). For a detailed account of trichomoniasis, see BonDurant and Honigberg (1994).

Aside from causing disease in humans and animals, the main impact of parabasalians on society is their role in the destruction of buildings by wood-eating termites. While *Cryptocercus* is found only within decaying tree trunks (Nalepa 1984), at least 370 of the 3000 living species of termites are considered pests. The most damaging of the termite pests are *Cryptotermes brevis*, *Cryptotermes domesticus*, *Cryptotermes dudleyi*, *Coptotermes formosanus*, *Coptotermes gestroi*, *Reticulitermes flavipes*, and *Reticulitermes lucifugus*; these all harbor symbiotic hindgut parabasalians (Krishna et al. 2013).

Habitats and Ecology

Parabasalians are all anaerobes, and most are intestinal symbionts or parasites. The majority of described species are obligate symbionts of wood-eating insects (the so-called "lower" termites and *Cryptocercus* wood-feeding roaches), and these associations in particular have received sustained attention in terms of evolutionary history and functional ecology. Each termite or wood roach usually harbors several species of parabasalians. These species help their host to digest cellulose, in cooperation with the other microorganisms present in the intestine. Their evolution as gut symbionts has led to many morphological adaptations including cell enlargement and multiplication of flagella in some lineages (see below). It has been shown that the symbiosis between termites and their parabasalians is obligate and that the insect host will starve to death despite continued feeding if the symbionts are removed (Cleveland 1925). The termite parabasalians are considered highly host specific and coevolving with their hosts, with few host switches (Kirby 1947; Kitade 2004; Noda et al. 2007; Tai et al. 2015).

Many parabasalian species found in vertebrates are understudied and have not been reported since the original description. The species living in the intestine are usually commensals, though a possible pathogenicity for the host is a consideration in some cases. The host specificity differs from species to species (e.g., Čepička et al. 2006). Some species seem to be restricted to a few closely related hosts or a single host lineage such *Tetratrichomonas limacis* from gastropods or several trichomonad species from guinea pigs (Nie 1950; Čepička et al. 2006). Others can infect many

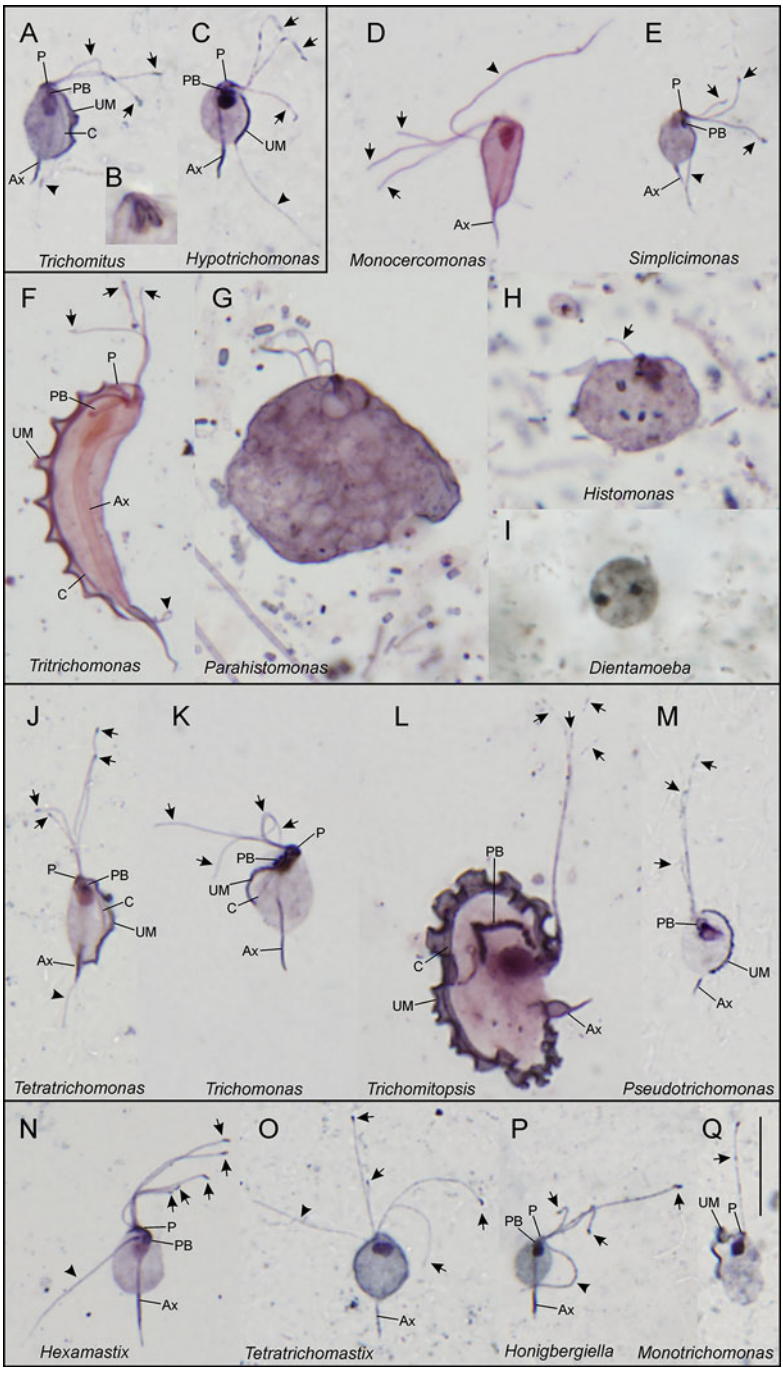

Fig. 1 (continued)

species representing one or even more vertebrate classes, e.g., *Trichomitus batrachorum* from a wide diversity of amphibians and reptiles, *Pentatrichomonas hominis* from many mammalian orders, *Tetratrichomonas gallinarum* from birds and primates, and *Tetratrichomonas* sp. "lineage 10" from tortoises, cattle, and primates (Honigberg 1953; Honigberg and Burgess 1994; Čepička et al. 2005; Smejkalová et al. 2012).

Several species of parabasalians, notably *Trichomonas* spp. and *Tritrichomonas foetus*, have colonized other internal organs, such as the oral cavity (e.g., *Trichomonas tenax* from humans and *Trichomonas gallinae* from birds) and genitourinary tract (*Trichomonas vaginalis* from humans and *Tritrichomonas foetus* from cattle). These species are often pathogenic for their hosts, causing various diseases. The trichomonads from extra-intestinal locations were generally believed to be highly host specific, with the exception of *Tritrichomonas foetus* that infects the intestine and nasal cavity of pigs as well as the genitourinary tract of cattle. Nonetheless, recently published studies have shown that the true host range may be wider in several cases (Šlapeta et al. 2012; Morin-Adeline et al. 2015).

Characterization and Recognition

Light Microscopy

Parabasalia is a morphologically diverse lineage and can be divided into two assemblages according to the cell complexity: trichomonads (relatively simple cells with up to six flagella per mastigont) and hypermastigotes (complex, often very large cells, with many flagella per mastigont). These two groups more or less correspond with the traditional orders Trichomonadida and Hypermastigida, but it has been shown that neither is monophyletic (see below). The trichomonads represent morphologically plesiomorphic forms of the Parabasalia, whereas the hypermastigotes are a polyphyletic assemblage of highly derived forms that are adapted to

phagocytosis of relatively large wood particles in the intestines of termites. Trichomonads are now classified among Trichomonadida, Honigbergiellida, Tritrichomonadida, Hypotrichomonadida, and Cristamonadida, while hypermastigotes belong to Trichonymphida, Lophomonadida, Spirotrichonymphida, and Cristamonadida, and one species is classified within Honigbergiellida (Čepička et al. 2010; Gile and Slamovits 2012; James et al. 2013).

Morphology of Trichomonad Cells

Trichomonad cells are usually spindle-shaped or pyriform (Figs. 1, 2). They do not possess any cytostome. Instead, phagocytosis generally occurs anywhere on the cell surface. Certain taxa tend to be amoeboid, for example, *Histomonas meleagridis* and *Parahistomonas wenrichi* (Fig. 1g, h). *Trichomonas vaginalis* also becomes amoeboid when attached to the vaginal epithelium, though it retains its flagella, as does the cristamonad *Gigantomonas herculea*, which forms gigantic plasmodia as part of its life cycle. *Dientamoeba fragilis* has completely lost its flagella and is the only true amoeba within Parabasalia (Fig. 1i). Cells of trichomonads from vertebrates measure about ten micrometers; trichomonads from termites may have much larger cells with diameters of tens or even hundreds of micrometers, for example, cells of *Mixotricha paradoxa* measure up to half a millimeter in length (Cleveland and Grimstone 1964; Brugerolle 2004).

Trichomonads are predominantly uninucleate. Many cells of *Dientamoeba fragilis* are binucleate, because they are arrested in the telophase stage of the cell cycle (Camp et al. 1974) (see Fig. 1i). The nucleus of a trichomonad is typically in close association with the flagellar basal bodies (which in simple forms are grouped together into a single "mastigont") and associated cytoskeletal fibers; in other words most trichomonads have a "karyomastigont." The number of flagella in a mastigont varies in trichomonads from zero in the amoeboid *Dientamoeba fragilis* (Fig. 1i) to six in the genera *Hexamastix*, *Pentatrichomonas*, *Pentatrichomonoides*, *Cochlosoma*, and *Cthylla* (Fig. 1m). The ancestral number is four (e.g., *Trichomitus*, *Tritrichomonas*, *Parahistomonas*, *Monocercomonas*, *Simplicimonas*, *Honigbergiella*, *Devescovina*; Figs. 1a–g, m, p and 2d, g), but five flagella are common (e.g., *Trichomonas*, *Tetratrichomonas*, *Pseudotrypanosoma*, *Trichomitopsis*, *Tetratrichomastix*; Fig. 1j–l, n), and trichomonads with three flagella (*Ditrichomonas*), two flagella (*Monotrichomonas*, Fig. 1q), or a single flagellum (*Histomonas*, Fig. 1h) are known as well.

Two independent lineages of Cristamonadida, the first one being represented by the genera *Calonympha*, *Stephanonympha*, and *Snyderella* and the second one by the genus *Coronympha*, have multiplied their nuclei and possess eight (*Coronympha* young forms) to dozens or even hundreds (e.g., *Snyderella*) of nuclei per cell (see Figs. 2h, j and 6c) (Harper et al. 2009; Gile et al. 2011). Such "polymonad" trichomonads are collectively called the calonymphs (Čepička et al. 2010). As in simpler trichomonads, the nuclei of calonymphs are each associated with flagellar basal bodies in a mastigont, forming an organelle system called the karyomastigont

(as above). In the genera *Calonympha* and *Prosnyderella*, there is a proliferation of mastigonts that lack an associated nucleus, the akaryomastigonts. Only in the genus *Snyderella* are the nuclei disassociated from the mastigonts and suspended in the cytoplasm. In this case, all flagella are found in akaryomastigonts across the surface of the cell. Each karyo- or akaryomastigont has four flagella. Although the calonymphs are multiflagellate, their mastigont organization is trichomonad-like and clearly derives from a multiplication of nucleomotor systems, rather than the proliferation of individual flagella that has occurred multiple times in hypermastigotes. Accordingly, two to four flagella are present in individual karyo- or akaryomastigonts.

Flagella of trichomonads insert apically or subapically. One flagellum is usually recurrent and runs posteriorly along the cell body, while the other flagella are directed anterolaterally (Figs. 1 and 2a, e, g). The posterior flagellum is acronematic, while the anterior flagella usually end with structures called "knobs" when stained (Fig. 1a, c, e, j, n–q), though the knobs may be artifacts due to the cell shrinkage during the fixation (Céza et al. 2015). The recurrent flagellum of some trichomonads is associated with the cell body, forming an undulating membrane. The undulating membrane may reach the posterior end of the cell (e.g., *Tetratrichomonas*, *Pentatrichomonas*, *Tritrichomonas*, *Trichomitus*; Fig. 1a, c, f, j, l), or it can be shorter (e.g., *Trichomonas*, *Ditrichomonas*, *Monotrichomonas*; Fig. 1k, q). In most cases, the recurrent flagellum extends beyond the undulating membrane (e.g., *Tetratrichomonas*, *Tritrichomonas*, *Trichomitus*), but in *Trichomonas* and *Pseudotrichomonas*, the recurrent flagellum is associated with the cell body along its whole length, and no free portion is developed (Fig. 1k, m). The undulating membrane is usually underlain by a fiber of varying thickness called a costa (Fig. 1a, f, j–l). Some genera, e.g., *Hypotrichomonas*, *Pseudotrichomonas*, *Ditrichomonas*, and *Monotrichomonas*, possess an undulating membrane but no costa (Fig. 1c, m, q). The undulating membrane of some members of Cristamonadida is instead underlain by a fibrous cresta (Fig. 2a, e) that is not homologous to the costa (Kirby 1942; Hollande and Valentin 1969b; Brugerolle 1976; Brugerolle and Lee 2000). The presence/absence of costa and cresta was historically suggested to be an important taxonomic feature (Kirby 1947; Honigberg 1963).

The karyomastigont of trichomonads is associated with characteristic cytoskeletal elements. Four of these are visible under the light microscope: costa/cresta, pelta, axostyle, and, with appropriate staining, parabasal fibers (Fig. 1). The axostyle is a hyaline rod and is differentiated into the proximal, spatulate capitulum, which laterally covers the nucleus, and a distal trunk, which usually protrudes from the posterior end of the cell. Trichomonad taxa differ in the shape of the capitulum,

thickness of the trunk, and shape of its ending. In general, two types of axostyles are recognized (Čepička et al. 2010): *Trichomonas* type, which tapers gradually (e.g., *Trichomonas*, *Trichomitus*, *Monocercomonas*, and many others; Fig. 1a, c, d, j, k, m–o), and *Tritrichomonas* type, which tapers abruptly (e.g., *Tritrichomonas*, *Simplicimonas*, and many cristamonad genera; Fig. 1e, f, l). The pelta is a crescent-shaped structure that curves over the anterior side of the nucleus. In the bird parasite genus *Cochlosoma*, the pelta has been modified to support an adhesive disc superficially resembling that of the diplomonad *Giardia* (Pecka et al. 1996). Each mastigont of the calonymphs includes an individual axostyle and pelta. Trunks of the axostyles are either separated from each other (e.g., in *Coronympha*) or they form a bundle along the cell's axis (e.g., *Calonympha* and *Stephanonympha*) (Kirby 1929; Rösel et al. 1996). Both axostyle and pelta are absent in the amoeboid *Dientamoeba fragilis* (Camp et al. 1974).

Usually one or two parabasal fibers run from the basal bodies into the cell. These are associated with the Golgi apparatus and together with the Golgi form the so-called parabasal body, which is the apomorphy for which Parabasalia is named. The parabasal body may be V-shaped (e.g., *Trichomonas*, *Trichomitus*, *Hypotrichomonas*; Fig. 1b), sausage-shaped (e.g., *Tritrichomonas*, *Monocercomonas*; Fig. 1f), discoid (e.g., *Tetratrichomonas* and *Pseudotrichomonas*; Fig. 1j, m), drop-shaped (e.g., *Pentatrichomonas*, *Simplicimonas*, *Hexamastix*; Fig. 1e, n), elongate (e.g., *Trichomitopsis*; Fig. 1l), or branched (*Pseudotrypanosoma*).

The parabasal body shape is particularly striking in the devescovinids, a grouping of large trichomonads from termite hindguts. In genera such as *Devescovina*, *Metadevescovina*, *Caduceia*, and *Macrotrichomonas*, the parabasal body winds around the axostyle, with the number of turns being used as a species-level taxonomic feature (Fig. 2f). The coiling of the parabasal body reminded Kirby of the snakes winding around Hermes' staff, the caduceus, and prompted him to name a new genus *Caduceia* (Kirby 1942). Apart from being larger than other trichomonads, the devescovinids have a similar overall morphology, with three anterior and one recurrent flagellum. The latter sometimes adheres to the cell, forming an undulating membrane. The recurrent flagellum is typically thickened to form a cord or a ribbon-like band (Foà 1905; Janicki 1915; Brugerolle and Lee 2000).

Morphology of Hypermastigote Cells

Hypermastigotes measure from several to several hundred micrometers in length and bear more flagella than trichomonads, ranging from several tens to several thousands. Almost all hypermastigote cells possess a single nucleus. Most structures typical for trichomonads, i.e., pelta, axostyle, and parabasal body, are also present in hypermastigotes but usually have been expanded or transformed. Three broad morphological categories of hypermastigotes can be recognized. Trichonymphida (e.g., *Trichonympha*, *Staurojoenina*; Fig. 3a–h) have many flagella arranged along and around a bilaterally symmetrical rostrum. Spirotrichonymphida (e.g., *Spirotrichonympha*, *Holomastigotes*; Fig. 4) lack a true rostrum, and the complex

cytoskeletal structure supporting the flagella is arranged in two counterclockwise spirals (Brugerolle and Lee 2000) (see below for more details). The third group, collectively and informally called the lophomonads, were placed together in early taxonomies because of their shared anterior tuft of many flagella but are now known to be polyphyletic. All lophomonads, with the exception of *Lophomonas* itself, belong to the Cristamonadida, though they do not branch together within that order. Another shared feature of lophomonads is the resorption of parabasal bodies, axostyle, flagella, and basal bodies during cell division (Brugerolle and Patterson 2001). Only the four privileged basal bodies (homologous to the ancestral four basal bodies, see below) are not resorbed. These are duplicated and then separated, and the

additional flagella and associated structures are rebuilt in each daughter cell (Hollande and Carruette-Valentin 1971).

Projoenia sawayai (Cristamonadida) displays the most plesiomorphic morphology among cristamonad hypermastigotes in general (Lavette 1970). Its cells are 45–100 μm long and strongly resemble cells of devescovinids by possessing a recurrent flagellum proximally supported by a cresta, a stout axostyle, and a single, spiral parabasal body, yet its mastigont is an apical flagellar area with as many as 500 flagella. The morphology of other cristamonad hypermastigotes (informally

referred to as "joeniids," e.g., *Joenia*, *Joenoides*, *Placojoenia*, *Joenina*, and *Joenopsis*) is similar to that of *Projoenia*, though the cells are more complex, bear more flagella, and lack the cresta (Brugerolle and Lee 2000) (Fig. 2i). Joeniid genera differ mainly in the shape of the flagellar area. *Rhizonympha jahieri* is a peculiar lophomonad whose cells are plasmodia with several hundred karyomastigonts, each containing multiple flagella (Grassé and Hollande 1951). *Kofoidia loriculata* is another unusual lophomonad with several bundles of flagella on the apex that are arranged in an open circle (Light 1927). Genera *Deltotrichonympha* and *Koruga* (which is likely a synonym of *Deltotrichonympha*) have rows of flagella extending down the cell body in addition to the apical flagellar area.

Lophomonas cells are 20–60 μm long and contain a single karyomastigont (Fig. 3i, j). The many flagella are arranged in an ear-shaped row partially encircling the nucleus. The axostyle is thin and can protrude through the cell body (Kudo 1926a, b; Hollande and Carruette-Valentin 1972).

In the monophyletic hypermastigote order Trichonymphida, cells are divided into a rostrum and postrostral area (Fig. 3a–h). The postrostral area contains the nucleus, which usually lies close to the boundary of the two areas. The rostrum is bilaterally or tetraradially symmetrical and bears two (most trichonymphids) or four (Staurojoeninidae; Fig. 3e) flagellar areas, each composed of longitudinal rows of flagella. The areas separate from each other during cell division and are distributed into the daughter cells (Hollande and Carruette-Valentin 1971). Some trichonymphids bear flagella also on the postrostral area: in Spirotrichosomidae (e.g., *Spirotrichosoma*, *Leptospironympha*, *Apospironympha*; Fig. 3c, d), the postrostral basal bodies are arranged in spiral rows, which makes them superficially similar to Spirotrichonymphida (see below), while in Trichonymphidae (Fig. 3g, h), the rows are longitudinal. In Teranymphidae, the postrostral flagella are either arranged in longitudinal rows as well (*Eucomonympha* and *Pseudotrichonympha*; Fig. 3a, b) or form multiple circular transverse rows (*Teranympha*). In Hoplonymphidae (e.g., *Hoplonympha*, *Barbulanympha*) and Staurojoeninidae (e.g., *Staurojoenina*), the postrostral area is devoid of flagella (Fig. 3e, f). The parabasal complex of trichonymphids is divided into numerous branches around the nucleus (*Trichonympha*) or consists of numerous bodies within the cell (Brugerolle and Lee 2000).

The flagella of Spirotrichonymphida are arranged in two or more counterclockwise spiral rows that are distributed into daughter cells during the division (Fig. 4). The number of flagellar lines can vary among cells of a single species (Brugerolle 2006a). Some genera (*Spirotrichonympha*, *Spironympha*, *Spirotrichonymphella*) possess an apical structure ("pseudorostrum") that resembles the rostrum of Trichonymphida, while the others (e.g., *Holomastigotes*, *Holomastigotoides*) do not. The axostyle is either absent (*Spirotrichonymphella*), split into individual filaments (*Spirotrichonympha* and *Holomastigotoides*), or resembles the axostyle of trichomonads (*Microjoenia*, *Micromastigotes*). Parabasal fibers and multiple, small parabasal bodies are associated with the flagellar rows or are scattered in the cytoplasm (Brugerolle and Lee 2000; Brugerolle 2001).

Cthulhu macrofasciculumque is the only hypermastigote member of Honigbergiellida (James et al. 2013). Its cells are only about 20 μm long and bear about 20 flagella. Otherwise, their morphology is largely trichomonad-like.

Structure of the Cytoskeleton

Although Parabasalia belongs to the supergroup Excavata, they do not possess the ventral feeding groove supported by cytoskeleton, which is typical for plesiomorphic excavates such as *Carpediemonas*, *Trimastix*, and *Jakoba*. Instead, they have developed a characteristic system of microtubular and non-microtubular cytoskeletal elements, for which homology with elements of the flagellar apparatus of typical excavates usually cannot be determined (Simpson 2003). The mastigont system that is most similar to the hypothetical last common ancestor of Parabasalia is found in some trichomonads (Fig. 5b, c) and comprises four basal bodies, three of which (here referred to as B2, B3, and B4) are parallel, are directed anteriorly, and bear the three anterior flagella. The remaining basal body (B1) lies in proximity to B2–B4 but is perpendicular to them and bears the recurrent flagellum. Note that in much of the Parabasalia literature, the basal body of the recurrent flagellum is instead designated R, and the anterior flagellar basal bodies are B1–B3. The B1–B4 scheme adopted here allows microtubular roots to be designated and compared across eukaryotic lineages (Moestrup 2000; Yubuki and Leander 2013; Yubuki et al. 2016). In genera with four anterior flagella, such as *Trichomonas*, *Tetratrichomonas*, and *Pseudotrypanosoma* (Trichomonadida), the basal body bearing the additional flagellum (B5) lies in the same plane as B2–B4 and is parallel to them, making a four-sided bundle (Fig. 5a). A fifth anterior flagellum has been added into the mastigont of Parabasalia in two different ways. In *Pentatrichomonoides* (Trichomonadida) and *Hexamastix* (Honigbergiellida), the basal body of the fifth anterior flagellum (B6) is adjacent and parallel to B2–B5 (Hampl et al. 2007; Fig. 5e, f). In *Pentatrichomonas* and *Cochlosoma* (Trichomonadida), on the other hand, B6 is separate and not parallel to the others (Honigberg et al. 1968; Pecka et al. 1996). In species with fewer than four flagella, the four basal bodies remain but one or more of them are barren. For example, *Ditrichomonas*, which has two anterior flagella, has one barren basal body, while *Histomonas*, with only one flagellum, has three barren basal bodies (Schuster 1968; Farmer 1993).

The basal bodies of the anterior flagella, B2–B4, bear striated rootlets running posteriorly into the cytoplasm. The rootlets of B3 and B4 are short and single, while B2 bears multiple, long fibers, called sigmoid fibers or preaxostylar filaments, that are curved toward the dorsal side of the cell and run toward the pelta-axostyle junction (Fig. 5a–c, f). In addition to striated rootlets, B3 and B4 each bear a short, hooked lamina along their length (Brugerolle 1991). Another typical cytoskeletal structure that originates from the area of the basal bodies (specifically, between B1 and B4) is the striated marginal lamella. It underlies the proximal part of the recurrent flagellum and participates in the undulating membrane structure (Fig. 5a, b, g).

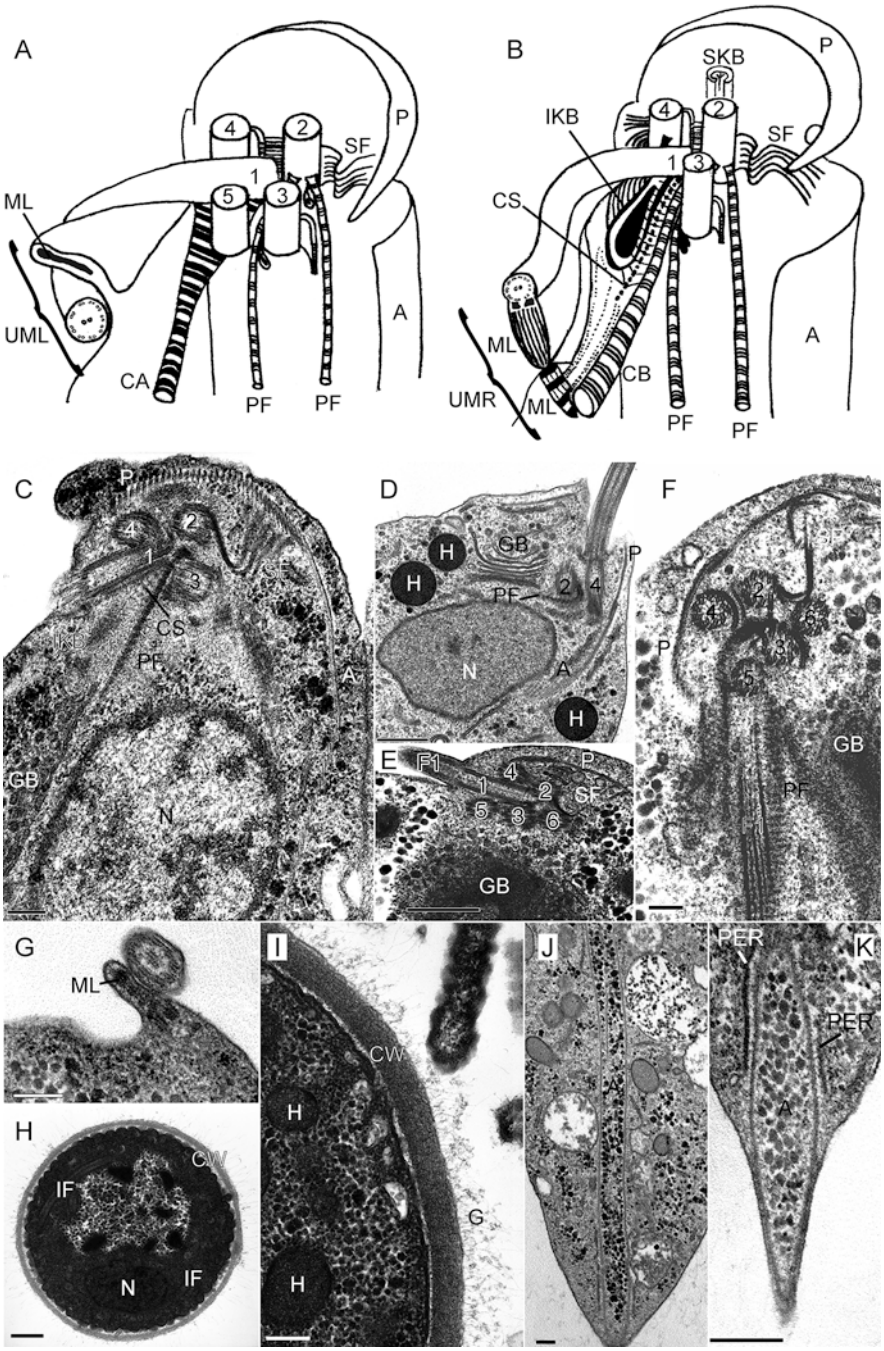

Fig. 5 Ultrastructure of trichomonads. **(a)** Organization of the cytoskeleton of *Tetratrichomonas* sp. (Trichomonadida). **(b)** Organization of the cytoskeleton of *Tritrichomonas muris*

The recurrent flagellum of some species is attached to the ventral cell surface, and an undulating membrane develops (Fig. 5a, b, g). The side of the cell where the recurrent flagellum runs is referred to as "dorsal" in the older literature, but here we consider it "ventral," because the ventral feeding groove had been located here before it was lost. There are two basic types of undulating membrane in trichomonads. The first one, called a lamelliform undulating membrane, is found in Trichomonadida, Honigbergiellida, and Hypotrichomonadida, and a very simple version is also seen in *Simplicimonas* (Tritrichomonadida) (Fig. 5a, g). It is formed by a thin cytoplasmic projection that is laterally supported by the recurrent flagellum. The recurrent flagellum usually has a typical structure with no modifications, but in some genera from termites, such as *Trichomitopsis*, *Pseudotrypanosoma*, *Trichomonoides*, and *Pentatrichomonoides*, it is enlarged and contains paraxonemal fibers (Hollande and Valentin 1968; Brugerolle et al. 1994; Brugerolle 1999). The distal part of the cytoplasmic projection of the cell body contains the marginal lamella. The second type of undulating membrane is found in the genus *Tritrichomonas* (Tritrichomonadida) and is called a "rail"-type undulating membrane (Brugerolle 1976) (Fig. 5b). Here, the recurrent flagellum is applied directly to the distal part of the cytoplasmic projection, which is much thicker than in the lamelliform undulating membrane. Both the cytoplasmic projection and recurrent flagellum contain electron-dense material derived from the marginal lamella. *Tritrichomonas* species differ considerably in the fine structure of the rail-type undulating membrane (Joyon et al. 1969) (see Fig. 5b–d in Brugerolle & Lee 2000). In some members of Cristamonadida, the recurrent flagellum adheres to the cell body as well, and a homolog of the rail-type undulating membrane is developed. In this case, however, there is no cytoplasmic projection, though a sharp transition can be seen where one side of the undulating membrane meets the cell membrane, and the enlarged recurrent flagellum applies directly to the cell surface and is subtended by an electron-dense fiber, the cresta (Fig. 6b). The cresta is thus not homologous to the costa that underlies the undulating membrane of many trichomonads, but instead

may be homologous to the proximal part of the rail-type undulating membrane of *Tritrichomonas* (Hollande and Valentin 1969b; Gile et al. 2015).

The undulating membrane of *Trichomitus* (Hypotrichomonadida), *Tritrichomonas* (Tritrichomonadida), and most members of Trichomonadida is underlain along its length by a thick striated fiber, the costa (Fig. 5a, b). Although costae are relatively uniform when observed under the light microscope, their structure and the exact site of their origin in the area of the basal bodies differ among lineages. Generally, two types are distinguished: A-type and B-type (historically, they had been also referred to as C_1- and C-type, respectively). The A-type costa is found in *Tritrichomonas* and *Trichomitus*. Its striations have a periodicity of about 40 nm and consist of repetitions of four transverse bands. In contrast, the B-type costa of Trichomonadidae, although with similar periodicity of 40 nm, consists of the repetition of a single basic line of dense filaments in cross section (Honigberg et al. 1972). The costa of most trichomonads is a rigid structure; in the closely related genera *Trichomitopsis* and *Pseudotrypanosoma*, it is contractile, and its movement contributes to the movement of the entire cell (Mattern and Honigberg 1971; Amos et al. 1979).

The parabasal apparatus is a defining feature of parabasalians. In trichomonads it includes two striated filaments (PF1 and PF2) with periodicity (ca. 40 nm) and structure very similar to that of the A-type costa (Mattern et al. 1967; Honigberg et al. 1971; Honigberg et al. 1972; Brugerolle 1976). They emerge from the basal bodies, run posteriorly into the cytoplasm, and are associated with the cisternae of stacked Golgi apparatus, which is extensively developed (Fig. 5d, f).

The axostyle and pelta are conspicuous structures of trichomonad cells under the light microscope (see above). Transmission electron microscopy revealed that each consists of a single, broad sheet of cross-linked microtubules (Brugerolle 1986) (Fig. 5c, f). Although pelta and axostyle are two separate structures, they meet in the area called the pelta-axostylar junction, where their microtubules overlap for some length. The inner side of the pelta-axostylar junction is associated with the sigmoid fibers that descend from B2. The pelta curves to the right and encircles the area where the basal bodies are located and supports the periflagellar canal, an external pit or chamber that houses the proximal portion of the flagella (Honigberg and Brugerolle 1990). The axostyle is divided into an anterior, spoon-shaped capitulum that curves over the nucleus (Fig. 5a–c) and a posterior, tubular trunk that extends axially to the posterior taillike tip of the cell (Fig. 5j, k). The axostylar trunk is formed from a sheet of microtubules, either with edges joined to form a hollow tube, as in *Simplicimonas* (Čepička et al. 2010), or rolled into a spiral, as in *Tritrichomonas* (Brugerolle and Lee 2000). In *Pentatrichomonoides* (Trichomonadida), the trunk has been modified into a microtubular corset that underlies most of the cell surface (Brugerolle et al. 1994).

There are several non-microtubular structures in the mastigont of trichomonads that are lineage specific. Some of these are various kinds of striated fibers. Although their structure has been well documented by TEM studies, their compositions and

functions are unknown. For example, the so-called infrakinetosomal body is typical for some Tritrichomonadida and Cristamonadida, and the comb-like structure has been documented from the mastigont of Tritrichomonadida, Cristamonadida, and Hypotrichomonadida (Fig. 5b, c; see Čepička et al. 2010).

Hypermastigotes have many unique ultrastructural features, though certain aspects of their cytoskeletons are directly comparable to those of simpler trichomonads. In particular, the "privileged" basal bodies, those that are homologous to the ancestral B1–B4, can be found among the many additional flagella (Hollande and Carruette-Valentin 1971). These are most clearly apparent in the lophomonads, where they are at the heart of the apical flagellar bundle and polarize the parabasal bodies and pelta-axostyle complex just as in trichomonads (Hollande and Carruette-Valentin 1972; Brugerolle 1991). Upon cell division, all flagella are resorbed and only the privileged basal bodies remain. The privileged basal bodies are arranged in the three anterior, one recurrent arrangement typical of trichomonads, with a hooked lamina on B2 and B4 (Honigberg and Brugerolle 1990). One exception to this is found in *Lophomonas*, where the direction of B1 has changed such that all four privileged basal bodies are parallel (Hollande and Carruette-Valentin 1972; Brugerolle 1991). This significant ultrastructural difference is consistent with the distant relationship between *Lophomonas*, and the cristamonad hypermastigotes according to molecular phylogenies (Gile and Slamovits 2012). Furthermore, the basal bodies of the proliferated flagella in *Joenia* and *Deltotrichonympha* (Cristamonadida) each bear a hooked lamina, suggesting they arose by multiplication of B2 or B4, while the proliferated flagella in *Lophomonas* have unadorned basal bodies, suggesting that they derive from B1 (Brugerolle 1991).

In Trichonymphida (Fig. 7), the proliferated flagella are organized into two regions, with the parabasal fibers forming a base plate for each. These plates meet along their longitudinal edges to form the distinctive rostral tube characteristic of *Trichonympha*, *Pseudotrichonympha*, and *Teranympha*, or they are separated by lobes of ectoplasm, as in, e.g., *Hoplonympha* and *Barbulanympha*. In *Staurojoenina*, there are four such rostral plates separated by four ectoplasmic lobes. At the apex of each rostral plate can be found one (*Staurojoenina*), two (*Trichonympha*), or three (*Urinympha*) privileged basal bodies (Hollande and Carruette-Valentin 1971; Brugerolle and Lee 2000).

In Spirotrichonymphida, the proliferated flagella are organized into two to six helical rows in which the basal bodies are connected by short connecting fibers and longer fibrous bands (Lingle and Salisbury 1995). Depending on the genera, these bands might reach the cell's posterior (e.g., *Spirotrichonympha*) or traverse most of the cell (e.g., *Holomastigotoides*) or remain confined to the cell's apex (*Microjoenia*) (Brugerolle 2001, 2005, 2006b; Brugerolle and Bordereau 2004). Parabasal bodies may be interspersed regularly or irregularly between the rows (Brugerolle and Lee 2000). Each flagellar line has a set of one to three basal bodies at its apex, one of which bears the hooked lamina characteristic of B2 and B4 of trichomonads, while homologs of the recurrent basal body (B1) have not been identified (Brugerolle 2001).

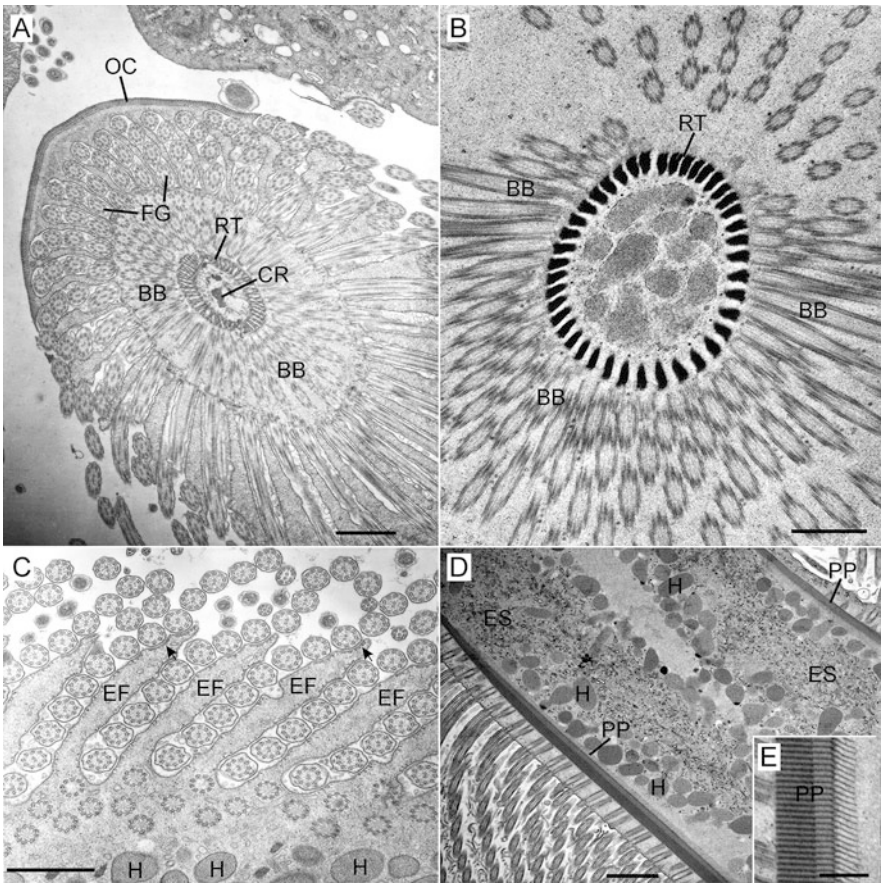

Fig. 7 Ultrastructure of *Trichonympha* spp. (a–c) and *Staurojoenina* sp. (d, e). (**a)** A lower-resolution, tangential section through the *Trichonympha* rostrum showing the microtubule-containing outer cap covering the flagellar grooves and the rostral tube with the centriolar rod. (**b)** The anterior tip of the *Trichonympha* rostrum with the electron-dense rostral tube, to which long basal bodies are attached. (**c)** A higher-resolution view of the postrostral region of *Trichonympha* in which ectoplasmic flanges separate flagellar grooves. (**d)** The rostral lobes of *Staurojoenina* are underlain by parabasal plates, in which basal bodies are embedded. **(e)** Detail of the striated parabasal plate of *Staurojoenina*. **Scale bars** = 1000 nm for **a**–**c**, 2000 nm for **d**, and 500 nm for **e**. **Labels**: *arrows* electron-dense material bound to the cytoplasmic side of the cell membrane that attaches axonemes to the flanges, *BB* basal bodies, *CR* central rod, *EF* ectoplasmic flanges separating flagellar grooves, *ES* endomembrane system, *FG* flagellar grooves, *H* hydrogenosome, *OC* outer cap, *RT* rostral tube

Hydrogenosomes

Parabasalians are characterized by a distinctive double-membrane-bounded organelle called the hydrogenosome. The hydrogenosome's basic biochemistry was first defined by Lindmark and Müller in *Tritrichomonas foetus* (1973). These organelles

function in anaerobic ATP generation via the partial oxidation of pyruvate to acetate, carbon dioxide, and molecular hydrogen (Tachezy 2008). They are homologous to mitochondria (although the precise evolutionary history vis-à-vis obligately aerobic mitochondria has been extensively debated; Martin and Müller 2007), a relationship that was demonstrated through molecular/biochemical evidence such as the presence within hydrogenosomes of mitochondrial-type chaperones (Germot et al. 1996) and of the NADH dehydrogenase module of the mitochondrial respiratory chain (Hrdý et al. 2004). Like most hydrogenosomes, those from parabasalians lack a genome (Turner and Müller 1983; Clemens and Johnson 2000; Van Der Giezen et al. 2005). The anti-trichomoniasis drug metronidazole (Flagyl) receives an electron in the hydrogenosome, making it cytotoxic (Benchimol 2009).

Using TEM, the hydrogenosome is seen as an organelle delimited by two closely appressed membranes, with a homogenous, granular matrix (Figs. 5d, g, 7c). It lacks cristae. In *Trichomonas vaginalis* the hydrogenosomes occupy about 6% of the cell volume (Nielsen and Diemer 1976). Hydrogenosomes proliferate in the cell by a fission process similar to that described for peroxisomes and mitochondria (Wexler-Cohen et al. 2014).

Mitosis and Reproduction

The mitotic process used by parabasalians in cell division is a form of "cryptopleuromitosis." In this case the nuclear envelope remains intact, while the chromosomes' kinetochores are embedded in the envelope. The mitotic spindle, also called a paradesmose, remains outside the nucleus and consists of pole-to-pole microtubules and pole-to-kinetochore microtubules. The spindle pole bodies, called atractophores, are associated with the mastigont structures, such that the spindle segregates the two groups of kinetosomes as it separates the two sets of chromosomes in the nucleus. This is best seen in Fig. 3.7 in Honigberg and Brugerolle (1990). The atractophore is a somewhat amorphous granular material in the trichomonads but has a distinctive bell-clapper appearance in the trichonymphid and spirotrichonymphid hypermastigotes (Hollande and Carruette-Valentin 1972; Ritter et al. 1978). Kubai (1973) gives a very detailed ultrastructural study of the kinetochores and their movement within the nuclear envelope prior to attachment to the spindle tubules in *Trichonympha*.

Mitosis of the multiple nuclei in calonymphs occurs simultaneously, whether in the nonmastigont-associated nuclei of *Snyderella* or in the karyomastigonts of all other genera, but the nuclei can then be segregated asymmetrically, so that the two offspring cells do not have the same number of nuclei. For example, a cell with 100 nuclei can divide into two cells of 70 and 30 nuclei (Dolan et al. 2000a, b). It is often difficult to resolve the chromosomes in these mitoses. Among all the trichomonad species described, only a few karyotypes have been reported (Zubáčová et al. 2008).

Most parabasalian species are assumed to reproduce only asexually. The sexual cycles of many *Cryptocercus* parabasalians have been studied extensively by Cleveland (1947) and involve whole cell fusion of haploid gametes. In *Trichonympha* the male gamete enters the female gamete from the posterior end and is fully absorbed. The male's organelles disintegrate, and the two nuclei fuse. The cell then undergoes meiosis. This sex cycle is triggered by ecdysone and the molting of the insect and does not occur otherwise. For a critical view of Cleveland's work, see Raikov (1995). Though not observed by other workers or in parabasalians outside the *Cryptocercus* hindgut, the presence of a sexual cycle in parabasalians is supported by genes for meiotic machinery in the genome of *Trichomonas vaginalis* (Malik et al. 2008).

Cysts

While many intestinal symbiotic protists are propagated between hosts by a cyst stage, few of the parabasalian gut flagellates do this. Certain hypermastigotes are the main exceptions to this rule, for example, *Staurojoenina* from *Neotermes* and *Macrospironympha* from the wood roach *Cryptocercus* (Cleveland et al. 1934; Dolan et al. 2004). *Trichonympha* from *Cryptocercus* encyst when their host molts. While encysted, the cells divide such that two daughter cells are released upon excystment (Cleveland et al. 1934). The cockroach symbiont *Lophomonas* also forms cysts in which one or more nuclear divisions take place (Kudo 1926a, b). Among non-termite gut parabasalians, true cysts have been observed from *Honigbergiella ruminantium* (Fig. 5h, i), *Trichomitus batrachorum*, *Trichomitus sanguisugae*, *Monocercomonas tipulae*, *Ditrichomonas honigbergii*, and possibly *Dientamoeba fragilis* (Brugerolle 1973; Farmer 1993; Hampl et al. 2007; Clark et al. 2014).

In other parabasalians, the rounded, resistant, resting form is called a pseudocyst because it lacks a cell wall (Pereira-Neves et al. 2003). Pseudocysts are particularly well characterized in *Trichomonas vaginalis* and *Tritrichomonas foetus* (Pereira-Neves et al. 2003; Pereira-Neves and Benchimol 2009). *Barbulanympha* forms pseudocysts upon molting of its host, *Cryptocercus* (Cleveland et al. 1934).

Prokaryotic Symbionts

Many of the parabasalian symbionts in the guts of termites and *Cryptocercus* are themselves host to a wide diversity of ecto- and endosymbiotic bacteria (Fig. 6a, b). A single host can harbor multiple types of bacterial symbionts that occupy distinct regions of the host cell (Sato et al. 2009; Strassert et al. 2010). While this has been known since early descriptions of the flagellates and was often incorporated into their name, e.g., *Devescovina striata* (Dolan 2001), only the development of molecular phylogenetic techniques has allowed researchers to place them into new and

existing bacterial phyla and study their metabolic interactions. Many of these bacterial symbionts are from the *Bacteroidales*, the *Elusimicrobia* (formerly Termite Group 1), and the *Spirochaetales*. They have been found to fix nitrogen, produce acetate, and serve as motility symbionts (Tamm 1982; Ohkuma et al. 2015). Just as many of the termite gut symbiotic parabasalians remain to be described, so are there many cases of bacterial symbioses of flagellates that need investigation. There is considerable evidence that these bacterial symbionts are specific to their host flagellates and that the two groups of organisms have coevolved within the termite's gut (Noda et al. 2007; Desai et al. 2010; Strassert et al. 2010).

Many of the cases of ectosymbiotic bacteria are from the order *Bacteroidales*. These include the ectosymbionts of the cristamonads *Joenia annectens* and *Devescovina* spp. and the *Cryptocercus* trichonymphids *Barbulanympha* and *Urinympha*, which are all likely nitrogen fixers (Noda et al. 2006; Strassert et al. 2010; Desai and Brune 2012; Tai et al. 2016). The order *Bacteroidales* is well represented on the termite's gut wall (Nakajima et al. 2006). It has been hypothesized that these ectosymbionts may consume small amounts of oxygen, in effect protecting the anaerobic host (Noda et al. 2006). A nitrogen-fixing *Bacteroidales* endosymbiont has been found in *Pseudotrichonympha grassii* from *Coptotermes formosanus* (Hongoh et al. 2008).

Spirochetes can be either ecto- or endosymbionts of parabasalians in the termite hindgut, or they may be free in the gut fluid (Ohkuma 2008). The cristamonad *Mixotricha paradoxa* from *Mastotermes darwiniensis* is an example of motility symbiosis with hundreds of spirochetes arrayed across the parabasalian cell surface, propelling the huge 500 micron-long flagellate through the gut (Cleveland and Grimstone 1964). Molecular phylogenetic work has found three species of *Treponema* spirochetes occupying distinct regions of the *M. paradoxa* surface, each associated with a *Bacteroides*-related rod-shaped bacterium (Wenzel et al. 2003; König et al. 2005). Three distinct spirochetes were also described from *Spirotrichonympha leidyi* in *Coptotermes formosanus* (Inoue et al. 2008). Acetogenesis and nitrogen fixation were confirmed from the complete genome of an unusual spirochete endosymbiont of *Eucomonympha* from the termite *Hodotermopsis sjoestedti*. In this case the spirochete is a short rod, devoid of its normal periplasmic flagella (Ohkuma et al. 2015).

Recent studies have found distinct termite gut lineages of several bacterial phyla associated with parabasalian flagellates, including the *Synergistes*, *Verrucomicrobia*, and *Elusimicrobia*. The motility symbionts on *Caduceia versatilis*, first reported by Tamm (1982), have been identified as affiliated with the *Synergistes* and named "*Candidatus* Tammella caduceiae" (Hongoh et al. 2007). The endonuclear organisms seen in *Trichonympha agilis* have been found to be *Verrucomicrobia* and named "*Candidatus* Nucleococcus spp." (Sato et al. 2014). The symbionts originally affiliated with Termite Group 1 have been named the *Elusimicrobia* and include the group Endomicrobia, which have been found widely in *Trichonympha* both from termites and *Cryptocercus* (Geissinger et al. 2009; Ikeda-Ohtsubo and Brune 2009).

Taxonomy

The taxonomic system of Parabasalia adopted here (outlined at the end of this section) consists of six classes, eight orders, and 17 families and corresponds as closely as possible to the current consensus of molecular phylogenetic analyses while remaining consistent with morphological data. However, molecular phylogenies are not resolved in all areas of the tree, and some parabasalians have not yet been included. Names may yet change as new data become available, as they have many times in the last century. In order to allow readers to understand the meaning of taxon names at different time points in the literature on parabasalians, a brief historical account of parabasalian taxonomy follows.

Traditionally, the Parabasalia was divided into two orders, Trichomonadida and Hypermastigida, according to the number of flagella per mastigont and cell complexity (e.g., Levine et al. 1980). Trichomonadida included the simpler forms along with polymonad ones (those whose nuclei and flagella were multiplied together) (Honigberg 1963; Pecka et al. 1996). Hypermastigida was divided into three suborders according to the arrangement of flagella. Lophomonadina had flagella arranged in a tuft at the cell apex, Trichonymphina had many flagella arranged along a bilaterally symmetrical rostrum, and Spirotrichonymphina had flagella arranged in spiral rows (Grassi and Foà 1911; Hollande and Carruette-Valentin 1971). Although early phylogenetic trees already showed that this classification system did not correspond to the actual phylogeny of Parabasalia because of a paraphyletic Trichomonadida and extensively polyphyletic Hypermastigida (see above), this taxonomy remained unrevised until the twenty-first century. Brugerolle and Patterson (2001) were the first to formally recognize the polyphyletic nature of hypermastigids in a taxonomic system and united certain genera of trichomonads and the whole Lophomonadina within a new order, Cristamonadida (Brugerolle and Patterson 2001).

Čepička et al. (2010) revised the higher taxonomy of Parabasalia in order to bring it in line with the contemporary results of molecular phylogenetic studies. They divided Parabasalia into six classes, Trichomonadea, Tritrichomonadea, Hypotrichomonadea, Cristamonadea, Trichonymphea, and Spirotrichonymphea. Most classes include a single order, but Trichomonadea was further divided into two orders, Trichomonadida and Honigbergiellida. The first three classes contain only trichomonads, whereas all members of Trichonymphea and Spirotrichonymphea are hypermastigotes; Cristamonadea and Honigbergiellida contain both trichomonads and hypermastigotes (though only a single hypermastigid species, *Cthulhu macrofasciculumque*, belongs to the latter). The system of six classes was adopted in the recently revised classification of eukaryotes (Adl et al. 2012).

Establishing an internal taxonomy for Cristamonadea has proven problematic. Molecular phylogenies have been unable to resolve the internal relationships. Similarly, while morphological and ultrastructural features are able to circumscribe

individual genera, few characters have been identified to group genera into families. Finally, some of the traditional families have proven non-monophyletic. For these reasons, all genera of Cristamonadea were lumped into a single family, Lophomonadidae (Čepička et al. 2010). However, it was later shown that the genus *Lophomonas* is not related to the rest of Cristamonadea, but instead forms a sister lineage to Trichonymphea (Gile and Slamovits 2012), making Lophomonadidae and Cristamonadea sensu Čepička et al. (2010) polyphyletic.

The problem of the polyphyly of Cristamonadea was addressed in a recent system by Cavalier-Smith (2013). He divided Parabasalia (which he treated as a superclass) into two classes, Trichomonadea and Trichonymphea. Trichomonadea was further divided into subclasses Eotrichomonadea (order Trichomonadida with suborders Trichomonadina and Honigbergiellina and order Tritrichomonadina) and Cristamonadea (orders Cristamonadida and Spirotrichonymphida). Trichonymphea was divided into orders Trichonymphida and Lophomonadida; the latter consisted of the genus *Lophomonas*. However, according to the current understating of the evolution of the phylogeny of Parabasalia, several taxa of this system are paraphyletic or polyphyletic (Cavalier-Smith 2013).

Here, we mostly follow the system of Čepička et al. (2010) and divide Parabasalia into six classes: Trichomonadea, Tritrichomonadea, Hypotrichomonadea, Cristamonadidea, Spirotrichonymphea, and Trichonymphea. We also recognize the order Lophomonadida sensu Cavalier-Smith (2013) (within Trichonymphea) as well as the family Lophomonadidae containing *Lophomonas* and Joeniidae as the only family of Cristamonadida comprising all genera contained in Lophomonadidae sensu Čepička et al. 2010 except *Lophomonas* itself. The detailed taxonomy used here is as follows:

Class Trichomonadea
- Order Trichomonadida
  - Family Trichomonadidae (*Cochlosoma*, *Lacusteria*, *Pentatrichomonas*, *Pentatrichomonoides*, *Pseudotrichomonas*, *Pseudotrypanosoma*, *Tetratrichomonas*, *Trichomitopsis*, *Trichomonas*, *Trichomonoides*)
- Order Honigbergiellida
  - Family Honigbergiellidae (*Ditrichomonas*, *Honigbergiella*, *Monotrichomonas*)
  - Family Hexamastigidae (*Hexamastix*, *Tetratrichomastix*)
  - Family Tricercomitidae (*Tricercomitus*)
  - Unplaced genera *Cthulhu* and *Cthylla*

Class Tritrichomonadea
- Order Tritrichomonadidae
  - Family Tritrichomonadidae (*Tritrichomonas*)
  - Family Dientamoebidae (*Dientamoeba*, *Histomonas*, *Parahistomonas*, *Protrichomonas*)
  - Family Monocercomonadidae (*Monocercomonas*)
  - Family Simplicimonadidae (*Simplicimonas*)

Class Hypotrichomonadea
  Order Hypotrichomonadida
    Family Hypotrichomonadidae (*Hypotrichomonas*, *Trichomitus*)

Class Cristamonadea
  Order Cristamonadida
    Family Joeniidae (*Achemon*, *Astronympha*, *Bullanympha*, *Caduceia*, *Calonympha*, *Coronympha*, *Criconympha*, *Cyclojoenia*, *Deltotrichonympha*, *Devescovina*, *Diplonympha*, *Evemonia*, *Foaina*, *Gigantomonas*, *Gyronympha*, *Hyperdevescovina*, *Joenia*, *Joenina*, *Joenoides*, *Joenopsis*, *Kirbyina*, *Kofoidia*, *Koruga*, *Macrotrichomonas*, *Macrotrichomonoides*, *Metadevescovina*, *Mixotricha*, *Pachyjoenia*, *Parajoenia*, *Parajoenopsis*, *Placojoenia*, *Polymastigotoides*, *Projoenia*, *Prosnyderella*, *Pseudodevescovina*, *Rhizonympha*, *Snyderella*, *Stephanonympha*)

Class Spirotrichonymphea
  Order Spirotrichonymphida
    Family Holomastigotoididae (*Holomastigotes*, *Holomastigotoides*, *Microjoenia*, *Micromastigotes*, *Rostronympha*, *Spiromastigotes*, *Spironympha*, *Spirotrichonympha*, *Spirotrichonymphella*, *Uteronympha*)

Class Trichonymphea
  Order Trichonymphida
    Family Trichonymphidae (*Trichonympha*)
    Family Hoplonymphidae (*Barbulanympha*, *Hoplonympha*, *Rhynchonympha*, *Urinympha*)
    Family Staurojoeninidae (*Idionympha*, *Staurojoenina*)
    Family Teranymphidae (*Eucomonympha*, *Pseudotrichonympha*, *Teranympha*)
    Family Spirotrichosomidae (*Apospironympha*, *Bispironympha*, *Colospironympha*, *Leptospironympha*, *Macrospironympha*, *Spirotrichosoma*)

Order Lophomonadida
  Family Lophomonadidae (*Lophomonas*)

Parabasalian genera *Incertae sedis*
  Trichocovina (Trichomonadida or Tritrichomonadida or Cristamonadida)
  Prolophomonas (Lophomonadida or Cristamonadida)
  Eulophomonas (Lophomonadida or Cristamonadida)
  Chilomitus (formerly Monocercomonadidae)

Maintenance and Cultivation

Many trichomonad species from vertebrates (including most species from humans) and some species from non-termite insects can be maintained relatively easily in polyxenic cultures with bacteria, using various media such as Dobell and Laidlaw's biphasic medium (Dobell and Laidlaw 1926) or liquid medium TYSGM-9 (Diamond 1982). Trichomonads from mammals and birds are maintained at 42 °C and are subcultured approximately every third day; those isolated from poikilotherms and insects are maintained at room temperature and are subcultured approximately once a week (Čepička et al. 2006). Free-living trichomonads such as *Pseudotrichomonas keilini*, *Tetratrichomonas undula*, or *Ditrichomonas honigbergii* were also cultured in Dobell and Laidlaw's biphasic medium or TYSGM-9 (Farmer 1993; Čepička et al. 2006; Yubuki et al. 2010), though various media used for free-living protists such as Sonneborn's *Paramecium* medium (ATCC medium 802), its 9:1 mixture with TYSGM-9, or 5% PYNFH medium (ATCC medium 1034) have been used as well (Yubuki et al. 2010).

Several species from vertebrates, such as *Trichomonas vaginalis*, *Pentatrichomonas hominis*, *Tritrichomonas foetus*, *Trichomitus batrachorum*, *Hypotrichomonas acosta*, *Monocercomonas colubrorum*, and *Simplicimonas moskowitzi* can be cultured axenically in the TYM medium. The pH of the medium is usually adjusted to 7.2; for *Trichomonas vaginalis*, the optimum pH is 6.2.

Most cultured species can be easily cryopreserved. Cells at early-stationary or late-log growth phase are supplemented by DMSO to a final concentration of 5%. The suspension is then cooled at 6 to 8 °C per minute to the point of release of the latent heat of fusion. Then, the suspension is subjected to rapid cooling to take the organisms past the latent heat of fusion zone within 1.5 minutes. Then, the suspension is cooled at the rate of 1 to 2 °C per minute to −60 °C, and then it is immersed in liquid nitrogen (Honigberg and Burgess 1994).

As obligate anaerobic symbionts, often with bacterial symbionts of their own, the parabasalians of the termite gut have proven difficult to culture. Only a few termite gut parabasalians, such as *Trichomitopsis termopsidis* (Cleveland) from *Zootermopsis angusticollis*, have been brought into axenic culture (Yamin 1978; Odelson and Breznak 1985). None has been cultured on a defined medium. In brief, a buffered salt solution (pH 6.9) is used: K_2HPO_4, 10.8 mM; KH_2PO_4, 6.9 mM; KCl, 21.5 mM; NaCl, 24.5 mM; $MgSO_4$, 5.2 mM; and $CaCl_2$, 0.53 mM. To this solution is added 0.1% (w/v) cellulose particles small enough for the cells to ingest. This salt solution supplemented with cellulose is boiled and then cooled, while bubbling with O_2-free N_2. The solution is poured into tubes and sealed under N_2 with rubber stoppers and autoclaved. N_2-flushed plastic syringes are used to add the following after autoclaving: $NaHCO_3$ to 10 mM and heat-inactivated fetal calf serum to 2.5% (v/v). After surface-sterilizing the termite with 70% ethanol, the hindgut is removed by forceps and broken open with a syringe plunger tip. The plunger is inserted in the syringe, which is flushed with N_2. The syringe is used to draw up medium from the tube and then to plunge the medium, with protist cells, back into the tube. Cultures are incubated at 27 °C with subcultures made every 2–4 weeks (Yamin 1978).

Evolutionary History

External Relationships

Parabasalia belongs to the Metamonada clade within the Excavata supergroup, a supergroup whose members are characterized in part by a feeding groove (Simpson 2003). Parabasalia is one of the three major subclades of metamonads, along with Preaxostyla (comprising Oxymonada and trimastigids) and Fornicata (comprising Diplomonadida, Retortamonadida, and *Carpediemonas*-like organisms) (Simpson 2003; Adl et al. 2012; Zhang et al. 2015). Though the Parabasalia and Oxymonada have lost the ancestral excavate-type feeding groove, molecular phylogenetic evidence links them to their more plesiomorphic relatives in Fornicata and the trimastigids. Multigene phylogenies suggest that Fornicata is the sister group of Parabasalia, while Preaxostyla is the deepest branch in the clade (Hampl et al. 2005, 2009; Katz and Grant 2015).

Metamonads are mostly anaerobic gut commensals. The most recent ancestor of Parabasalia was probably a gut commensal, and the free-living species are secondarily adapted to life outside an animal host. However, the free-living species have not yet been included in rooted, multigene analyses, so the possibility that they might form the deepest branches cannot be completely excluded (Hampl et al. 2007; Noda et al. 2012). The other two metamonad lineages have deep-branching, free-living representatives, e.g., *Trimastix* in Preaxostyla and *Carpediemonas* in Fornicata (Kolisko et al. 2008; Zhang et al. 2015), so it is likely that Metamonada as a whole is ancestrally free-living.

Parabasalia is likely a relatively young phylum. Parabasalia certainly predates the origin of termites, which has been dated back to the Jurassic/Cretaceous boundary, roughly 150 million years ago (Misof et al. 2014; Bourguignon et al. 2015). This provides a minimum age for the group. There are no sound estimates to provide a maximum age: molecular clock age estimates have not yet been applied to the Parabasalia specifically, and such age estimates for Excavata are highly method sensitive and range between 900 million and 1.8 billion years (Parfrey et al. 2011; Eme et al. 2014). Parabasalians attributable to the orders Trichonymphida, Cristamonadida, and Spirotrichonymphida have been described from 100-million-year-old early Cretaceous amber (Poinar 2009).

Internal Relationships

Inferences of character evolution in Parabasalia depend largely on the position of the root for the clade, an inference that eluded molecular phylogenetic analyses for years (Hampl et al. 2004). Outgroup rooting with SSU rDNA or protein sequences failed to find a supported position for the root but tended to place the root near or within the Trichonymphida (Keeling et al. 1998; Ohkuma et al. 2000, 2007a). This position is clearly artifactual, deriving from the attraction of the long stem branch of Parabasalia to the long branches of the Trichonymphida (Keeling and Palmer 2000; Hampl et al.

2004). Also, the Trichonymphida rooting contradicts morphology-based scenarios in which the simpler, smaller cells are considered most similar to the ancestral form (Kirby 1947; Honigberg 1963; Brugerolle 1976). With the addition of elongation factor 1-alpha sequences to multi-protein analyses, a different root position was inferred, between the clade of Trichomonadida and Trichonymphida on one hand and Hypotrichomonadida, Spirotrichomonadida, Tritrichomonadida, and Cristamonadida on the other (see Fig. 8). Honigbergiellida, Lophomonadida, and free-living members of Trichomonadida were not included in the analysis (Noda et al. 2012). This root position results in simpler parabasalians forming the deeper branches and the complex hypermastigotes arising later, a more intuitively plausible scenario (Fig. 8).

The ancestral morphology of parabasalians under this rooting was therefore likely similar to *Trichomitus* and *Hypotrichomonas* (Hypotrichomonadida): small cells with four flagella, a costa, and a lamelliform undulating membrane (Čepička et al. 2010). Variations on this body plan have taken different directions among the simpler parabasalians. The undulating membrane has been lost several times, for example, in *Honigbergiella*, *Simplicimonas*, *Monocercomonas*, and Dientamoebidae, and altered to a rail type in Tritrichomonadida (Brugerolle 1976; Čepička et al. 2010). Flagellar number is particularly changeable among trichomonads and has increased to five or six in the Trichomonadida and Honigbergiellida and reduced to three or two in certain Honigbergiellida and to zero in *Dientamoeba*, with an anomalous increase to at least 20 flagella in *Cthulhu* (James et al. 2013).

It is in the hypermastigote taxa that the most impressive morphologies have evolved. Though traditionally united on the basis of many flagella but just one nucleus, molecular phylogenetic analyses have demonstrated the polyphyly of hypermastigotes. While trichonymphids and spirotrichonymphids are each monophyletic groups, their complex multiflagellate morphologies evolved independently of each other. Lophomonads, on the other hand, are actually polyphyletic. *Lophomonas* forms the sister lineage to trichonymphids (Gile and Slamovits 2012); *Kofoidia* is closely related to the cristamonad genera *Devescovina* and *Metadevescovina*, which have trichomonad cell organization (Tai et al. 2014); and the rest, genera such as *Joenia*, *Joenina*, *Joenoides*, and *Deltotrichonympha*, branch separately near the base of the Cristamonadida (Ikeda-Ohtsubo et al. 2007; Noda et al. 2009).

The evolutionary tendency to multiply flagella is restricted to parabasalians that live in the termite or roach hindgut. It is difficult to count the number of distinct flagellar multiplication events in Parabasalia because relationships among cristamonads are not resolved, but within the boundaries of this uncertainty, there must have been at least five and possibly more than seven distinct instances (not including cases of nuclear multiplication). This number includes the recently described genus *Cthulhu*, which bears at least 20 flagella and branches with *Hexamastix* and *Cthylla* in the Honigbergiellida (James et al. 2013). The termite/roach hindgut environment also appears to favor evolutionary increases in cell size, as, for

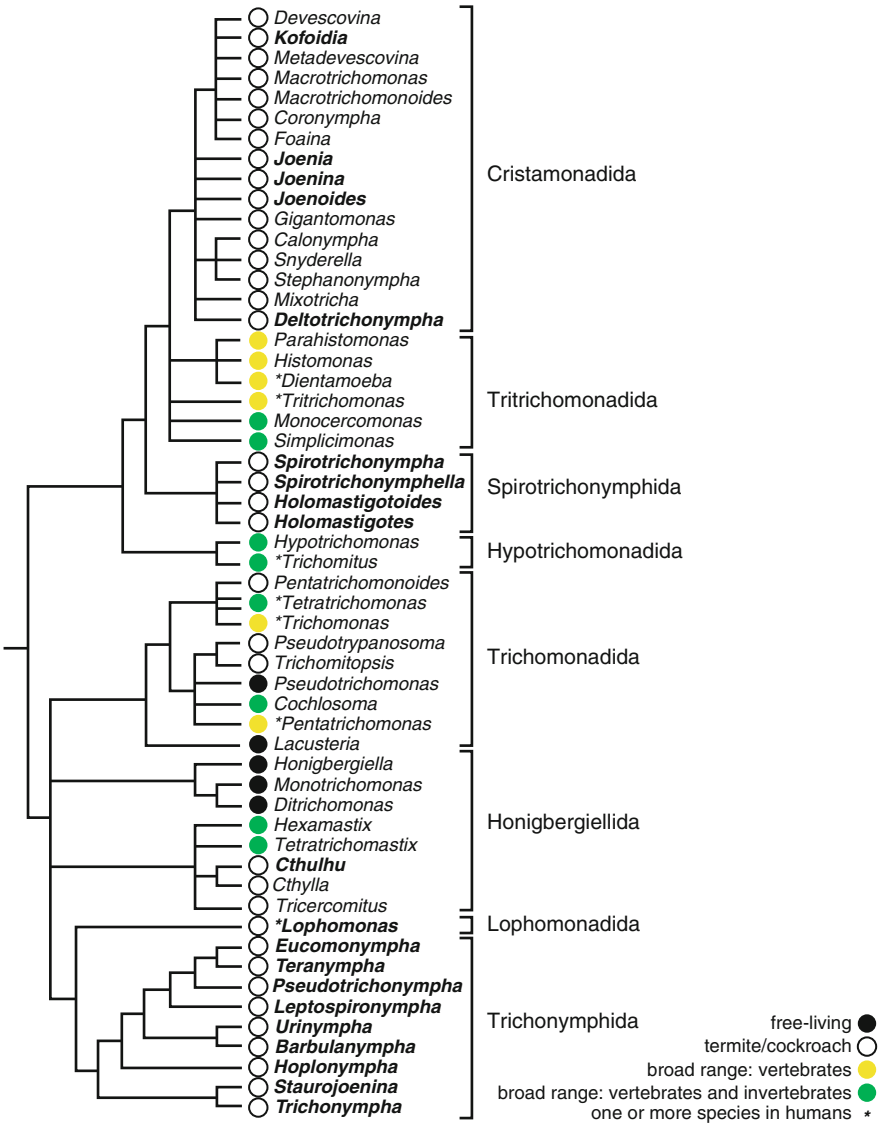

Fig. 8 Schematic phylogenetic tree of Parabasalia based on multiple molecular phylogenetic analyses (see text for details). The eight orders according to this scheme, based on Čepička et al. (2010) and Cavalier-Smith (2013), are indicated to the *right*. *Circles* at tips indicate habitat: genera with *open circles* are exclusive to termite and/or cockroach hindguts. *Black circles* indicate genera with free-living species. *Colors* indicate a broad host range of described species, *yellow* for vertebrates and *green* for vertebrates and invertebrates. *Asterisks* indicate genera in which one or more species has been found in humans. *Bold type* indicates "hypermastigote" genera, i.e., parabasalians with many flagella

example, in the large (50–100 μm long) trichomonad *Trichomitopsis termopsidis* (Keeling 2002) and in cristamonads such as *Devescovina* and *Macrotrichomonas* that have only four flagella despite reaching lengths of 80–90 μm (Brugerolle and Lee 2000; Gile et al. 2015). Meanwhile, parabasalians that are not restricted to the roach or termite hindgut tend to remain small (under 30 μm, usually under 20 μm) and retain six or fewer flagella (Brugerolle and Lee 2000).

Intergeneric relationships in the Parabasalia are resolved to differing degrees in different parts of the tree. The schematic representation of these relationships (Fig. 8) is a synthesis of results from multiple phylogenetic analyses: some using protein-coding sequences (Gerbod et al. 2004; Ohkuma et al. 2007; Čepička et al. 2010; Noda et al. 2012), but most using SSU rDNA (Gerbod et al. 2002; Hampl et al. 2004; Hampl et al. 2006; Noël et al. 2007; Noda et al. 2009; Carpenter et al. 2010; Čepička et al. 2010; Yubuki et al. 2010; Gile et al. 2011; Gile and Slamovits 2012; Tai et al. 2014; Gile et al. 2015). Most genera with at least some molecular data are included in the figure, but many important genera have yet to be included in molecular phylogenetic analyses and are not represented. Some evolutionary trends in Parabasalia are also indicated in Fig. 8. Multiplications of flagella (hypermastigote genera) are indicated by bold text. Termite and cockroach gut residents are indicated by open circles. Note that the orders Cristamonadida, Spirotrichonymphida, and Trichonymphida have radiated entirely within this habitat (Lophomonadida are from cockroaches but not termites). Many trichomonad genera have broad host ranges, with species found across vertebrates (yellow circles) or across vertebrates and invertebrates, in some cases including the termite/roach hindgut (green circles). The few free-living species belong to genera indicated by black filled circles.

Acknowledgments The authors would like to thank Guy Brugerolle for the kind permission to use the micrograph featured in Fig. 6c; the Department of Special Collections and University Archives of the W.E.B. Du Bois Library, University of Massachusetts, Amherst, for the use of the David Chase micrographs in Fig. 7a–c; Dale Callaham for the micrographs used in Fig. 7d, e; Michael Kotyk for micrographs 3A–D and G; Jaroslav Kulda for lending us protargol preparations of *Monocercomonas*, *Tritrichomonas*, *Parahistomonas*, *Histomonas*, *Dientamoeba*, and *Trichomonas*; and Johana Rotterová for creating Fig. 5a, b. This work was supported by the Czech Science Foundation (project GA14-14105S).

Diplomonadida

33

Rodney D. Adam

Abstract

The diplomonads ("two units") are characterized by their possession of two nuclei that are similar in appearance, replication, and function. Together with the *Carpediemonas*-like organisms and retortamonads, the diplomonads are classified within Fornicata. Each "unit" of the diplomonad cell includes a karyomastigont that has one nucleus and (usually) four flagella, which are used for locomotion. Thus, most diplomonads have two karyomastigonts. However, the "enteromonads" present an exception in that they have a single karyomastigont per cell. The diplomonads have anaerobic metabolism and lack conventional mitochondria, so they were thought to be pre-mitochondriate organisms. However, they have subsequently been shown to have highly reduced mitochondria called mitochondrion-related organelles (MRO) that perform some of the functions of conventional mitochondria. The most studied diplomonads are the *Giardia* species, which are intestinal pathogens or commensals for a variety of vertebrates from amphibians to mammals and include pathogens of humans. Like *Giardia* spp., the *Spironucleus* species also replicate in the host intestine, in this case in vertebrates or invertebrates and include notable fish pathogens. In contrast, *Hexamita* and *Trepomonas* species can be either free-living or parasitic.

Introduction

The diplomonads are small anaerobic flagellates originally defined by the remarkable binary axial symmetry of the cell body, with each of its two "karyomastigont" systems facing outward from the central axis. Each karyomastigont system has a single nucleus with four basal bodies (kinetosomes); typically, a flagellum emerges from each, so there are four flagella per karyomastigont. One flagellum is recurrent and associated with the cytostome or forms the intracellular axis of the cell. In addition to the genera with two karyomastigonts, some unizoic forms (*Enteromonas* and *Trimitus* spp.) have been identified as part of the diplomonad assemblage by morphological and molecular criteria (Kolisko et al. 2008). These unizoic organisms lack the twofold symmetry, having only a single karyomastigont.

The first published description of a diplomonad was by Antony van Leeuwenhoek in 1681, when he gave a recognizable description of *Giardia lamblia* (syn. *Giardia duodenalis*, *Giardia intestinalis*) from his own diarrheic stools, making it one of the first protists on record (Dobell 1920). Lambl (1859) gave a formal

description of the human *Giardia*'s size, shape, and sucking disk; (Grassi 1881) added an account of the flagella and nuclei in the trophozoite and described the cyst. The most commonly observed genera of free-living diplomonads, *Trepomonas* and *Hexamita*, were described by Dujardin in 1841 (Dujardin 1841).

Diplomonads are now placed phylogenetically within a large clade of anaerobes called Metamonada and specifically within the subgroup Fornicata (Cavalier-Smith 2013; Simpson 2003). A recent classification system considered Fornicata as a superclass comprising the classes Carpediemonadida and Eopharyngia. In turn, the Eopharyngia are made up of the orders Diplomonadida and Retortamonadida (Cavalier-Smith 2013). Alternatively, a molecular evaluation of multiple *Carpediemonas*-like organisms (CLOs) placed the CLOs into several clades within Fornicata and did not use Eopharyngia as part of the classification system (Kolisko et al. 2010). The evolutionary relationships within Fornicata are a complex topic and are discussed in depth in another chapter (▶ Retortamonads).

The diplomonads provide a remarkable model system for testing some of the current ideas regarding parasite biology and evolution, since the taxon includes free-living, commensal, and pathogenic organisms. Those that are parasitic infect a wide variety of invertebrates and vertebrates. The obligate parasite *Giardia* has relatively little biosynthetic function. Which of those synthetic functions are maintained by free-living or other parasitic diplomonads?

Habitats and Ecology

Most diplomonads are parasitic, surviving in the alimentary canals of their hosts, and some cause diseases in their host organisms. However, *Trepomonas* species are free-living (Xu et al. 2016) and *Hexamita* species may be free-living or parasitic (Xu et al. 2016). For example, *Hexamita inflata* is a free-living organism, but other *Hexamit*a species are parasitic to a variety of invertebrate and vertebrate hosts (Kulda and Nohynkova 1978). *Hexamita parva* may cause extensive intestinal disease in infected turtles and tortoises and may invade the kidney and bladder as well as other organs (Zwart and Truyens 1975). *Hexamita nelsoni* infects oysters and has been found in the stomach and pericardium, but not necessarily associated with a high mortality (Scheltema 1962).

Spironucleus species are primarily intestinal organisms and are parasitic in a wide variety of vertebrates, from fish to birds and mammals. They are recognized as significant pathogens for salmon and other fish. *Spironucleus salmonicida* has also been isolated from muscle abscesses of salmon from fish farms in Norway and from "systemically" infected fish, suggesting the ability of these parasites to cause invasive infection (Fard et al. 2007; Jorgensen and Sterud 2006; Sterud 1998). Increased mortality has been associated with heavy infection of trout by *Spironucleus salmonis*, accompanied by hepatocellular necrosis and abdominal ascites (Poynton et al. 2004). *Enteromonas* species are intestinal parasites and

Enteromonas hominis infects humans, possibly causing disease on occasion (Spriegel et al. 1989). *Brugerolleia algonquinensis* has been identified in the blood of a frog (Desser et al. 1993).

Giardia lamblia, the most common human parasite, causes infection of the small intestine that may be symptomatic or asymptomatic. When symptomatic, people have subacute diarrhea that is commonly accompanied by nutrient malabsorption and weight loss (Ortega and Adam 1997). Infection results when the environmentally stable cyst is ingested and, after passing through the stomach, excysts as the vegetative trophozoite in the proximal small intestine. Some of the organisms then encyst in the small intestine and are passed in the feces to continue the cycle of transmission. Trophozoites attach to the lumen of the small intestine via their ventral disks (see Fig. 4 for EM of the ventral disk) by a mechanism that is probably mechanical (Elmendorf et al. 2003). There is no known receptor-mediated attachment and no intracellular or intraluminal invasion. There is some villous disruption during infection as well as observable lymphocyte infiltration in the *lamina propria*, but whether these or other phenomena are responsible for the diarrhea is not yet known. The secretory IgA response has been proposed as the major means of eradicating the infection and is supported by the observation of refractory diarrhea due to *Giardia* in patients with X-linked hypogammaglobulinemia. However, more recent studies using animal models suggest that that cell-mediated immunity may also be important in eradication of infection (Singer and Nash 2000). Diagnosis of human infection is documented by the identification of cysts or trophozoites in fecal specimens, trophozoites in small intestinal contents, or *Giardia* antigen (by ELISA or DFA) in fecal specimens. Zoonotic transmission to humans has been controversial in part because of the confusing results obtained with cross-transmission studies. However, "human" genotypes have been found in beavers, and beavers have been implicated as the source for a number of human infections. In contrast, dogs, cats, and livestock generally have different genotypes and are unlikely to be important sources of human infection.

Characterization and Recognition

General Morphology and Classification

The diplomonads typically have bilateral axial symmetry, with each half of the trophozoite having a karyomastigont consisting of a nucleus and four basal bodies. Typically, a flagellum emerges from each basal body (exceptions to this general rule are described below). One flagellum is recurrent and associated with the cytostome (in the Hexamitidae) or forms the intracellular axis of the cell. The unizoic forms (*Enteromonas* and *Trimitus* spp.) lack the twofold symmetry, having only a single

karyomastigont. At an ultrastructural level, the diplomonads lack some of the canonical eukaryotic organelles, including classical mitochondria (though highly modified forms remain – see below), perixosomes, and a well-organized Golgi (Desser et al. 1993; Poynton and Sterud 2002).

The diplomonads have been classified by using a combination of morphological and molecular characteristics. Although the names of the genera have been constant, the classification systems have evolved far more quickly than the organisms being described, including names and rankings of the groups. However, all recent classification systems place the diplomonads into two monophyletic groups; Hexamitinae (or Distomatina (Cavalier-Smith 2013)) and Giardiinae. The genera can be distinguished by the pattern of flagellar organization and/or the shape of the nuclei and by electron microscopic features (Table 1).

Among the Heximatidae, the *Hexamita* species have round nuclei with the basal bodies located on the external surface of the nucleus (Fig. 1). Each of the flagella in a karyomastigont has a different orientation and role, so the flagella in a cell can be considered to form four functional "pairs," with each pair consisting of one flagellum from each karyomastigont. Three pairs of flagella emerge anteriorly, while the other pair is recurrent, running lateral to the nucleus. The recurrent flagella each run through a cytostomal canal or flagellar pocket. These pockets allow nutrients to pass for internalization. The nuclei of the *Spironucleus* species are spiral-shaped and subapical in location (Fig. 2). The recurrent flagella run medial to the nucleus along a flagellar pocket. Despite this distinctive architecture, phylogenies of the *Spironucleus* species based on SSU rDNA sequences place them into three different clades that differ as much from each other as from *Hexamita* spp. (Jorgensen and Sterud 2007). Even two *Spironucleus* species (*Spironucleus barkhanus* and *S. salmonicida*) that are in the same clade and are morphologically identical nonetheless demonstrate substantial differences at a genomic level (Andersson et al. 2007; Roxstrom-Lindquist et al. 2010).

The cell body of *Trepomonas agilis* (the most commonly reported member of the genus by far) is oval- to pear-shaped and has two oral grooves, one on each side (Eyden and Vickerman 1975). The cells have elongated nuclei that each has an apex posteriorly where the basal bodies are located. The organisms are notable for food vacuoles that rapidly move phagocytosed bacteria and other nutrients within the trophozoite. *Trigonomonas* cells are triangular- or spindle-shaped and 8–30 μm long, with the posterior end of the cell flattened. Only three flagella are inserted at the base of each nucleus; one flagellum is longer than others and used for locomotion. Cytostomal grooves extend from the flagella emergence to the posterior of the body. The organism rotates around its axis while swimming (as in *Trepomonas*). The cells of the rarely recorded genus *Gyromonas* are smaller, with subtle depressions on each side of the cell, rather than well-defined grooves. *Gyromonas* cells have just two flagella per karyomastigont.

The *Enteromonas* and *Trimitus* species differ from other diplomonads by their possession of only one karyomastigont and thus, one nucleus and up to four flagella (four in *Enteromonas*, three in *Trimitus*).

Table 1 Genera of Diplomonadida. Diplomonadida and Hexamitinae classified according to Brugerolle et al. (Brugerolle 1975), Giardinae according to Kulda and Nohynkova (1978); given suborder ranking in Cavalier-Smith (2013)

Suborder	Genus	Morphologic features	Ecology
Hexamitinae (~ Distomatida) (phagotrophs with two cytostomes, alternate genetic code)	*Enteromonas* (da Fonseca 1915)	Three free, one recurrent F, one karyomastigont, and one N	Entozoic (mammals including man), nonpathogenic
	Trimitus (Alexeieff 1910)	One karyomastigont with one N, two free, one recurrent F	Entozoic (poikilotherms)
	Trepomonas (Dujardin 1841)	Two large ant. pyriform N; two free locomotory F, three in each large lateral cytostome	Free-living or entozoic (poikilotherms), nonpathogenic
	Hexamita (Dujardin 1838)	Two spherical ant. N; six free locomotory F; recurrent F initially in intracellular channels opening at broad caudal cytostomes	Free-living or entozoic (invertebrates and vertebrates), some species pathogenic in fish, oysters, tortoises
	Gyromonas (Seligo 1886)	Small (6–10 μm) with two N and two pairs of F. Each side mostly occupied by two posterior and largely opened grooves	Free-living
	Trigonomonas (Klebs 1892)	Two N; three F at the base of each nucleus; one flagellum is longer than others and used for locomotion; cytostomal grooves extend from the flagella emergence to the posterior of the cell; moving contractile vacuole	Free living in freshwater
	Spironucleus (Lavier 1936)	Two "S"-shaped ant. N; six free locomotory F; recurrent F in narrow channels opening at small posterolateral cytostomes	Entozoic (vertebrates), frequently pathogenic (fish poultry, laboratory rodents)

(*continued*)

Table 1 (continued)

Suborder	Genus	Morphologic features	Ecology
Giardiinae (osmotrophs without cytostomes; ciliary roots between nuclei)	*Octomitus* (Prowazek 1964)	Two bean-shaped ant. N; six free locomotory F recurrent F initially intracytoplasmic; cytostomes absent	Entozoic (vertebrates), nonpathogenic
	Brugerolleia (Desser 1993)	Two spherical ant. N; three pairs of F emerging on side of N, one pair of F run parallel through cytoplasm to emerge posteriorly; rudimentary cytostome	Entozoic (frogs)
	Giardia (Kunstler 1882)	Two oval sub-ant. N; attachment to the host intestine by the ventral sucking disk; anterolateral F, posterolateral F, and caudal F with initially intracytoplasmic axonemes; ventral flagella beat in ventrocaudal groove; cytostomes absent	Entozoic (tetrapods including man), may be pathogenic

There remains good consensus regarding the placement of these nine genera within the Diplomonadida. There is also good agreement regarding the placement of *Giardia*, *Octomitus*, and *Brugerolleia* within a single clade and *Trepomonas*, *Hexamita*, and *Spironucleus* within another clade. The remainder of relationships and hierarchy within the diplomonads is less clear. Earlier classification systems place *Caviomonas* spp. within the diplomonads, but more recent data suggests that they are more accurately placed with the *Carpediemonas*-like organisms (Yubuki et al. 2016)
ant anterior, *F* flagellum, flagella, *N* nucleus, nuclei

The Giardiinae are characterized by the lack of a cytostome or cytostomal canal. The recurrent flagella run through the cytoplasm rather than through a flagellar pocket. Among the three genera, the ventral disk is unique to *Giardia* species. *Giardia* and *Octomitus* species lack a cytostome altogether, while *Brugerolleia algonquinensis* has rudimentary cytostomal homologues (Desser et al. 1993). The *Giardia* nuclei are round, while the *Octomitus* and *Brugerolleia* nuclei are kidney-shaped.

Giardia species were initially named on the basis of host of origin, but in subsequent seminal work by Filice (1952), three major morphological types were proposed: (i) *Giardia lamblia* (syn. *Giardia intestinalis* and *Giardia duodenalis*, the latter being the name used by Filice; of mammals and birds), (ii) *Giardia muris* (rodents), and (iii) *Giardia agilis* (amphibians). These are distinguishable from one another by light microscopy by the shape of the cell body, the relative length of the adhesive disk, and the shape and position of the median bodies. *Giardia agilis* has a

body shape but sucking disk less than half the cell length and an elongated claw-shaped median body that lies across the cell.

A subsequent work in defining species has concentrated on the large group of organisms found with the morphologic type described by Filice (Filice 1952) as *Giardia duodenalis* (Figs. 3, 4, and 5). Morphological differences observable at the EM level accompanied by DNA sequence data were used to describe separate species found in psittacine birds (*Giardia psittaci*) (Erlandsen and Bemrick 1987) and herons (*Giardia ardeae*) (Erlandsen et al. 1990) and voles (*Giardia microti*) (van Keulen et al. 1998). The group of organisms left within the *Giardia lamblia* group after separating out these species is found exclusively within mammals but is comprised of at least eight distinct genetic groups (assemblages or genotypes), each with a distinct molecular type and with at least some degree of host specificity (Caccio and Ryan 2008; Lasek-Nesselquist et al. 2010). It is likely that at least some of these genotypes will eventually be accepted as separate species, thus returning us partially to the original descriptions based on host of origin. In the current chapter, we have used the name *Giardia lamblia* to refer to all eight of these genotypes. Only genotypes A (Nash Groups 1 and 2; (Nash and Keister 1985; Nash et al. 1985) and B (Nash Group 3) are found in humans, and these two are so different that they have already been proposed as separate species (Adam et al. 2013; Nash and Keister 1985; Nash et al. 1985). The current phylogenetic grouping of *Giardia* species and *Giardia lamblia* genotypes argues against a strict application of host-parasite coevolution in that *Giardia muris* is actually far more distant from *Giardia lamblia* than the more recently identified bird species, *Giardia psittaci* and *Giardia ardeae* (Abe et al. 2012; van Keulen et al. 1993).

Giardia lamblia was not generally accepted as a human pathogen until the 1960s, when it was associated with a series of waterborne outbreaks of human diarrhea. Axenic cultivation of *Giardia lamblia* was first achieved in 1970 (Meyer 1970) and has been followed by axenization of several other diplomonad species (see below). The subsequent decades have seen an explosion of our knowledge of *Giardia*, culminating in the publication of the *Giardia* genome in 2007 (Morrison et al. 2007), which was done using the Genotype A isolate WB (Smith et al. 1982). Subsequently, the Genotype B isolate GS (Nash and Keister 1985; Nash et al. 1985) has been sequenced in a genome survey (Franzen et al. 2009) followed by a more complete genome sequence (Adam et al. 2013). Our knowledge of other genera is rudimentary in comparison, although recent genomic (Andersson et al. 2007; Roxstrom-Lindquist et al. 2010; Xu et al. 2014), biochemical (Lloyd and Williams 2014; Millet et al. 2011a), and structural (Millet et al. 2013) analyses of *Spironucleus* species have been published.

Flagella and Cytoskeleton

The morphology of the flagella and cytoskeleton is the central defining feature of the diplomonads. There are typically three microtubular fibers that emerge from the basal bodies, although the extent of the fibers varies among genera. The supranuclear fiber arises from basal body 1 (= basal body 2 under terminology that is universal to other protists (Simpson 2003)) and passes in front of or over the nucleus. In *Trepomonas*, these fibers are well developed and curve to the rear to reinforce the anterior crests. In *Giardia*, the two supranuclear fibers fuse to form the striated disk that supports the ventral disk (see below). The infranuclear fiber originates at the recurrent flagellum (= flagellum 1 in universal numbering). In *Trepomonas*, *Hexamita*, and *Spironucleus*, the two infranuclear fibers cross over beneath the nuclei and appear to maintain them in their anterior position; these fibers taper at their distal end where they reinforce the cytostome on the opposite side. They are absent in *Giardia*, *Octomitus*, and *Brugerolleia* (Desser et al. 1993).

The third band of microtubules (direct fiber) also arises from the base of the recurrent flagellum but keeps to its own side of the cell body. This fiber borders the flagellar depression (*Enteromonas*) or the cytostome (*Trepomonas*; *Hexamita*, Fig. 1; *Spironucleus*; Fig. 2) or runs alongside the intracellular axoneme (*Octomitus*, *Giardia*). A lamina with periodic structure also arises from the base of the recurrent flagellum and supports the cytostome in the Hexamitinae; although it is present in *Octomitus*, it is lacking in *Giardia.*

Locomotion

Giardia species have four pairs of flagella, anterolateral (sometimes called anterior), posterolateral, caudal, and ventral, each emerging from a single basal body. Interestingly, the dyad symmetry of the flagella does not match the symmetry of the basal

bodies (Nohynkova et al. 2006). In *Giardia*, the trophozoites spend most of their life attached to intestinal villi, where the ventral flagella beat continually, leading, historically, to the hydrodynamic model of trophozoite attachment (see below). Conversely, the anterolateral (sometimes called anterior) flagella beat asynchronously only during swimming and appear to mediate forward motion (Holberton 1973). The caudal flagella may provide direction for the swimming trophozoite (Elmendorf et al. 2003).

The two powerful F1s are the locomotory flagella of *Trepomonas* and propel the organism rapidly through the water, while F2, F3, and FR lie in the oral groove (under universal terminology, these flagella are F2, F3, F4, and F1, respectively, i.e., the recurrent flagellum, FR becomes F1 (Simpson 2003). In the other common free-swimming diplomonads and in *Enteromonas*, F1, F2, and F3 participate in locomotion, but this is less rapid in the parasitic forms. The recurrent flagella of *Spironucleus* and *Octomitus* beat to assist locomotion, but those of *Hexamita* and *Giardia* usually trail passively.

Attachment to Host Surface

Giardia species replicate in the intestine of the host without tissue or cell invasion. Thus, a mechanism is required to allow the trophozoite to attach to the intestinal wall to avoid being swept downstream, while at the same time, facilitating nutrition acquisition. The attachment to the intestinal wall is facilitated by the ventral adhesive disk, which bites into the microvillar border of the host's epithelium. This disk is a unique attachment organelle supported by a complex cytoskeleton and delimited by a ridge, the lateral crest (Figs. 3, 4, and 5). The cytoskeleton is composed of a single layer of M1 microtubules wound in a clockwise spiral from the K1 basal bodies and initially connected to the disk's cytoplasmic membrane by short filamentous processes. From each microtubule, a "dorsal ribbon" extends into the cytoplasm. The ribbons have a periodicity of 12–15 nm and are each composed of two sheets of globular subunits separated by a fibrous inner core. The ribbons contain tubulin and beta-giardin (Brugerolle 1991), but alpha-giardins (annexins) and gamma-giardins are probably not part of the ventral disk (Elmendorf et al. 2003). The mechanism by which the ventral disk mediates attachment to the intestinal lumen is not yet certain. Lectin-mediated attachment has been proposed (Inge et al. 1988), but the presence of lectins on all surfaces of the cell and the ability of the cell to attach to inanimate surfaces such as glass argue that if lectins play a role, it is a secondary one. A hydrodynamic model in which the ventral flagella cause a fluid flow that generates negative pressure under the disk (Holberton 1974) does not easily explain the lack of correlation of flagellar beating with attachment and detachment (Elmendorf et al. 2003). At this time, the best hypothesis appears to be that attachment is mediated by contraction of the lateral crest and ventrolateral flange. The *Giardia* genome contains a single actin gene, but myosin and other classic microfilament-associated proteins are absent (Morrison et al. 2007).

Cytostome and Feeding

Endocytosis occurs through a specialized site or cytostome in the bacteriophagous genera. In *Enteromonas*, there is a shallow oral gutter beneath the recurrent flagellum; in *Trepomonas*, this groove or pocket is broad, and flagella F2, F3, and FR (= F3, F4, and F1) lie inside it, drawing bacteria into a cytostomal pit at the base of the flagella. In *Hexamita* and *Spironucleus*, the FR (= F1) on either side of the cell lies in an intracellular channel which opens at the posterior extremity of the body (Fig. 1); the two channel openings serve as cytostomes and bacteria pass along them to be engulfed near the basal body. Bidirectional cyclosis of food vacuoles has been demonstrated (Eyden and Vickerman 1975) in *Trepomonas agilis* and may occur in other phagotrophic forms. The pathways of cyclosis follow the direct fibers and infranuclear fibers (referred to as the M2 and M3 microtubular bands, respectively, by Eyden and Vickerman (1975)); in flattened specimens, vacuoles apart from these bands are stationary. A cytoproct is situated at the posterior extremity of the cell (Brugerolle 1975). In the nonphagocytic genera *Octomitus*, *Giardia*, and *Brugerolleia*, there is no special cytostome and pinocytosis can occur from the surface of the body. In these taxa, the FRs (F1s) pass to the posterior extremity as intracellular axonemes and not in cytostomal channels.

Contractile Vacuole

Present in free-living freshwater species only, this organelle differs from that of other protists in that systole takes place at a site distant from that of diastole. In *Trepomonas agilis*, small clear vacuoles carried in the cyclosis streams fuse to form a large contractile vacuole just behind the post-nuclear vortex of the two streams. The diastole of the stationary vacuole is followed by its transport along a median pathway to the posterior extremity, where systole occurs at the cytoproct site. Several contractile vacuoles may be observed at any one time in a given organism; systole occurs at 30–50 s intervals (Eyden and Vickerman 1975).

Nuclear Structure and Replication

Most of the advances of the last two decades have been through studies of *Giardia lamblia* because of its status as a human pathogen and the ability to culture the organism axenically. Therefore, the following will concentrate primarily on what is known about *Giardia*. Trophozoites have five chromosomes ranging in size from approximately 1–4 Mb, for a total haploid genome size of 12 Mb (Adam et al. 1988; Perry et al. 2011). Trophozoites are approximately tetraploid, as demonstrated by size variants of chromosome homologues (Adam 1992; Adam et al. 1988; Hou et al. 1995), by heterozygosity of repeat-containing alleles (Yang and Adam 1994, 1995; Yang et al. 1994), and by quantitative ascertainment of DNA content of individual organisms (Bernander et al. 2001). However, cytogenetic data suggest some degree of aneuploidy, with individual trophozoites containing from 19 to 21 chromosomes (expected number 20) (Tumova et al. 2007). DNA replication occurs relatively early, and trophozoites spend most of their time in the G2 phase of replication; these organisms actually contain eight copies of each chromosome (Bernander et al.

2001). Trophozoites replicate by binary fission with semi-open mitosis (Poxleitner et al. 2008) with the two nuclei replicating at approximately the same time (Wiesehahn et al. 1984), and both are transcriptionally active (Kabnick and Peattie 1990). Left/right nuclear asymmetry is maintained during trophozoite replication, such that each daughter trophozoite receives one right and one left nucleus; however, it is not as clear whether the nuclei switch from right to left at each division (Ghosh et al. 2001; Sagolla et al. 2006) or not (Yu et al. 2002), although more recent data suggests alternating sides (Poxleitner et al. 2008). When trophozoites are transfected with an episomal plasmid, the plasmid replicates in a single nucleus and is never found in both nuclei, indicating lack of transfer of DNA between nuclei during trophozoite replication (Poxleitner et al. 2008; Yu et al. 2002). The lack of genetic exchange makes it difficult to understand the extremely low degree of allelic sequence heterozygosity found in the genome isolate, WB (Morrison et al. 2007), since sequence difference should accumulate within and between nuclei; yet the degree of allelic heterozygosity for the WB isolate is less than 0.01%, while the allelic heterozygosity for the DH (Genotype A2) and GS (Genotype B) isolates is 0.037% and 0.425% (Adam et al. 2013). These levels of heterozygosity are all in the range expected for sexually reproducing organisms, but the reason for the greater than two-log difference in heterozygosity levels among genomes has not been studied. The suggestion of sexual reproduction has also supported by the finding that the genes known to be required for meiosis are present in *Giardia* (Ramesh et al. 2005). In addition, population genetic data in a region highly endemic for giardiasis near Lima, Peru, identified patterns that suggested recombination between isolates of a single genotype (Cooper et al. 2007, 2010). One study suggested recombination among *Giardia* isolates (Lasek-Nesselquist et al. 2009), but recombination among genotypes has not been supported by other studies (Cooper et al. 2010; Xu et al. 2012). These observations suggest the possibility of sexual reproduction within genotypes, but not between genotypes, and provide support for the designation of these genotypes as separate *Giardia* species. However, it remains possible that sexual reproduction in *Giardia* is parasexual rather than meiotic (Birky 2010), as has been shown for the yeast *Candida albicans* (Butler et al. 2009; Forche et al. 2008). All the findings to date could be explained by either meiotic or parasexual reproduction, so further studies will be required to distinguish which is occurring in *Giardia*.

Encystation and Excystation

Giardia cysts are oval-shaped and 5 by 7–10 μm in diameter. Light microscopic examination reveals two to four nuclei, depending on the maturity of the cyst, as well as flagellar axonemes and ventral disk segments. Electron microscopic examination of the axonemes reveals the 9 + 2 microtubule arrangement and that the periphery of the cyst has multiple vacuoles (Feely et al. 1990).The outer portion of the cyst wall is formed from four major proteins as well as galactosamine (Adam 2001).

Giardia cysts are relatively inert, with a metabolic rate about 10–20% that of trophozoites and are able to survive for up to a month outside the host in a cool moist environment. The survival in cool environments may explain the frequent

occurrence of waterborne transmission of *Giardia* in colder climates (some of the well-documented outbreaks have been from Norway, Russia, and Canada). The cyst survives its passage through the gastric acid of the host, and excystation into trophozoites may be induced by exposure to an acidic environment in vitro (Bingham and Meyer 1979). However, excystation may also be induced in a neutral pH environment (Feely et al. 1991). Encystation of some trophozoites occurs in the small intestine as a result of exposure to bile salts (Gillin 1987) or from cholesterol deprivation (Lujan et al. 1996). Although it is rather difficult, in vitro-derived cysts may be excysted to again form trophozoites (Schupp et al. 1988).

Each cyst is formed from a single trophozoite by mitotic division rather than by the fusion of two trophozoites (Carpenter et al. 2012). During encystation, nuclear anterior/posterior separation of the two nuclei is followed by nuclear replication. During the entire process, the dyad symmetry is maintained so that each daughter trophozoite receives a left and a right nucleus, rather than two right or two left nuclei (Carpenter et al. 2012). This observation rules out instant homogenization of the nuclear pairs. However, there is evidence that after nuclear migration, nuclear fusion may occur in which one progeny from each of the two nuclei fuses their membranes and exchanges genetic material (diplomixis) (Carpenter et al. 2012; Jirakova et al. 2012; Poxleitner et al. 2008). This nuclear fusion involves only two of the four nuclei but provides a mechanism by which the nuclear contents can be homogenized. Whether this exchange involves whole chromosomes and/or homologous recombination has not yet been determined (Carpenter et al. 2012). After the fusion, the nuclei separate, forming a cyst with four nuclei. Then during excystation, cytokinesis is completed followed by a round of nuclear replication and cytokinesis, resulting in four trophozoites (Bernander et al. 2001).

Cysts have been documented in a number of other diplomonad species, including *Trepomonas* (Brugerolle 1975) and many but not all *Spironucleus* species. Cysts have been identified in *S. meleagridis* (Wood and Smith 2005) and *S. muris* (Januschka et al. 1988). In addition, the survival of *S. vortens* in feces outside the host for 30 days suggests the possibility of a cyst form for this species (Williams et al. 2013). The *Giardia* and *Spironucleus* cysts are very similar at the light microscopy level, although the *Spironucleus* cysts are somewhat smaller. At the TEM level, *Giardia* cysts have parts of the ventral disk and median body, while *Spironucleus* cysts have a striated rootlet fiber, a flagellar sheath, and glycogen rosettes (Januschka et al. 1988). A genomic analysis of *S. salmonicida* has demonstrated orthologs of the genes known to be involved in the encystation process for *G. lamblia* (Xu et al. 2014). In addition, the *S. salmonicida* ortholog of *G. lamblia* cyst-wall protein-1 (CWP-1) gene encodes a protein that functions as a cyst wall protein in a *G. lamblia* encystation assay.

Biochemistry and Metabolism

As a group, the diplomonads are anaerobic organisms with moderate aerotolerance (Lloyd and Williams 2014). Those that have been specifically studied include *Spironucleus vortens* (Millet et al. 2011a, 2013) and *Hexamita inflata* (Biagini et al. 2003). *Giardia* trophozoites are facultatively anaerobic and, in vitro, are

grown in an oxygen-deprived environment (Adam 2001). Glucose is the major carbohydrate source of energy, which is generated by anaerobic glycolysis. *Giardia* has the nearly universal pyruvate kinase, but also has pyrophosphate-dependent pyruvate kinase, found in bacteria and other anaerobic protists (*Entamoeba* spp. and *Trichomonas* spp.), which can generate five rather than two ATPs from one molecule of pyruvate. In vitro (Hrdy et al. 1993) and in vivo (Feng et al. 2008) studies have suggested that this is the predominant pathway for energy synthesis from pyruvate.

Arginine metabolism is also a potentially important source of energy in *Giardia* (Edwards et al. 1992; Schofield et al. 1990) via an arginine dihydrolase pathway. Alanine and ethanol are the major end products of metabolism under anaerobic conditions, while acetate is the major product during aerobic conditions (Paget et al. 1990). More limited studies of energy metabolism have been done with the free-living organism *Hexamita inflata* (Biagini et al. 1998, 2003). These studies have demonstrated activity of the arginine dihydrolase pathway enzymes and have indicated that ethanol, alanine, acetate, and lactate are the predominant end products of energy metabolism, with a predominance of ethanol in a nutrient-rich medium with reduced oxygen tension (Biagini et al. 2003). It appears that arginine metabolism is favored under anaerobic conditions, while sugar fermentation (in this case, maltose) predominates under more aerobic conditions (Biagini et al. 1998). A genome survey of *Spironucleus salmonicida* identified the arginine dihydrolase pathway enzymes, but biochemical studies of *Spironucleus vortens* indicated the lack of the arginine dihydrolase pathway, at least during growth in rich medium. However, glutamate can act as a carbon source for *S. vortens* (Lloyd and Williams 2014). *Spironucleus vortens* also contrasts with *Giardia* in the predominant antioxidant system. While *Giardia* utilizes cysteine as the major thiol compound, glutathione is the predominant nonprotein thiol in *S. vortens* (Lloyd and Williams 2014).

As noted above, none of the diplomonads has typical eukaryotic mitochondria (Embley and Martin 2006). The canonical eukaryotic mitochondria are characterized by a separate genome, a double membrane, and the components of a citric acid cycle for generation of ATP. As early as 1973, hydrogenosomes had been reported from *Trichomonas vaginalis* (Lindmark and Muller 1973) and named because of the substantial production of hydrogen. Subsequent studies identified the hydrogenosome as an organelle with some but not all characteristics of a canonical eukaryotic mitochondrion. These organelles have double membranes and have proteins that are characteristic of mitochondria such as HSP60, mitochondrial HSP70, and HSP10 (Bui et al. 1996). Although ATP is produced, it uses pyruvate as the primary substrate and lacks a citric acid cycle, cytochromes, or DNA (Martincova et al. 2012; Shiflett and Johnson 2010). Thus, hydrogenosomes are one of several types of mitochondria-related organelles (MRO). Recent studies have demonstrated substantial levels of hydrogen generation in *Spironucleus* species, at a level comparable to that of *T. vaginalis*. Double-membrane organelles about 500 nm in size contain PFOR and FeFe-hydrogenase. These hydrogenosomes have been identified both in *S. vortens* (Millet et al. 2013) and in *S. salmonicida* (Jerlstrom-Hultqvist et al. 2013). Subsequent phylogenetic analysis has suggested that hydrogenosomes were

present in a common ancestor of the Fornicata (containing diplomonads) and parabasalids (e.g., *Trichomonas vaginalis*) (Jerlstrom-Hultqvist et al. 2013).

In 2003, a much more limited form of MRO, called the mitosome, was reported from *Giardia* (Tovar et al. 2003). The *Giardia* mitosome retains only the iron-sulfur cluster assembly function of canonical mitochondria and contains just 20 proteins, including nine that form the FeS cluster (Lloyd and Williams 2014). Unsurprisingly, it differs substantially from the *Spironucleus* MRO at a proteomic level (Martincova et al. 2015). These observations suggest that *Giardia* mitosomes represent an example of extreme reductive evolution.

Giardia has no carbohydrate, fatty acid, or nucleic acid synthesis and the only amino acid synthesis appears to be related to energy generation. Correspondingly, the genes for these processes are absent from the genome (Morrison et al. 2007). The growing information on genomics and biochemistry of the *Spironucleus* species will allow informative comparisons and contrasts with the synthetic processes of *Giardia* spp. (Lloyd and Williams 2014; Xu et al. 2014).

Protein Transport

The diplomonads lack a conventional Golgi apparatus that can be visualized using electron microscopy, so the mechanism of protein transport in these organisms is of interest. Despite the lack of conventional Golgi, *Giardia* trophozoites have perinuclear structures that co-localize the ER and Golgi functions (Lanfredi-Rangel et al. 2003). There are peripheral vacuoles that fulfill the functions of the endosomes and lysosomes (Lanfredi-Rangel et al. 1998; Rivero et al. 2012; Touz et al. 2012). Furthermore, relatively conventional Golgi complexes actually do appear during the process of encystation (Reiner et al. 1990) and are involved in protein sorting, which includes the sorting of cyst wall proteins into encystation-specific vesicles (ESV) followed by their transport to the cell membrane. In addition, protein sorting occurs in vegetative trophozoites and can be inhibited by brefeldin A, an inhibitor of Golgi function (Lujan et al. 1995). It is of note that Golgi-specific genes have been identified in *Giardia lamblia* as well as in *S. barkhanus* (Dacks et al. 2003).

VSP Genes and Antigenic Variation

Giardia lamblia trophozoites display on their surfaces a repertoire of variably expressed proteins, called variant-specific surface proteins (VSPs). The WB genome encodes a repertoire of approximately 270 genes encoding these VSPs (Adam et al. 2010), while the *vsp* gene repertoires of other *Giardia lamblia* genotypes range from about 120–500 (Adam et al. 2013). One *vsp* gene is expressed at a time and expression switches from one VSP to another by a mechanism that does not require DNA rearrangements or sequence changes (Yang and Adam 1994; Yang et al. 1994) and is epigenetic in nature (Kulakova et al. 2006). There is evidence for a role of microRNAs in the control of *vsp* gene expression (Li et al. 2012; Prucca et al. 2008). However, the expression of a *vsp* gene from only one of the four alleles, despite the identical sequence of all four alleles (Yang and Adam 1994), suggests additional mechanisms involved in the control of expression. In addition to the spontaneous switching seen in individual trophozoites, a whole population may switch during the

process of encystation and excystation (Svard et al. 1998). In humans and in animal models of infection, switching may correlate with the antibody response of the infected host, but in infected gerbils, switching does not continue to occur after the first week (Aggarwal and Nash 1988), while it does in immunodeficient mice (Gottstein and Nash 1991). Therefore, it is not yet clear whether antigenic variation is primarily or secondarily responsible for evasion of the host immune response. The role and function of the VSPs are also not known, but the high level of expression, the devotion of 3–6% of the genome to the VSP repertoire, and the maintenance of antigenic variation all suggest the great importance of the VSPs. The observation that different antigen types have different protease susceptibilities raises the possibility that these proteins are involved in helping the organisms adapt to different intestinal environments (Nash et al. 1991). The genome contains an additional 61 cysteine-rich protein genes (HCMP) (Davids et al. 2006) that are not related to the VSPs; their function is not yet known.

A genome survey of *Spironucleus salmonicida* also identified a large repertoire of cysteine-rich protein genes (Andersson et al. 2007). Further analysis of the *S. salmonicida* genome has demonstrated the presence of three groups of cysteine-rich protein genes (Xu et al. 2014). The first, encoding CRMP-1 (cysteine-rich membrane protein 1) is a family of 125 genes and has similarities with the *Giardia vsp* genes, notably including the frequent CXXC motif. Whether these proteins undergo antigenic variation has not yet been reported. The second, CRMP-2 is a family of 195 genes and has similarities with *Giardia* HCMP. There is a third group of 52 genes (CRP) with similarity to neither of the above.

Maintenance and Cultivation

Giardia lamblia cultures can be established by direct culture of organisms acquired from the intestine, or by excystation of fecally derived cysts, either directly or after passage through laboratory animals. Trophozoites were first cultured axenically in HSP1 medium (Meyer 1976), and are currently grown in modified TYI-S-33 (Keister 1983), in which the trophozoites have a generation time of about 8–12 h. Each 100 ml of modified TYI-S-33 medium contains 100 mg K_2HPO_4, 60 mg KH_2 PO_4, 2.0 g trypticase, 1.0 g yeast extract, 1.0 g glucose, 200 mg NaCl, 200 mg cysteine-HCl monohydrate, 20 mg ascorbic acid, 2.28 mg ferric ammonium citrate, and 50–100 mg dehydrated bovine bile with 10% bovine serum. The pH is adjusted to 7.0–7.2 and the medium is filter-sterilized. Trophozoites are grown in small sealed tubes at an incline at 37 °C and form confluent layers at the top of the tube, reaching densities of up to 10^6 per ml. Trophozoites can be cloned by limiting dilution in 96-well plates enclosed in sealed plastic with an anaerobic generator. *Giardia lamblia* is the only *Giardia* species that has been cultured axenically, and axenic culture has not been reported for the genotypes of *Giardia lamblia* that are not found in humans (genotypes C through H). *Giardia muris* has not been cultivated in vitro but can be maintained in the laboratory by serial passage through mice.

Hexamita inflata, a free-living organism, can be grown axenically at 25 °C in 2% trypticase, 0.1% yeast extract, 0.5% maltose, 1% L-cysteine, 10 mM K phosphate buffer, and 10% fetal calf serum at pH 7.2, supplemented with gentamicin 50 μg/ml to prevent bacterial growth (Biagini et al. 1997).

Trepomonas agilis (ATCC 50336) can be grown xenically in ATCC medium TYGM-9 (Cavalier-Smith and Chao 1996). For 1 l of medium, 2.8 g K_2HPO_4, 0.4 g KH_2PO_4, 2.0 g casein digest, 1.0 g yeast extract, 7.5 g NaCl, and 2.0 g gastric mucin are added to 970 ml distilled water and autoclaved. Heat-inactivated bovine serum (3%) and 0.5 ml filter-sterilized Tween 80 in absolute ethanol are added and the medium is added to 8 ml capped tubes. This is followed by the addition of 0.15–0.40 ml 5% rice starch solution which has been heated at 150 °C for 2 h and brought to pH 7.4 in phosphate-buffered saline. Some *Trepomonas* species (e.g., *Trepomonas steini*) have been grown in Sonneborn's *Paramecium* medium with cerophyll (ATCC #802) (Kolisko et al. 2008).

Spironucleus vortens trophozoites have been isolated from the small intestines of fish and grown in modified TYI-S-33 (Keister 1983; Millet et al. 2011b; Poynton et al. 1995). A more detailed evaluation of the in vitro growth requirements for *S. vortens* revealed an optimum pH of 6.5–7.5 and an optimum temperature of 28 °C (acceptable range 22–31 °C) (Sangmaneedet and Smith 2000). Parasites grew better without bile supplementation. *Spironucleus salmonicida* has been grown under similar conditions, although without as much detail in the determination of optimal growth requirements (Sterud 1998).

Species of *Enteromonas* can be cultivated with bacteria in the biphasic media formerly used for intestinal amoebae, e.g., HSre – a slope of heat-coagulated horse serum overlain by egg white diluted 1:10 with mammalian Ringer solution (Dobell and Laidlaw 1926); (Kolisko et al. 2008). Cultures initiated with fresh feces show abundant growth within 24 h at 37 °C, and for several days, cysts may be produced after 2–4 days. Subculture is difficult but once established with a suitable bacterial microbiota, strains can be maintained indefinitely. *Trimitus* spp. have also been grown xenically in the Dobell and Laidlaw medium (Kolisko et al. 2005).

Evolutionary History

The diplomonads lack some of the usual eukaryotic features, such as peroxisomes, as well as conventional Golgi apparatus and mitochondria. Therefore, they were proposed as members of the Archezoa (Cavalier-Smith 1983) which were thought to be the earliest branching members of the eukaryotic tree, predating the acquisition of these key eukaryotic features, especially mitochondria. This hypothesis was supported by early analyses of SSU rRNA sequence data from *Giardia lamblia* (Sogin et al. 1989). However, subsequent findings have identified remnants or reduced forms of mitochondria in diplomonads, and similar findings have been made for the other main groups proposed to be Archezoa.

The initial evidence against diplomonads being pre-mitochondriate organisms was the identification of the mitochondrial cpn60 gene in *Giardia lamblia* (Roger

et al. 1998) and *Spironucleus barkhanus* (Horner and Embley 2001). Subsequent studies identified mitosomes in *Giardia lamblia* trophozoites (Tovar et al. 2003) and hydrogenosomes in *Spironucleus vortens* (Millet et al. 2013) and *Spironucleus salmonicida* (Jerlstrom-Hultqvist et al. 2013) (see section on "Biochemistry and Metabolism"). Thus, these organisms are no longer considered to be pre-mitochondriate (Morrison et al. 2007); rather, they have reduced forms of these canonical eukaryotic organelles. Likewise, cell biology studies have identified the presence of other eukaryotic organelles, including Golgi in encysting *Giardia lamblia* trophozoites (Reiner et al. 1990) and peripheral vacuoles that fulfil the functions of endosomes and lysosomes (see "Protein Transport" section).

The presence of alternative genetic code in some but not all diplomonads is very useful in rooting the diplomonad tree. This altered codon usage has been documented in numerous Hexamitinae genera, but in none of the Giardiinae. Two of the three canonical termination codons (TAA and TAG) are used instead to encode glutamine in *Spironucleus* spp. and *Hexamita inflata* (Keeling and Doolittle 1996) as well as in *Enteromonas* and *Trimitus* species (Kolisko et al. 2008). Since the acquisition of an alternative genetic code is an exceedingly rare event, it is likely that this change occurred after the divergence of *Giardia* spp. but is ancestral to the divergence of these other genera.

One controversial question in the evolutionary history of Diplomonadida has been the relative placement of single vs. binucleate organisms. Some hypotheses have placed the enteromonads (*Enteromonas* and *Trimitus*), which have single nuclei, in one clade and the binucleate diplomonads in another (Levine et al. 1980). However, molecular phylogenetic analyses have indicated that the enteromonads do not form a single clade but that all of them fall inside Hexamitinae, where they are closely related to *Trepomonas* and *Hexamita*. This has led to the alternative proposal that reduction from two nuclei to one (or alternatively an increase from one to two) has occurred multiple times (Kolisko et al. 2005, 2008).

A second controversial question has been the relative placement of the free-living and parasitic organisms. The free-living diplomonads do not segregate neatly from the parasitic organisms in molecular phylogenies. Such analyses usually divide the Hexamitinae into three groups (Groups II to IV of the diplomonads; the Giardiinae form Group I) (Xu et al. 2016). *Spironucleus* species are found in Groups II, III, and IV, and all free-living species identified to date belong to Group IV. Because the complexity of feeding and metabolism is greater for the free-living organisms, the common assumption has been that the usual evolutionary direction is that parasitism arises from the free-living state, but if so, the phylogeny of diplomonads suggests a large number of independent adoptions of parasitism/commensalism. Genomic evidence suggests that the reverse may have occurred within the diplomonads, resulting in the transition of *Trepomonas* from a parasitic to a free-living state, in part by acquiring essential genes from bacteria by lateral transfer (Xu et al. 2016). On the other hand, other molecular and genomic comparisons have found substantial variability among the *Spironucleus* species (Andersson et al. 2007; Jorgensen and Sterud 2007; Roxstrom-Lindquist et al. 2010).

Phylogenetic and morphological assessments of organisms within the diplomonads, and comparisons with other protists, have contributed substantially to our understanding of adaptation to parasitism as well as free-living states, as well as how complex organelles can be reduced as organisms fill certain niches. It is likely that further structural and genomic approaches involving additional species of these organisms will lead to further improvement in our understanding of these phenomena.

Retortamonadida (with Notes on *Carpediemonas*-Like Organisms and Caviomonadidae)

34

Jaroslav Kulda, Eva Nohýnková, and Ivan Čepička

Abstract

Retortamonadida (retortamonads) is a group of bacterivorous metamonads belonging to Fornicata, currently represented by the single family Retortamonadidae, with two genera, *Retortamonas* and *Chilomastix*, and about 60 species. They are adapted to low-oxygen environments and live predominantly as endocommensals in intestines of animal hosts, including humans. Two species were reported to be potential pathogens causing diarrhea in humans (*C. mesnili*) or unadapted avian hosts (*C. gallinarum*). One species (*C. cuspidata*) is free-living in hypoxic water sediments. Retortamonads are typical excavates with a single karyomastigont possessing four basal bodies and two or four flagella. One flagellum is recurrent, has two or three lateral vanes, and is associated with a ventral feeding groove. Double-membrane-bounded organelles without cristae, assumed to be mitochondrial derivatives, were found in *Chilomastix*. Retortamonads reproduce by binary division and produce a resistant cyst stage. The cysts of endobiotic species are discharged with feces and serve to spread the infection. Recent phylogenetic analysis and ultrastructural observations indicate that *Retortamonas* species from insects are close relatives of *Chilomastix*, while species from vertebrates appear to be relatives of Diplomonads and should be excluded from this genus. *Carpediemonas*-like

organisms (CLOs) comprise a few species of small, free-living Fornicata. They are typical excavates and are biflagellated, though usually possess three or four basal bodies in the mastigont. CLOs form a paraphyletic grade in phylogenetic trees, having retortamonads, diplomonads, and Caviomonadidae (i.e., the rest of Fornicata) nested within them. Caviomonadidae is a group of morphologically reduced uniflagellates that were thought to belong to Diplomonadida until recently. Instead, they are closely related to the CLO genera *Hicanonectes* and *Aduncisulcus*. Caviomonadidae includes three endobiotic species and one undescribed free-living, marine isolate.

Introduction

General Characteristics

Retortamonads are small (5–20 μm) bacterivorous protists with two or four flagella. They possess a large ventral feeding groove elaborated into a conspicuous cytostome-cytopharynx complex supported by microtubules and other cytoskeletal components (Kulda and Nohýnková 1978). One of the flagella, equipped with vanes, is directed posteriorly and runs through or is confined to the cytostomal cavity. Motion of this flagellum generates the feeding current. Retortamonads lack classical mitochondria, peroxisome-like organelles, and a morphologically developed Golgi apparatus, but possess double-membrane-bounded organelles that resemble hydrogenosomes in their morphology (Hampl and Simpson 2008). The life cycle of retortamonads includes two stages: the motile trophozoite stage, which multiplies by longitudinal binary fission, and the resting cyst stage, which is protected by a thick cyst wall (Kulda and Nohýnková 1978). Because no biochemical or pertinent genomic data are available, the physiology and cell biology of retortamonads are largely unknown. No sexual processes have been observed. At present only one family, Retortamonadidae, and two genera, *Retortamonas* and *Chilomastix*, are recognized, with about 60 species described (Kulda and Nohýnková 1978). Molecular phylogenetic analyses show that Retortamonadida is not monophyletic with its current composition (Cepicka et al. 2008; Takishita et al. 2012).

Occurrence

Retortamonads typically exist as endocommensals in the digestive tracts of vertebrate and invertebrate animals; two species *Retortamonas intestinalis* and *Chilomastix mesnili* are found in the human large intestine (Kulda and Nohýnková 1978). *Chilomastix cuspidata* is a free-living species of this group that inhabits hypoxic water sediments (Bernard et al. 2000).

Literature

General information on retortamonads can be found in protozoology books such as Doflein and Reichenow (1952) and Levine (1973). The most complete data can be found in Grassé (1952) and Kulda and Nohýnková (1978). Brugerolle and Mignot (1990) and Brugerolle and Lee (2000) published comprehensive chapters on these organisms. Numerous earlier studies provide information on the morphology, taxonomy, and cell division of different retortamonad species based on light microscopy. Of these, publications by Bělař (1921), Boeck and Tanabe (1926), Bishop (1931, 1935), Wenrich (1932), Geinman (1935), Nie (1948, 1950), Kirby and Honigberg (1950), Moskowitz (1951), and McDowell (1953) deserve particular attention. The ultrastructure of *Retortamonas* and *Chilomastix* was examined by Brugerolle (1973, 1977) and Bernard et al. (1997). Molecular phylogenetic analyses based on sequences of the small subunit ribosomal RNA (SSU rRNA) gene were presented by Silberman et al. (2002) and Cepicka et al. (2008), and a multigene phylogenetic analysis was presented by Takishita et al. (2012).

History of Knowledge

Grassi (1879) described the first species of *Retortamonas* in the intestine of the mole cricket *Gryllotalpa.* The generic names *Embadomonas* and *Waskia* were used thereafter for several species described in insects and vertebrates (e.g., Brug 1922; Hegner and Schumaker 1928; see also Wenrich 1932). Later, the three names were treated as subjective synonyms, and only a single genus of biflagellate retortamonads, *Retortamonas*, was recognized (Wenrich 1932). Alexeieff established the quadriflagellate genus *Chilomastix* in 1912. Synonyms of *Chilomastix* include *Macrostoma*, *Fanapepea*, *Tetrachilomastix*, *Cyathomastix*, and *Difamus*. Both Alexeieff (1912) and Mackinnon (1915) observed the morphological similarity between *Retortamonas* and *Chilomastix*, but Alexeieff (1917) was the first to unite these genera into a single family, designated Embadomonadidae. Wenrich (1932) confirmed the relationship, restored the name *Retortamonas* for the genus possessing two flagella, and established the family Retortamonadidae. This classification, however, was not generally accepted, because it conflicted with the traditional grouping of flagellates in Protomonadida and Polymastigida, based on the number of flagella. Accordingly, *Retortamonas* (possessing two flagella) and *Chilomastix* (four flagella) were usually assigned to different orders of Mastigophora. Grassé (1952) dismissed this rigid concept and proposed a more natural grouping based on comparative morphology. He introduced several new orders of flagellates, including Retortamonadida, which comprised Wenrich's family and again brought together *Chilomastix* and *Retortamonas*. Subsequent electron microscopic observations (Brugerolle 1973, 1977) confirmed this relationship.

During the period 1926–1938, investigators published valuable observations on the morphology of members of the Retortamonadida based on light microscopy. The

introduction of the protargol staining method in the early1950s (see Nie 1950 for a workable protocol) allowed for a better resolution of karyomastigont structures, thus contributing to the definition of taxonomically sound morphological characters. The work of investigators from the Wenrich and Kirby schools during this period represents the best light microscopic morphology studies of the retortamonads and other intestinal flagellates. Electron microscopic studies by Brugerolle (1973, 1977, 1991) and Bernard et al. (1997) revealed the subcellular organization of both *Chilomastix* and *Retortamonas* and provided useful morphological data for phylogenetic considerations of retortamonads in the context of other "excavate taxa" (Simpson 2003). Early molecular phylogenetic analyses based on the SSU rRNA gene and involving several strains of *Retortamonas* from vertebrates (Silberman et al. 2002) showed a close relationship between retortamonads and diplomonads. When *Chilomastix* SSU rRNA gene sequences were included in analyses (Cepicka et al. 2008; Takishita et al. 2012), the monophyly of the Retortamonadida, though expected on the basis of ultrastructural observations (Brugerolle 1973, 1977), was not supported. As mentioned by Cepicka et al. (2008), these discrepancies may result from different taxon sampling, as all *Retortamonas* strains subjected to molecular phylogenetic analyses were isolated from vertebrates, whereas ultrastructural studies were performed on species from insects only. It is therefore likely that the genus *Retortamonas* is polyphyletic, which should lead to substantial taxonomic revision of the group in the future.

Practical Importance

Most members of the Retortamonadida are assumed to be harmless commensals; however, two species, *Chilomastix mesnili* in humans and *Chilomastix gallinarum* in poultry, have been reported as potential pathogens.

The medical importance of *Chilomastix mesnili* is marginal. The parasite is distributed worldwide and shows a low incidence in standard surveys (0.2–1%; e.g., Waikagul et al. 2002; Jacobsen et al. 2007; Nasiri et al. 2009). No marked differences in incidence have been observed in surveys performed in different geographic areas; however, an increased prevalence of 11–40% has been reported in specific groups of people suffering from diarrhea, including a closed community of institutionalized children (Červa and Větrovská 1958), military troops deployed on overseas missions (Oyofo et al. 1997), and selected groups of diarrheic patients (Felsenfeld and Young 1946). Although the association of *Chilomastix* infection with diarrhea does not necessarily reflect a causal relationship in all reported cases, the pathogenic potential of this species cannot be ruled out (Westphal 1939; for further information, see Kulda and Nohýnková (2006)). No specific treatment is recommended for asymptomatic infections; successful treatment of symptomatic patients by carbasone (Červa and Větrovská 1958) or metronidazole (Barnham 1977) has been reported. Because the infection is acquired by swallowing cysts released from the feces of an infected person, good sanitation and personal hygiene are the most effective preventive measures.

Chilomastix gallinarum, a common commensal in the ceca of chicken, turkeys, pheasants, and ducks, is potentially pathogenic to unadapted avian hosts, such as quail. Davis et al. (1964) described an outbreak of acute diarrhea and mortality in young pen-raised quail involving 35,000 birds. *Chilomastix*, which was abundant in the lower digestive tract of the affected birds, was identified as the etiologic agent, and its pathogenicity in quail was experimentally confirmed.

Habitat and Ecology

A common feature of the retortamonads is their adaptation to low-oxygen environments. Most retortamonad species live in the intestines of various animals; species of both *Retortamonas* and *Chilomastix* can be found in the human intestine. It seems that the typical association of retortamonads with particular hosts is commensalism (Kulda and Nohýnková 1978). Transmission among susceptible hosts occurs via ingestion of resistant cysts discharged into the environment from the feces of infected individuals. Most retortamonad species are most likely host specific, but a few of them may exhibit a wider host spectrum, including either related animals or members of a common biotope.

Species of the genus *Retortamonas* live in the intestines of both vertebrates and invertebrates. The typical habitat is the midgut or hindgut of insects, such as mole crickets, cockroaches, water-dwelling larvae of crane flies and beetles, and some termites (Grassé 1952; Brugerolle 2006). Their primary habitat in vertebrates is in the cecum and colon of mammals and the cloaca of amphibians and reptiles (Kulda and Nohýnková 1978). The ostrich *Struthio camelus* is the only avian host of *Retortamonas* reported thus far (Martínez-Díaz et al. 2001). *Retortamonas intestinalis* is an infrequent nonpathogenic inhabitant of human cecum, with low prevalence (up to 2%) even in populations with poor hygiene standards. Species of *Chilomastix* have been recorded in numerous vertebrates, including humans (Kulda and Nohýnková 1978), and in a few invertebrates (the horseleech *Haemopis sanguisuga* and some termites). The localization of these species in vertebrates is similar to that of *Retortamonas*. The free-living species C*hilomastix cuspidata* has been reported in hypoxic sediments of marine, brackish, and freshwaters in Australia, the United States, Northern Ireland, and Denmark (see Bernard et al. 1997 for pertinent references).

Recognition and Characterization

The Trophozoite

Light Microscopy

Trophozoites of both retortamonad genera are pyriform or carrot-shaped cells that are rounded anteriorly and tapered posteriorly, with a posterior spike in some species. In *Chilomastix*, the cell is ventrally flattened, dorsally convex, and

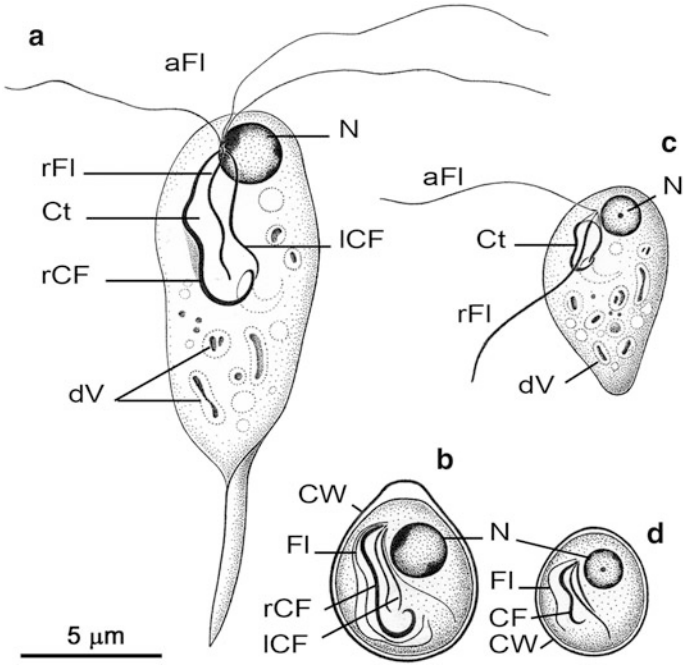

Fig. 1 Diagrammatic representation of *Chilomastix* and *Retortamonas* trophozoites and cysts, based on light microscopic observations. (**a**) *Chilomastix* trophozoite. Ventral view. The cell bears four flagella, three anterior (*aFl*), and one recurrent (*rFl*) that is located in the cytostomal pouch (*Ct*). There are two cytostomal fibers, the right (*rCF*) and the left one (*lCF*) outlining the margins of the cytostome on each side. The more prominent right cytostomal fiber is hooked posteriorly. All flagella and both fibers originate in the basal body complex situated close to the lower right margin of the nucleus (*N*). The cytoplasm contains numerous digestive vacuoles (*dV*) with ingested bacteria. (**b**) The pear-shaped *Chilomastix* cyst is enveloped by a thick cyst wall (*CW*) and contains a single nucleus (*N*), both cytostomal fibers (*RCF*, *LCF*), and internalized flagella (*Fl*). (**c**) *Retortamonas* trophozoite. The cell bears two flagella inserted near the nucleus (*N*). One is directed anteriorly (*aFl*); the other is recurrent (*rFl*), passing through the cytostomal pouch (*Ct*) and extending outside by its distal portion. Digestive vacuoles (*dV*) containing bacteria are present in the cytoplasm. (**d**) The cyst of *Retortamonas* showing a cyst wall (*CW*), nucleus (*N*), internalized flagella (*Fl*), and cytostomal fibers (*CF*)

sometimes twisted in its posterior portion. The most conspicuous feature is the cytostome, a large pouch-like oral aperture on the ventral side (Fig. 1a, c). The cytostomal cavity extends into a tubelike cytopharynx through which food particles enter the interior of the cell and are endocytosed. After protargol or hematoxylin staining, two fibers supporting the lips that surround the cytostome become evident. The right fiber is more prominent and longer than the left. The former is curved posteriorly and forms a hook along the cytopharynx.

The spherical nucleus is located near the anterior margin of the cell, dorsally, and to the left of the cytostome. The flagella and both cytostomal fibrils originate in a basal body complex above the arched anterior margin of the cytostome, close to the

nucleus. In both genera, one flagellum is directed backward into the cytostome, and the others emerge anteriorly as free flagella. There are three anterior flagella in *Chilomastix* (Fig. 1a), but only one in *Retortamonas* (Fig. 1c). The recurrent flagellum (also known as the cytostomal flagellum) is usually short and entirely located in the cytostomal cavity in C*hilomastix* (Fig. 1a), but the recurrent flagellum of *Retortamonas* is proportionately longer, extending through the cytostomal groove and emerging outside with a free terminal portion (Fig. 1c). The beating of anterior flagella moves the cell, and undulations of the recurrent flagellum propel food into the cytopharynx. Detailed descriptions of some species were published by Wenrich (1932) and Nie (1948).

Ultrastructure

Cytoskeleton

Although the two genera of retortamonads differ in the number of flagella, electron microscopy reveals that the kinetids are tetrakont in both, possessing four basal bodies (kinetosomes) arranged in two orthogonal pairs. Whereas all basal bodies in *Chilomastix* bear flagellar axonemes (Fig. 3c), one basal body in each pair is barren in *Retortamonas* (Figs. 2 and 5a). All flagella have the typical 9 + 2 organization of axonemal microtubules. The cytostomal (recurrent) flagellum is modified by two or three lateral vanes stiffened by paraxonemal lamellae (Figs. 2, 3a, e, and 5c, d). Electron microscopy provides unequivocal evidence that the recurrent/cytostomal flagellum of retortamonads does not form an undulating membrane attached to one of the cytostomal lips, thus correcting earlier interpretations based on light microscopy (Boeck and Tanabe 1926; Nie 1948).

The basal bodies also give rise to several different fibrillar roots, most of which integrate into the complex cytoskeleton of the cytostome. The most prominent is the microtubular root that descends from the basal body of the recurrent flagellum (root 2, according to the nomenclature recommended by Yubuki et al. 2013), a major support of the right cytostomal lip. In the kinetosomal area, this root originates as a hooked row of microtubules that is rolled into an incomplete cylinder on its left side (Fig. 2). The cavity of this "gutter" (Fig. 5b) opens posteriorly into the cytostomal groove (Fig. 5b, d). The curved band of the gutter microtubules separates from the main row to form the inner subroot (the hooked band), which extends into the cytopharynx as its microtubular support (Figs. 2 and 3b). The right portion of the root gradually expands into a flat ribbon through the addition of microtubules and serves as a major support of the right wall of the cytostomal groove (Figs. 2 and 3b). The second microtubular root originating at the recurrent basal body descends to the left wall of the groove, strengthening the left cytostomal lip (root 1, according to Yubuki et al. 2013; Figs. 2 and 5d).

Another prominent structure originating at the kinetosomes is the striated (paracrystalline) lamella (composite fiber), which is adjacent to the inner face of the microtubular root of the right cytostomal wall and extends posteriorly into the cytopharynx (Figs. 2, 3a, b, e, f, and 4). Both lips of the cytostome are connected at the top of the groove by an arched microfibrillar bundle, the

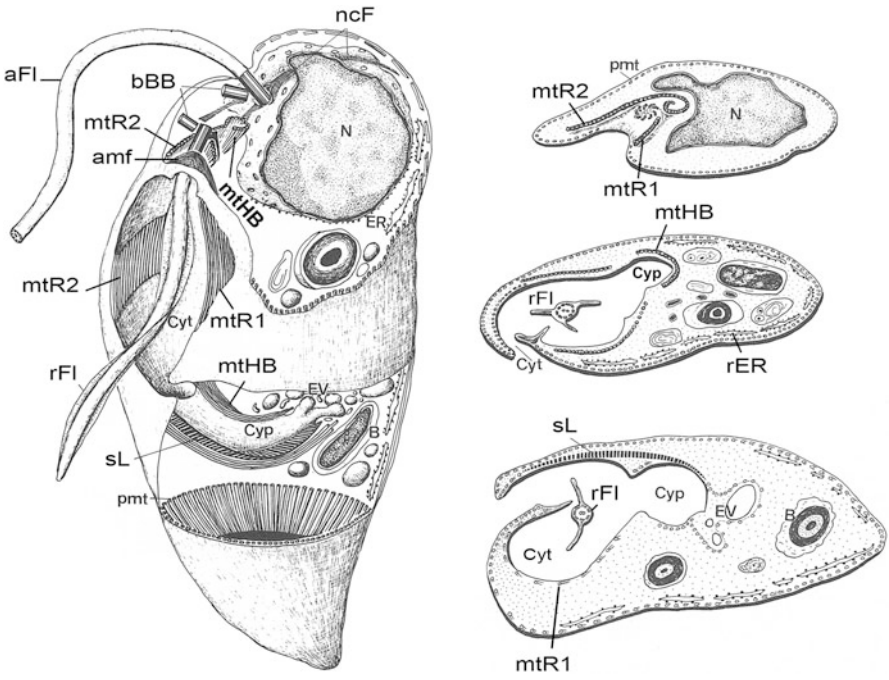

Fig. 2 Diagrammatic reconstruction of the *Retortamonas* trophozoite ultrastructure. The cell is surrounded by a corset of subpellicular microtubules (*pmt*). Four basal bodies, arranged in two pairs, are positioned near the nucleus (*N*). Only one basal body from each pair gives rise to a flagellum; the other two are barren (*bBB*). The free anterior flagellum (*aFl*) extends from the cell subapically. The recurrent flagellum (*rFl*) enters the cytostomal cavity (*Cyt*) and continues its course backward, extending out of the cytostome posteriorly. The left and right cytostomal lips are connected at the top by the arched bundle of microfilaments (*amf*) and maintained by microtubular roots (*mtR1*, *mtR2*). The root of the right cytostomal wall (*mtR2*) is reinforced by a striated lamina (*sL*) which extends along the cytopharyngeal region (*Cyp*). The hooked left side of the mtR2 root is rolled anteriorly into an incomplete cylinder and eventually separates as a hook band (*mtHB*) reinforcing the cytopharyngeal tube. The striated fiber "nuclear connector" (*ncF*) extends from kinetosomal complex to the top of the nucleus. Endocytotic vesicles (*EV*) are mainly formed at the end of the cytopharynx. The endoplasmic reticulum (*ER*) occurs along the subpellicular microtubules. Numerous endocytic vesicles (EV) and food vacuoles containing ingested bacteria (*B*) occur in the cytoplasm (From Brugerolle and Mignot 1990, slightly modified)

"arched fiber" (Figs. 2 and 3a). A fine striated fiber (the "nuclear connector") extends from the basal body complex to the proximal surface of the nucleus (Figs. 2 and 5a).

Both retortamonad genera possess a complete corset of interconnected "subpellicular" microtubules that maintain cellular rigidity (Figs. 2, 3d, and 5b, d). These microtubules originate in an electron-dense rim ("lapel") that extends dorsally around the site of flagellar emergence (Fig. 3c). Further information on cytoskeletal components of *Chilomastix* and *Retortamonas* (the latter from insect hosts only) are provided by Brugerolle (1973, 1977, 1991) and Bernard et al. (1997). Simpson

(**g**) *Chilomastix aulastomi* cyst from the horseleech, surrounded by a thick cyst wall (*Cw*) and containing the nucleus (*N*), internalized flagella (*Fl*), and cytostomal fibers (*Cyt*) (From Brugerolle and Mignot 1990)

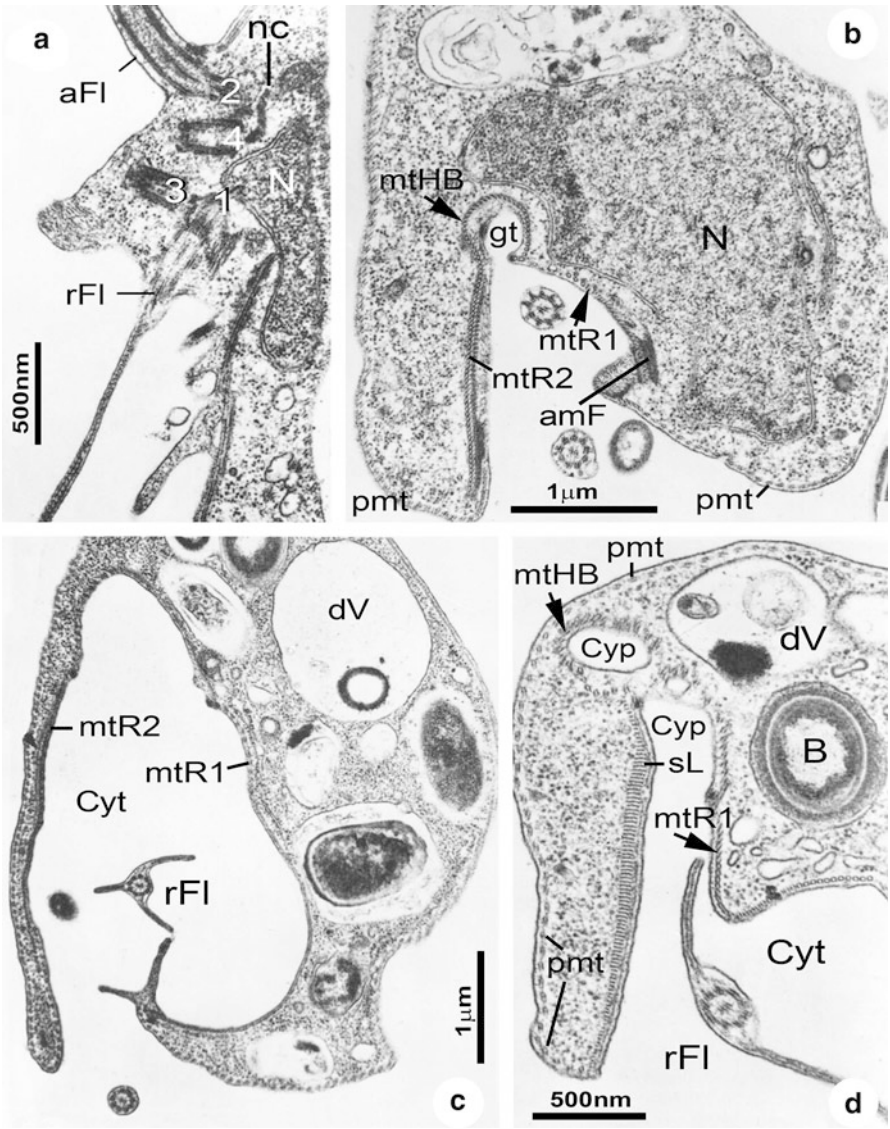

Fig. 5 The ultrastructure of *Retortamonas* from crane fly larvae. (**a**) Basal body arrangement in *Retortamonas*. The basal bodies, localized close to the nucleus (*N*), are grouped in two pairs: the anterior pair (*2*, *4*) and the posterior pair (*3*, *1*). Basal body 2 gives rise to the anterior flagellum (*aFl*); the recurrent flagellum (*rFl*) originates from basal body 1. The basal bodies 3 and 4 are barren. The origin of the nuclear connector fiber (*nc*) can be seen at the base of the basal body 2. (**b**) Transverse section through the upper part of the cytostomal pocket, showing the opening of the gutter (*gt*) into the cytostomal cavity to form the cytopharyngeal tube. The density attached distally to mtR1 microtubules is an anchoring point for microfilaments of the "arched fiber" (*amF*). The cell membrane of *Retortamonas* is supported by a corset of subpellicular microtubules (*pmt*). (**c**) Transverse section through the central part of the cytostomal pocket showing the recurrent

The authors found that in addition to its localization in the basal body area, the centrin signal colocalized with the tubulin signal along a microtubular root that passes through the cytostomal pouch. The major site of centrin association was most likely the hook band subroot of the cytostomal skeleton. Centrin is a calcium-binding protein that is a known component of the pericentriolar complex, but it is also involved in contractility and a variety of signal functions. Weerakoon et al. (1999) speculated that root-associated centrin in the *Chilomastix* cytostome might be involved in signaling related to the capture and endocytosis of food particles in the cytopharynx.

Nucleus and Cytoplasmic Organelles

The nucleus is always located in the most anterior part of the cell, close to the basal bodies (Figs. 1a, c, 2, and 3a). Its shape is almost spherical, with some depressions in the area facing the basal bodies and the intracytoplasmic portion of the recurrent flagellum axoneme. Condensed material visualized by transmission electron microscopy in the posterior part of the interphase nuclei of *Retortamonas* and *Chilomastix* (Brugerolle 1973, 1977) most likely represents the nucleolus and apparently corresponds to the membrane-associated chromatic plaques that give a negative result in Feulgen reactions, as described by Nie (1948).

The cytoplasm of the retortamonads contains numerous pinocytotic vesicles and large digestive vacuoles with ingested bacteria. Endocytosis occurs in the terminal parts of the cytopharynx, where the cytoskeletal armature is discontinuous. The rough endoplasmic reticulum is present, but it is usually not abundant. A single or double layer of reticulum cisternae is typically located at the cell periphery and around the nucleus (Figs. 2 and 3a, e). No Golgi apparatus is apparent (at least in the form of organized stacks of dictyosomes), and peroxisome organelles are absent. Brugerolle (1973) observed in *Chilomastix* a circular reticulum of smooth cisternae beneath the nucleus, but the function of this structure is unknown. Retortamonads do not possess typical mitochondria; however, double-membrane-bounded organelles without cristae that resemble hydrogenosomes have been demonstrated in *Chilomastix cuspidata* (Hampl and Simpson 2008) and other *Chilomastix* species (Fig. 4). Additional cytoplasmic components of retortamonads include free ribosomes and inclusions of multigranular glycogen.

Fig. 5 (continued) flagellum (*rFl*) with three vanes and the microtubular roots supporting the right (*mtR2*) and the left (*mtRl*) wall of the cytostome (*Cyt*). Digestive vacuoles (*dV*), some with ingested bacteria, are present in the cytoplasm. (**d**) Transverse section through the posterior part of the cytostome (*Cyt*) and the cytopharynx (*Cyp*) showing the recurrent flagellum (*rFl*) with two vanes sectioned, the microtubules of the left cytostomal wall (*mtR1*), the striated lamina (*sL*) which extends to the cytopharyngeal tube, and the cytopharyngeal derivatives of the hooked band microtubules (*mtHB*). A digestive vacuole (*dV*) and an endocytosed bacterium (*B*) are shown in the cytoplasm. Note the corset of subpellicular microtubules (*pmt*) (Pictures by courtesy of G. Brugerolle)

The Cyst Stage

The cyst is the resting stage that is resistant to unfavorable environments and serves to transmit infection. Retortamonad cysts are ovoid, pyriform, or lemon-shaped and exhibit a thick cell wall made of filamentous material (Figs. 1b, d and 3g). There is no operculum or pore in the cyst wall. The interior of the cyst contains basal bodies with internalized flagella, the retained cytoskeletal armature of the cytostome and cytopharynx, glycogen granules, and a single nucleus (Fig. 3 (12)). Brugerolle (1973) observed precystic stages of *Chilomastix* with flagella withdrawn into the cytoplasm, partly disorganized "subpellicular" microtubules, and numerous secretory vesicles trafficking cyst wall material to the cell surface. Retortamonads do not divide inside the cyst. A previous description of within-cyst division by Kofoid and Swezy (1920) has not been confirmed by subsequent investigators (Geiman 1935).

Reproduction

Trophozoites of retortamonads reproduce by binary fission, but the details of their mitosis and cell division are not well known. Somewhat conflicting observations by early authors and electron microscopic evidence (Brugerolle 1973, 1977) suggest that the process is similar to that observed in diplomonads (Brugerolle 1974). Mitosis proceeds inside the nucleus, which is enveloped by the persisting nuclear membrane, with the aid of intranuclear microtubules, but the mitotic spindle nucleates outside the nucleus as a "hemispindle" (i.e., the process is a type of semi-open mitosis). The two pairs of basal bodies (kinetosomes) separate during prophase and localize to the nuclear poles (Boeck and Tanabe 1926). The spindle microtubules then nucleate in the perikinetosomal area of the polar basal bodies (see Fig. 7 in Brugerolle 1973). The formation of a "paradesmose" (the extranuclear spindle characteristic of mitosis in Parabasalia), reported by some investigators (Bishop 1934, 1935; Geiman 1935), does not in fact occur in retortamonads.

The chromosomes condense in early prophase; six have been detected in *Chilomastix intestinalis* by the Feulgen reaction (Nie 1948). The cytostome of the parent cell disintegrates by the end of the prophase, and the de novo assembly of the daughter organelles is completed during telophase (Nie 1948). The daughter mastigonts are fully reorganized during the final phase of cytokinesis. The parent flagella are probably retained and redistributed to the daughter mastigonts (Bishop 1931, 1934). Further studies employing advanced methodology are necessary to gain better insight into mitosis and cell division in retortamonads.

Taxonomy

Grassé (1952) established the order Retortamonadida and placed it in the superorder Metamonadina, which at the time encompassed oxymonads, retortamonads, and several orders of parabasalids. Metamonads were later transferred to Archezoa (Cavalier-Smith 1983, 1998; see below). Alternatively, Simpson and Patterson (1999) proposed an "excavate hypothesis" grouping flagellates equipped with a

ventral groove associated with the recurrent flagellum and a characteristic cytoskeleton. After several revisions of the metamonad grouping, Cavalier-Smith (2003) returned to something similar to Grassé's concept, which he modified by including diplomonads and the free-living anaerobe *Carpediemonas*. Cavalier-Smith (2003) also abandoned Archezoa as a taxon and placed the Metamonada as a phylum of the Excavata infrakingdom. Meanwhile, Simpson (2003) proposed Fornicata as a taxon to include a phylogenetically coherent subset of metamonads, consisting of retortamonads, diplomonads, and *Carpediemonas* (and later including the subsequently characterized *Carpediemonas*-like organisms; see below and Kolisko et al. 2010). In the revised classification of eukaryotes proposed by the International Society of Protistologists (Adl et al. 2012), Retortamonadida, together with Diplomonadida and *Carpediemonas*-like organisms, are placed in the Fornicata Simpson 2003, a subgroup of Metamonada Cavalier-Smith 1987, as emended by Cavalier-Smith (2003), within the supergroup Excavata Cavalier-Smith 2002, as emended by Simpson (2003).

Order: Retortamonadida Grassé 1952

Retortamonadida are Fornicata with a single karyomastigont possessing four basal bodies and two or four flagella. One flagellum is recurrent, has two or three lateral vanes, and is associated with the ventral cytostomal pouch. In the phylogenetic tree of Fornicata (Fig. 6), Retortamonadida is split into two different clades, indicating that Retortamonadidae is currently polyphyletic (see section "Evolutionary History").

Family: Retortamonadidae, Wenrich 1932

Characteristics as for order Retortamonadida

Genus: *Retortamonas* Grassi 1879

Objective synonym: *Plagiomonas* Grassi 1881

Subjective synonyms: *Embadomonas* Mackinnon 1911; *Waskia* Wenyon and O'Connor 1917.

Members of the genus possess one anterior and one recurrent flagellum. The recurrent flagellum is directed into the cytostomal pocket, from which a free distal portion of the flagellum extends. Distinctive morphological characters among species include body shape and size, the size of the posterior spike, the relative length of the flagella, the length of the free portion of the cytostomal flagellum, and the size of the cytostome. All known species are intestinal endobionts of insects and vertebrates.

Type species:

Retortamonas gryllotalpae Grassi 1879 [Synonym: *Plagiomonas gryllotalpae* Grassi 1881], from the intestine of the mole cricket. The species was redescribed by Wenrich (1932).

More than 20 species of *Retortamonas* have been described. The retortamonads from crane fly larvae, *Retortamonas agilis* (Mackinnon 1911) and *Retortamonas*

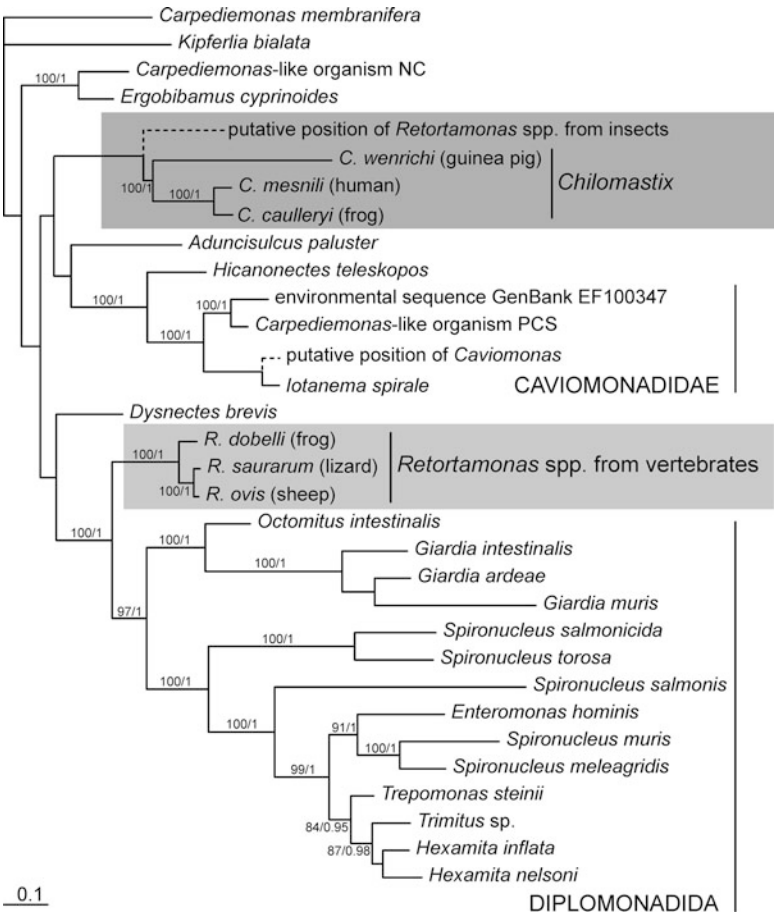

Fig. 6 Phylogenetic tree of Fornicata based on SSU rDNA sequences. The tree was constructed by the maximum likelihood method in RAxML (GTRGAMMAI model). The values at the branches represent statistical support in bootstrap values (RAxML)/posterior probability (MrBayes); support values below 50/0.95 are not shown. The putative position of *Retortamonas* from insects is shown in the tree

alexeieffi (Mackinnon 1912), were subjected to relatively detailed electron microscopic studies (Brugerolle 1977) and thus represent the model species of the genus, though Brugerolle (2006) also briefly described the ultrastructure of *R. hodotermitis*. Other *Retortamonas* species were found in larvae of beetles (*R. caudacus*, *R. phylophagae*), in roaches (*R. blattae*), termites (*R. termitis*, *R. hodotermitis*), water bugs (*R. belostomae*), amphibians (*R. dobelli*), reptiles (*R. boae*, *R. saurarum*, *R. testudae*), and various mammals including humans (e.g.,

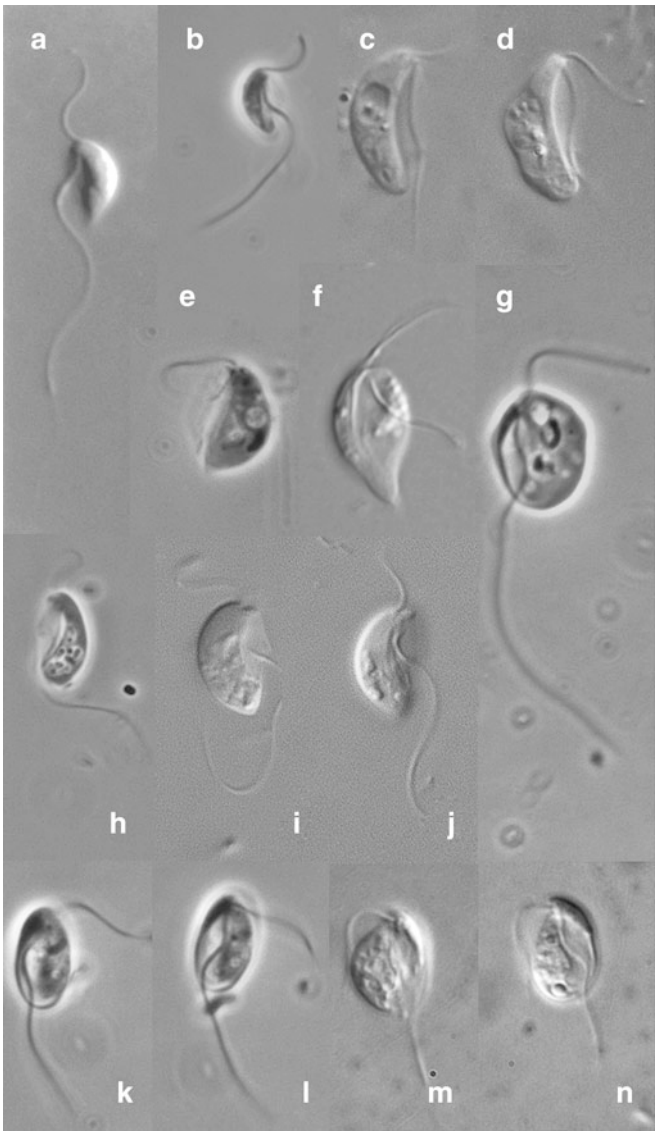

Fig. 7 Light microscopic photographs of free-living *Carpediemonas*-like organisms. (**a**), (**b**) *Carpediemonas membranifera.* (**c**), (**d**) *Kipferlia bialata*. (**e**) *Dysnectes brevis.* (**f**) *Dysnectes* sp. SIVOTA. (**g**) *Hicanonectes teleskopos*. (**h**) *Ergobibamus cyprinoides*. (**i**), (**j**) *Carpediemonas*-like organism NC. (**k**), (**l**) *Aduncisulcus* sp. PCE. (**m**), (**n**) *Aduncisulcus paluster*. R. intestinalis, *R. bradypi*, *R. cuniculi*, *R. mitrula*, *R. ovis*, *R. caviae*, *R. ruminantium*). The ostrich *Struthio camelus* is only avian host of retortamonas reported (MartinezDiaz et al. 2001). For an almost complete list of *Retortamonas* species, see Ansari (1955).

Genus *Chilomastix* Alexeieff 1912

Objective synonym: *Macrostoma* Alexeieff 1909

Subjective synonyms: *Fanapepea* Prowazek 1911; *Cyathomastix* Provazek and Werner 1915; *Difamus* Gäbel 1914; *Tetrachilomastix* da Fonseca 1915.

Members of this genus are endobiotic or free-living Retortamonadidae with three anterior and one recurrent flagellum. The recurrent flagellum is located in the cytostomal pocket and does not extend from it. Distinctive features among species include body size and shape; the relative length of the posterior spike; the relative length of the anterior flagella; the size, shape, and position of the cytostome; and, in some species, the supposed host specificity. Members of the genus are intestinal endobionts of many classes of vertebrates (including humans) and some invertebrates. One species is free-living.

Type species:

Chilomastix caulleryi (Alexeieff 1909) [*Macrostoma caulleryi* Alexeieff 1909]

This species is commonly found in the cloaca of amphibians. The original generic name *Macrostoma* was rejected because it is a junior homonym of *Macrostoma* Risso 1826.

Over 30 species of *Chilomastix* have been described. Light microscopic studies of general importance were published by Boeck and Tanabe (1926), Geiman (1935), Bishop (1935), Nie (1948, 1950), McDowell (1953), and Russel Gabel (1954). The ultrastructure of the genus was studied by Brugerolle (1973) and Bernard et al. (1997).

Examples of *Chilomastix* species:

Chilomastix mesnili (Wenyon 1910) [Synonyms: *Fanapepea intestinalis* Prowazek 1911, *Cyathomastix hominis* Prowazek and Werner 1914, *Difamus tunensis* Gäbell 1914, *Tetrachilomastix bengalensis* Chatterjee 1923] occurs in the cecum and colon of humans, monkeys, and pigs. The susceptibility of monkeys and pigs to human isolates was confirmed experimentally (Kessel 1924, 1928). The potential pathogenicity of this species in humans is discussed above.

Other *Chilomastix* species with mammalian hosts were described from horses, goats, cattle, hares, and rabbits. The major rodent species, with relatively wide host spectra, are *Chilomastix bettencourti* da Fonseca 1915 and *Chilomastix intestinalis* Kuczynski 1914. The former is commonly found in laboratory and wild rats, as well as mice, hamsters, voles, and gerbils. The latter occurs in guinea pigs, hamsters, and rabbits. Another frequent inhabitant of guinea pig cecum is *Chilomastix wenrichi* Nie 1948.

Chilomastix gallinarum Martin and Robertson 1911 is a common avian species present in the ceca of chicken, ducks, turkeys, pheasants, quails, and partridges. Boeck and Tanabe (1926) and McDowell (1953) published morphological studies of this species. Its pathogenic potential is discussed above. Three *Chilomastix* species were recorded in marine fishes (Lavier 1936), and *C. bursa* Moskowitz 1951 in the intestines of frogs.

The type species of the genus *C. caulleryi* (Alexeieff 1909) is found in the cloaca of anuran and urodelan amphibians. This large species can apparently infect the horseleech *Haemopis sanguisuga* in shared biotopes; however the autochthonous species of the horseleech, *C. aulastomi* Bělař 1921, is also identifiable by morphology.

The host list, with pertinent references and further information on *Chilomastix* species from vertebrates, is available from Kulda and Nohýnková (1978). Species living in invertebrates such as termites and sea urchins are listed by Grassé (1952).

The free-living species *Chilomastix cuspidata* (Larsen and Patterson 1990), originally assigned to the genus *Percolomonas*, is widely distributed in anoxic marine, brackish, and freshwater habitats (Bernard et al. 1997, 2000).

Maintenance and Cultivation

Various species of the Retortamonadida from vertebrates, including humans, can be isolated and maintained in xenic cultures (i.e., cultures containing a concomitant mixture of unidentified bacteria). None of the retortamonad isolates have been grown axenically, and no attempts to obtain monoxenic cultures (or any other type of gnotobiotic cultures) have been reported. Some isolates of *Retortamonas* and *Chilomastix* spontaneously form cysts in culture.

The crude biphasic media originally developed for the cultivation of intestinal amoebae, such as Locke-egg-serum medium (Boeck and Drbohlav 1925) or serum-Ringer-egg medium (Dobell and Laidlaw 1926), are still the best choices for the isolation of primary cultures of endobiotic species. Cultures established in biphasic media can usually be transferred and maintained in simple liquid media, such as Loeffler's serum-Ringer medium (Wenrich 1947) or TYSGM medium (Diamond 1982). The optimal pH for the cultivation of retortamonads is 7.2–7.4, and the recommended temperatures for mammalian and avian species are 35–37 °C and 38–40 °C, respectively. Under these conditions, cultures should be transferred at 2- to 3-day intervals. Isolates from amphibians, reptiles, and some invertebrates grow at room temperature (18–25 °C), and transfers at 1- or 2-week intervals are recommended.

The free-living species C*hilomastix cuspidata* can be maintained in sea-water-Cerophyl medium (ATCC Medium 1525, American Type Culture Collection, www.attc.org). The medium consists of a 1:1 mixture of filter-sterilized artificial

seawater and an autoclaved solution prepared by boiling rye grass Cerophyl or its equivalent.

In our experience, isolates of retortamonads can be cryopreserved in the presence of 5% dimethyl sulfoxide using a standard procedure and stored indefinitely in liquid nitrogen.

Reports on the cultivation of retortamonads from humans and animals were published by Hogue (1921), Boeck (1921), Boeck and Tanabe (1926), Collier and Boeck (1926), Bishop (1934), and Dobell (1935); brief procedures are also available in publications of Silberman et al. (2002), Cepicka et al. (2008), and Takishita et al. (2012).

Chilomastix cuspidata and two *Retortamonas* cultures can be obtained from the American Type Culture Collection; several isolates of *Retortamonas* and *Chilomastix* from mammals, amphibians, and reptiles are available in the culture collection of the Department of Parasitology, Charles University in Prague.

Evolutionary History

Retortamonads were once thought to belong to the "Archezoa," a group of putatively primitive eukaryotes that diverged before the acquisition of mitochondria by an ancestor of all living eukaryotes with this organelle (Cavalier-Smith 1983, 1987). Famously, the "archezoa hypothesis" has declined in popularity in the twenty-first century, as organelles interpreted as mitochondrial derivatives (e.g., hydrogenosomes and mitosomes) have been found in most putative archezoans (see Lindmark and Müller 1973; Simpson and Roger 2004; Tovar et al. 1999, 2003; Tachezy and Šmíd 2007). Double-membrane-bounded organelles resembling hydrogenosomes have been found also in *Chilomastix cuspidata* (Hampl and Simpson 2008) and some other *Chilomastix* species (Fig. 4). However, aside from gross morphology, no data are currently available on the biogenesis and function of these organelles in retortamonads.

The retortamonads are currently classified within the taxon Fornicata (Simpson 2003). According to phylogenetic analyses based on the SSU rRNA gene and a concatenate of several protein-coding genes (Takishita et al. 2012; Cepicka et al. 2008), the genera *Retortamonas* and *Chilomastix* form two unrelated clades. *Retortamonas*, represented by species from vertebrates, appears to be the closest relatives of diplomonads, while *Chilomastix* branched within the paraphyletic grade of *Carpediemonas*-like organisms. Cepicka et al. (2008) suggested that *Retortamonas* might be polyphyletic as well, because species from insects possess a complete microtubular corset, similar to that of *Chilomastix*, while the species from vertebrates seem to lack it (Cepicka et al. 2008). Accordingly, sequence data from *Retortamonas* species from insects, presented by Smejkalová et al. at the International Congress of Protistology in Vancouver, Canada (2013), indicate that insect retortamonads are closely related to *Chilomastix*, thus confirming the polyphyly of the genus *Retortamonas* (see also Fig. 6). These findings indicate that taxonomic revision of Retortamonadida can be expected soon.

Coda: *Carpediemonas*-Like Organisms and Caviomonadidae

Introduction

Carpediemonas-like organisms (CLOs) are a small assemblage of poorly known excavates. CLO cells are usually biflagellate, with one anterior and one recurrent flagellum, and possess a longitudinal ventral groove. All CLOs are anaerobic and almost all are free-living, occurring in marine hypoxic sediments. They seem to be relatively common in such environments and have been isolated worldwide. Various media for anaerobic free-living marine protists were shown to be suitable for free-living CLOs (see Kolisko et al. 2010). It was shown only recently that the endobiotic genus *Caviomonas*, which had been previously thought to be a highly reduced diplomonad, belongs to CLOs, being closely related to the endobiotic genus *Iotanema* and free-living, marine isolate PCS (Yubuki et al. 2016). Because caviomonads substantially differ from other CLOs by possessing a single flagellum and a highly reduced flagellar apparatus, they will mainly be treated in a separate section (see below). Together with diplomonads and retortamonads, the CLOs form the clade Fornicata. Recent molecular phylogenetic analyses showed that CLOs are paraphyletic.

The first known CLO was *Kipferlia bialata*, described by Ruinen (1938) as *Cryptobia bialata*. This species was, however, neglected for more than 50 years and was not recorded again before the end of the twentieth century (Fenchel et al. 1995). Two species of *Caviomonas* were described in 1950 and 1970, respectively (Nie 1950; Navarathnam 1970). *Carpediemonas membranifera*, the best known CLO, was described by Larsen and Patterson (1990) as *Percolomonas membranifera*, but was later transferred by Ekebom et al. (1996) to their newly created genus *Carpediemonas*. An ultrastructural study of *C. membranifera* by Simpson and Patterson (1999) was crucial for the formulation of the so-called excavate hypothesis. The morphological similarity of *Carpediemonas membranifera* and *Cryptobia bialata* was noted by Lee and Patterson (2000), who transferred the latter species to the genus *Carpediemonas*. The remaining species of free-living CLOs, *Dysnectes brevis*, *Hicanonectes teleskopos*, *Ergobibamus cyprinoides*, and *Aduncisulcus paluster*, were all described recently, as was the caviomonad *Iotanema spirale* (Yubuki et al. 2007, 2016; Park et al. 2009, 2010). At the same time, it was shown by SSU rRNA gene phylogenies that *Carpediemonas membranifera* and *C. bialata* are not closely to each other, and the genus *Kipferlia* was therefore created for *C. bialata* (Kolisko et al. 2010); the distant relationship between *Carpediemonas* and *Kipferlia* was corroborated by a multigene phylogenetic analysis of Fornicata (Takishita et al. 2012) and an ultrastructural study of *Kipferlia bialata* (Yubuki et al. 2013).

Light Microscopy

CLOs are small flagellates (5–18 μm) with two heterodynamic flagella and a conspicuous ventral groove (but see below for Caviomonadidae). The trophozoites are naked and possess a single, anteriorly located nucleus. The flagella are inserted slightly

subapically, on the ventral side of the cell, close to the nucleus. One flagellum (anterior flagellum, F2) is directed anteriorly and is approximately the same length as the cell. The other flagellum (recurrent, R, F1) is directed posteriorly, runs through the ventral groove, and continues behind the cell. This flagellum is usually substantially longer than the cell; in *Dysnectes*, however, the recurrent flagellum is shorter than the cell body. The recurrent flagellum beats in the ventral groove and creates a current that draws bacteria into the posterior part of the groove where they are ingested. The longitudinal groove occupies almost the whole ventral side of the cell.

Slow movement with little rotation is typical of *Carpediemonas* and *Ergobibamus*; occasional and very slow swimming is characteristic of *Dysnectes*, which usually lies on the substratum and rocks back and forth by moving the anterior flagellum. *Kipferlia* also swims slowly and often adheres to the substratum (Yubuki et al. 2013), whereas *Hicanonectes* rotates rapidly while moving (Park et al. 2009).

Flagellar Apparatus

In general, the organization of the flagellar apparatus of CLOs is similar to that of retortamonads (but see below for Caviomonadidae). Most CLOs possess two flagella (members of Caviomonadidae possess a single flagellum; see below), the recurrent flagellum (F1, R) and the anterior flagellum (F2) (Fig. 8a–e). Transmission electron microscopy shows that they differ in the number of basal bodies, however; in addition to the two basal bodies bearing flagellar axonemes (i.e., basal bodies 1 and 2), there are barren basal bodies: one in *Carpediemonas*, and two in *Kipferlia* (Fig. 8b), *Ergobibamus*, *Aduncisulcus*, and *Hicanonectes* (while the caviomonads *Caviomonas* and *Iotanema* have one and three barren basal bodies respectively; see below). Ultrastructurally, the basal bodies and the flagellar axonemes have a typical eukaryotic organization. As in retortamonads, the anterior flagellum of CLOs is smooth with no accessory structures, whereas the recurrent flagellum has one to three longitudinal vanes, each supported by a paraxonemal lamella with different ultrastructures and unknown biochemical composition (though these have been lost in Caviomonadidae). The ventral vane is always the broadest and is the only vane present in *Kipferlia* (Fig. 8c).

The two flagella-bearing basal bodies are arranged almost perpendicularly or at a slightly obtuse angle (Fig. 8a). The basal body of the anterior flagellum (basal body 2) is associated with the anterior root which consists of a single (*Kipferlia*, *Dysnectes*) (Yubuki et al. 2007, 2013) or several microtubules (e.g., two in *Carpediemonas*, five in *Aduncisulcus*, six in *Ergobibamus*, and nine in *Hicanonectes*; Simpson and Patterson 1999; Park et al. 2009, 2010; Yubuki et al. 2016). The anterior root (also known as root 3; see Yubuki et al. 2013) originates from the anterior side of basal body 2 and curves to run posteriorly down the left side of the cell (except in *Hicanonectes*, where the root travels anteriorly). In *Aduncisulcus*, *Carpediemonas*, *Ergobibamus*, and *Hicanonectes*, the anterior root is closely associated with microtubules of a dorsal fan, which supports the dorsal cell membrane, much like the subpellicular microtubules in *Retortamonas* and

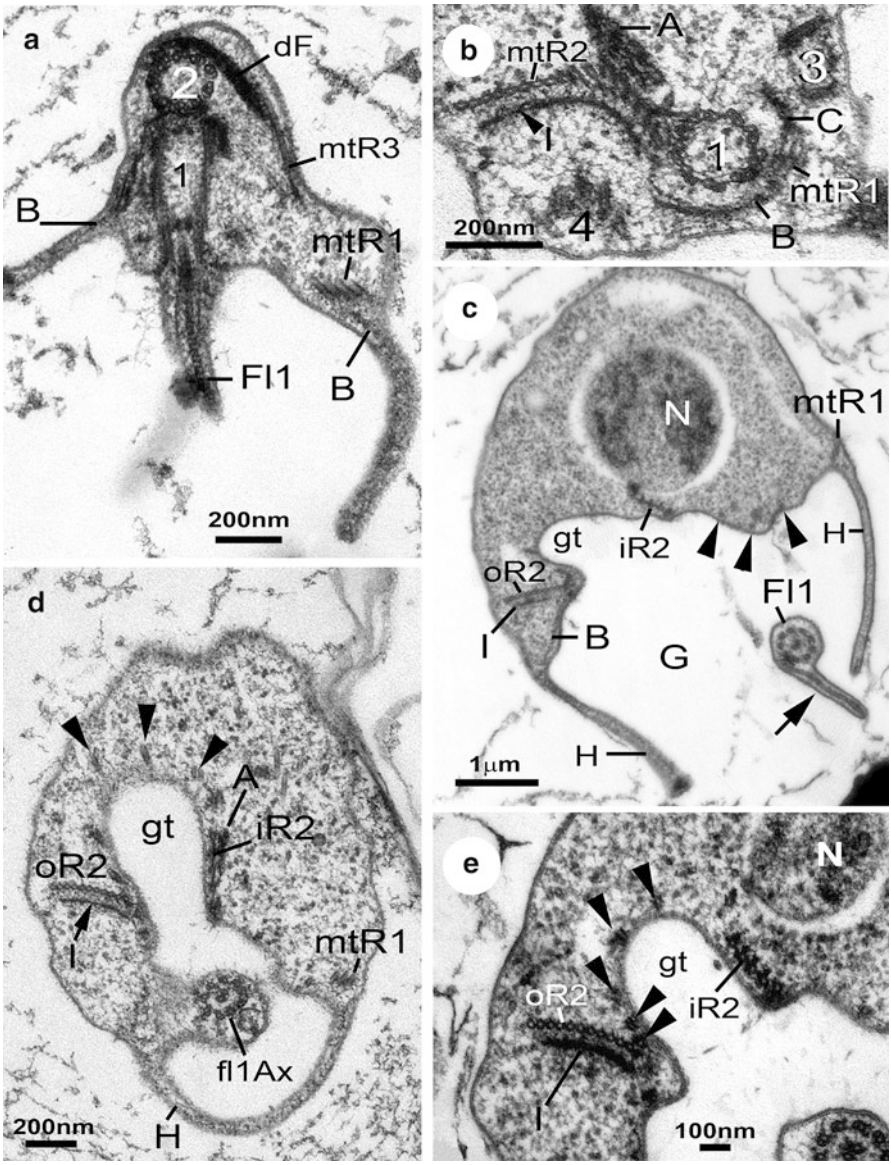

Fig. 8 The ultrastructure of *Kipferlia bialata*. (**a**) A longitudinal section through the anterior part of the cell showing perpendicularly arranged basal bodies of the recurrent flagellum (*1*) and anterior flagellum (*2*) and a dense fiber (*dF*) originating dorsally to basal body 2 and extending along the microtubular root 3 (*mtR3*). The recurrent flagellum (*Fl1*), microtubules of the left root (*mtR1*), and the B fiber can also be seen. (**b**) A transverse section through the anterior part of the cell showing the basal body of the recurrent flagellum (*1*), the barren basal bodies *3* and *4*, and associated structures of the mastigont including the left and the right microtubular roots (*mtR1* and *mtR2*), and the *A*, *B*, *C*, and I fibers. The I fiber (*arrowhead*) reinforces the ventral face of mtR2. The B fiber stretches from *mtR1* to *mtR2* (and the I fiber), around the ventral side of the recurrent basal body (*1*). (**c**) Transverse section

Chilomastix. The extent of the fan differs across CLO genera and is entirely absent in *Kipferlia* and *Dysnectes* (Yubuki et al. 2007, 2013).

The basal body of the recurrent flagellum (basal body 1 or R) is associated with cytoskeletal structures that support the ventral groove, namely, the left microtubular root (R1 or LR), the right microtubular root (R2 or RR), the singlet microtubular root, and several non-microtubular fibers (A, B, C, and I fibers) (Fig. 8b).

The right root originates from the right (or right dorsal) side of the basal body 1 as a single concavely curved row of 15–18 microtubules (Fig. 8b) that splits into two branches near the distal end of the basal body 1: a narrow inner branch (iR2 or IRR) and a more conspicuous outer branch (oR2 or ORR) (Fig. 8c–e). Both branches extend posteriorly. In most CLOs, the outer branch expands through additional microtubules and forms a ribbon supporting the right wall of the groove; the inner branch is associated with the floor of the groove. In *Kipferlia*, the only CLO with a deep gutter within the ventral groove, the outer and inner root branches support the right and left walls of the gutter, respectively (Fig. 8c–e).

The right root is accompanied by two fibers: the short A fiber (on the dorsal side) and the layered I fiber closely associated with its ventral side through fine fibrous connections between the fiber and the root microtubules (Fig. 8b). Posterior to the root splitting, the I fiber continues with the outer branch only and usually terminates halfway down the groove, whereas the root microtubules extend farther. *Kipferlia* and *Hicanonectes* cells have a prominent, posteriorly located cytopharynx, and this is supported by several microtubules ultimately derived from the right root.

The left root originates from the left side of basal body 1. It is formed from a single row of closely adjacent microtubules, which extend posteriorly to support the left margin of the ventral groove. The left root is associated with two fibers. The C fiber is found on the dorsal side of the left root (Fig. 8b). The fiber is short, terminating at the level of the groove opening, except in *Ergobibamus* in which the C fiber runs farther along the left root. The B fiber connects the left and right roots. The fiber traverses the ventral side of the basal body of the recurrent flagellum (Fig. 8b). The left region is always short and located ventral to the left root. The right region, beneath the cell membrane, descends the right side of the groove with the outer branch of the right root. In *Kipferlia*, the B fiber is the main support for the hood, a

Fig. 8 (continued) through the anterior part of the cell showing the ventral groove (*G*) bordered by the hood (*H*) and the gutter (*gt*) on the groove floor. The mtR1 root and individual microtubules (*arrowheads*) support the left wall of the groove. Note two microtubular bands (*oR2* and *iR2*) resulting from splitting of the right root. The I fiber reinforces the oR2 band. The recurrent flagellum with a prominent vane (*arrow*), the nucleus (*N*), and the B fiber supporting the hood are also visible. (**d**) Transverse section through the anterior part of the gutter and its associated structures: the microtubular bands oR2 and iR2, microtubules (*arrowheads*) beneath the gutter membrane, and the fibers I and A. The left root supports the left wall of the apical part of the ventral groove covered by the hood. The axoneme of the recurrent flagellum (*fl1Ax*) is visible shortly before the flagellum descends into the ventral groove. (**e**) A detailed view of the gutter region (more posteriorly than in *d*) to show organization of cytoskeleton that supports the wall of the gutter. *oR2* and *iR2*, five individual microtubules (*arrowheads*), and the I fiber are shown (Pictures courtesy of N. Yubuki)

membranous lip covering the anterior region of the cell above the anterior flagellum and extending down the left and right margins of the ventral groove (Fig. 8c; Yubuki et al. 2013).

Flagellar Transformation

During the cell division of *Kipferlia bialata*, the parental anterior flagellum (F2) becomes the recurrent flagellum (F1) in one daughter cell, while the parental recurrent flagellum (F1) remains recurrent in the other daughter cell. In both daughter cells, the anterior flagellum is formed de novo (Yubuki et al. 2013). Thus, the flagella in *K. bialata* are inherited in a semiconservative way, and the recurrent flagellum is older than the anterior flagellum. *Kipferlia* thus represents the first "typical excavate" in which flagellar transformation has been thoroughly documented (see Nohýnková et al. (2006) for flagellar transformation in the related, but atypical *Giardia intestinalis*).

Nucleus and Cytoplasmic Organelles

The nucleus of the CLOs is always located at the anterior part of the cell, in close association with the basal bodies. Its shape is mostly spherical except for the ovoid nucleus of *Ergobibamus*. The nucleus lacks a central nucleolus. Instead, electron-dense material forms a large mass located either subcentrally (*Carpediemonas*) or on one side of the nucleus (*Hicanonectes* and *Aduncisulcus*); alternatively this mass may form several small aggregates beneath the nuclear envelope, as in *Ergobibamus* (Simpson and Patterson 1999, Park et al. 2009, 2010).

Typical mitochondria are absent; however, double-membrane-bounded organelles that resemble hydrogenosomes are present in all CLO genera, at an abundance of several per cell. The limiting membranes of these organelles are very closely adjacent and do not form cristae. In most genera, these organelles are rounded and are 300–500 nm in diameter, though in *Carpediemonas*, they are elongated or dumbbell-shaped (Simpson and Patterson 1999; Park et al. 2009, 2010; Yubuki et al. 2007, 2013, 2016).

No discrete Golgi apparatus was observed in most CLOs. The exception is *Carpediemonas membranifera*, in which a single Golgi dictyosome with three to four cisternae is placed left of the ventral groove and ventral to the nucleus (Simpson and Patterson 1999).

Food vacuoles are usually located in the posterior two-thirds of the cell.

Ultrastructure of Cysts

The cyst stage of *Hicanonectes teleskopos* and *Iotanema spirale* (the latter a member of Caviomonadidae - see below) was observed by TEM (Park et al. 2009; Yubuki

et al. 2016). The rounded cyst of *Hicanonectes* is covered by a relatively thin, single-layered cyst wall, which is separated by empty space from the cytoplasm. The nucleus, hydrogenosome-like organelles, and internalized flagellar axonemes are located within the cytoplasm. Only a single cyst of *Iotanema spirale* was documented, and almost no details were observed (Yubuki et al. 2016).

Taxonomy and Evolutionary History

The CLOs are members of the Fornicata. To date, six species of free-living CLOs have been described (see below for Caviomonadidae), each currently belonging to a separate genus: *Aduncisulcus paluster*, *Carpediemonas membranifera*, *Dysnectes brevis*, *Ergobibamus cyprinoides*, *Hicanonectes teleskopos*, and *Kipferlia bialata* (Ekebom et al. 1996; Kolisko et al. 2010; Larsen and Patterson 1990; Park et al. 2009, 2010; Ruinen 1938; Yubuki et al. 2007, 2016). This assignment of known CLOs to described genera is now replacing a more informal division into clades labeled CL1-CL6 (Kolisko et al. 2010).

Cavalier-Smith recently (2013) divided CLOs into three families: Carpediemonadidae Cavalier-Smith 2003 (*Carpediemonas*, *Hicanonectes*, and *Ergobibamus*), Kipferliidae Cavalier-Smith 2013 (*Kipferlia*), and Dysnectidae Cavalier-Smith 2013 (*Dysnectes*). However, the family Carpediemonadidae sensu Cavalier-Smith 2013 is paraphyletic. *Aduncisulcus* has not been accommodated in any family (Yubuki et al. 2016).

Almost all CLOs were unknown before the end of the twentieth century, and consequently their phylogenetic affinities were barely considered. Simpson and Patterson (1999) recognized the so-called excavate taxa, to which they assigned *Carpediemonas membranifera* (among others), based on the presence of the ventral groove and the associated cytoskeleton. The specific relationship of CLOs, diplomonads, and retortamonads was revealed in 2002, when sequence data for *Carpediemonas membranifera* became available (Simpson et al. 2002); the three groups were subsequently united in the taxon Fornicata (Simpson 2003). It was later shown by analyses of the SSU rRNA gene that the CLOs are diverse and likely represent several distinct lineages (Kolisko et al. 2010; Park et al. 2009; Yubuki et al. 2007). Notably, *Dysnectes brevis* appeared to be the closest relative of the Diplomonadida + vertebrate *Retortamonas* clade (except for the report of Yubuki et al. 2007 in which this species branched more basally than *Carpediemonas membranifera*), but the SSU rRNA gene showed little power to resolve interrelationships within the Fornicata. A multigene analysis (Takishita et al. 2012) confirmed that the CLOs are paraphyletic, with diplomonads and retortamonads nested within them. Briefly, Fornicata split into four clades without resolved interrelationships: (1) *Carpediemonas*, (2) *Ergobibamus*, (3) *Hicanonectes* and *Aduncisulcus* (and Caviomonadidae, see below), and (4) *Chilomastix*, *Kipferlia*, *Dysnectes*, *Retortamonas*, and Diplomonadida. Within the latter *Dysnectes* was closely related to the *Retortamonas* + Diplomonadida lineage.

Recently it was established that the endobiotic genus *Caviomonas*, which had previously been considered an enteromonad diplomonad, actually descended independently from CLOs (see below).

Morphology, Ultrastructure, and Ecology of Caviomonadidae

Family Caviomonadidae, originally created by Cavalier-Smith (2013), currently consists of genera *Caviomonas* and *Iotanema* and an undescribed isolate PCS. Members of Caviomonadidae are small uniflagellate organisms with a single nucleus and no clear ventral groove (Fig. 9a–d). Preliminary electron microscopy of *Caviomonas* and *Iotanema* shows a simple flagellar apparatus, with two or four basal bodies, respectively (Brugerolle and Regnault 2001; Yubuki et al. 2016). One basal body (B2) bears the single flagellum, which was identified as F2 (i.e., homologous to the anterior flagellum of CLOs and other excavates). One (*Caviomonas*) or three (*Iotanema*) basal bodies are barren, including B1, which bears the recurrent flagellum F1 in other fornicates. The cytoskeleton associated with the basal bodies is simple and consists of a single microtubular fiber (called the nuclear fiber) and a dorsal fan of microtubules. The nuclear fiber is accompanied by a multilayered fiber and a connecting fiber (both are non-microtubular; the latter was observed only in *Iotanema*). It has been putatively homologized with root R1 of typical excavates, though more data are needed (see Yubuki et al. 2016). Mitochondria have not yet been detected in Caviomonadidae.

Genus *Caviomonas* comprises two endobiotic species, *C. mobilis* and *C. frugivori*, found in the large intestine of rodents (Nie 1950; Navarathnam 1970); they are considered harmless commensals. The only species of *Iotanema*, *I. spirale*, was obtained from feces of a gecko (Yubuki et al. 2016). By contrast, the organism "PCS" is free-living and was isolated from marine anoxic sediments

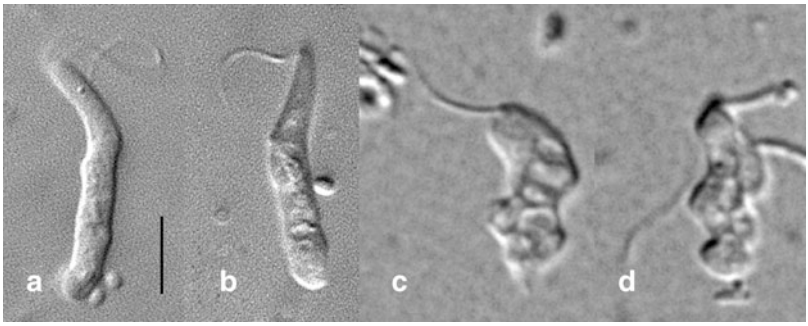

Fig. 9 Light microscopic photographs of Caviomonadidae. (**a**), (**b**) Free-living strain PCS. (**c**), (**d**) *Iotanema spirale*. Scale bar is 5 μm for all figures ((**a**), (**b**) from Kolisko et al. 2010, with permission of the Society for Applied Microbiology and Blackwell Publishing Ltd.; (**c**), (**d**) by courtesy of N. Yubuki)

(Kolisko et al. 2010). *Iotanema spirale* was successfully cultured in serum-Ringer-egg medium (Dobell and Laidlaw 1926); see Kolisko et al. (2010) for suitable culture medium for PCS.

Phylogenies of the SSU rRNA gene of *Iotanema* and PCS show a close relationship with the CLO *Hicanonectes* (Yubuki et al. 2016); sequence data from *Caviomonas* are still unavailable. It was concluded that Caviomonadidae are descended from CLOs, losing most of the typical excavate features and, in the case of *Caviomonas* (and almost certainly *Iotanema*), becoming endobionts. Therefore, they represent the third origin of the endobiotic lifestyle in Fornicata, independent of both retortamonads sensu stricto and the diplomonads + "vertebrate *Retortamonas*" lineage.

Acknowledgments The authors would like to thank Guy Brugerolle for the kind permission to use the micrographs featured in Fig. 3a–g and Naoji Yubuki for the kind permission to use the micrographs featured in Figs. 8a–e and 9c, d. This work was supported by the Czech Science Foundation (project GA14-14105S).

Amoebozoan Lobose Amoebae (Tubulinea, Flabellinea, and Others)

35

O. Roger Anderson

Abstract

The amoebozoans included here are amoeboid protists that locomote by forward flowing of the internal cytoplasm and protrusion of peripheral, fingerlike or fan-shaped pseudopodia, excluding the myxomycetes and other slime molds, and Archamoebae, which lack classical mitochondria. These lobose Amoebozoa are an eclectic collection of amoeboid organisms. Some are naked without any surface covering, while other species may have a thin organic surface coat (glycocalyx) or delicate scales deposited on the outer cell membrane, with shapes that are species specific. Lobose testate amoebae are enclosed within an organic or mineralized shell (test) with an oral aperture where the tubular pseudopodia emerge. The lobose amoebozoans consume prey (e.g., bacteria, algae, smaller protists, yeast, etc.) by phagocytosis. They are widely distributed globally in aquatic and terrestrial environments. They become dormant cysts under unfavorable conditions, such as lack of adequate food or drying of the environment, but excyst and become active when environmental conditions improve (or form freeze-resistant, winter resting stages that are not encysted in some soil-dwelling amoebae in temperate regions). The amoebozoan lobose amoebae are significant members of aquatic and terrestrial microbial communities and serve as important linkages in food webs between microbes and higher organisms, such as invertebrates. Like other Amoebozoa, the lobose amoebae typically have tubular mitochondrial cristae, which partially distinguish them from the heterolobosean

amoebae, with discoidal/flattened cristae. Molecular phylogenetic evidence indicates that Amoebozoans are monophyletic, with most, but not all, lobose amoebae falling into one of two subclades: Tubulinea (which includes the lobose testate amoebae or Arcellinida) and Discosea.

Introduction

General Characteristics

The Amoebozoa broadly include amoeboid organisms, with or without an enclosing shell or test, that locomote largely by extension of pseudopodia and internal cytoplasmic streaming. Only the lobose amoebae with pseudopodia that are tubular and finger shaped (Figs. 1 and 2) or anteriorly broad and fan shaped, sometimes bearing extensions (e.g., subpseudopodia, Fig. 1c), are treated here. Other members of the Amoebozoa that are not (exclusively) lobose amoebae are treated in other chapters (see ▶ Archamoebae, ▶ Dictyostelia, ▶ Myxomycetes and ▶ Protosteloid Amoebae (Protosteliida, Protosporangiida, Cavosteliida, Schizoplasmodiida, Fractoviteliida, and Sporocarpic Members of Vannellida, Centramoebida, and Pellitida)). In some species of lobose amoebae, locomotion is by protoplasmic streaming of the cytoplasm within the body of the amoeba that continuously propels the amoeba forward; while in others the elongated pseudopodia attach to the substrate and provide traction, drawing the body of the amoeba forward.

The lobose amoeboid protists were, until recently, included in the taxon Rhizopoda, defined originally by Von Siebold (1845) and described in the twentieth century by Levine et al. (1980) as protozoa that locomote "by lobopodia, filopodia or by protoplasmic flow without production of pseudopodia." The assemblage included the naked lobose amoebae, shell-bearing testate amoebae, Heterolobosea (amoeboid organisms with flagellated life stages), Foraminifera (with branching and anastomosing granular rhizopodia), and other rhizopodal amoeboid organisms (e.g., Margulis and Schwartz 1988). Prior classification schemes were based substantially on the morphology of the pseudopodia, including the Levine et al. (1980) system. However, fine structural and molecular genetic evidence confirms that these characteristics are not indicative of natural groups and in some cases are clearly a result of convergent evolution, thus leading to a substantial revision of the taxonomy based on more conservative features. Modern research has considerably refined our knowledge of the natural affinities among amoeboid organisms, and newer classifications no longer recognize Rhizopoda as a higher-level taxonomic group. The lobose amoeboid protists are currently included in the Amoebozoa (e.g., Adl et al. 2005, 2012). Additional more detailed taxonomic treatments of some of the other pseudopod-bearing organisms, based on modern revisions, are presented in other chapters of this book.

In this chapter, much of the focus will be on naked amoebae, with some attention to the lobose testate amoebae and their relatives. The naked amoebae, previously categorized as "gymnamoebae," lack a substantial cell covering but may be enclosed by a thin or thickened organic surface coat (e.g., Page 1976, 1981, 1983, 1988), a variety of vertical, towerlike glycostyles (Page 1976, 1983), or in some cases mineral or organic scales adhering to a flexible organic matrix (Kudryavtsev 2006; Page 1983, 1988). The testate amoebae are enclosed by an aperture-bearing test or shell.

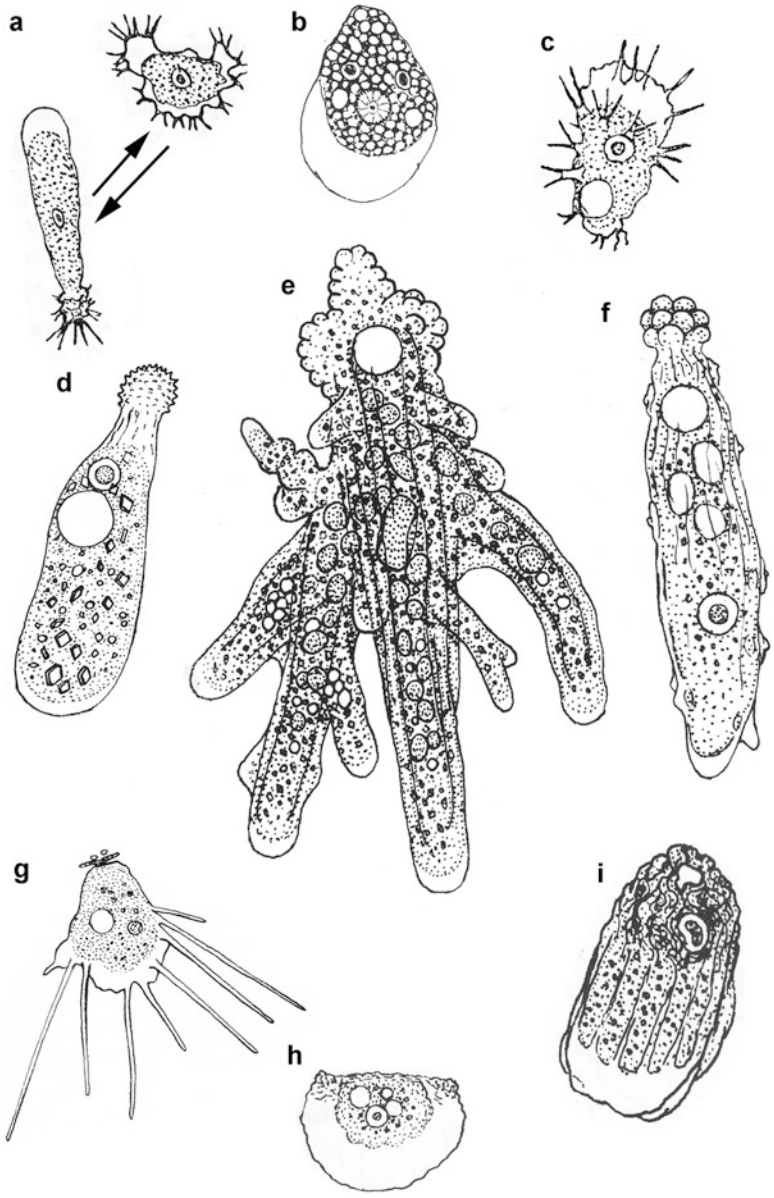

Fig. 1 Diagrammatic illustrations of some naked lobose amoebae. (**a**) *Rhizamoeba polyura*, showing an elongated motile stage and contracted stationary stage with fine lateral-radiating pseudopodia. (**b**) *Entamoeba histolytica* (actually a member of Archamoebae). (**c**) *Acanthamoeba castellanii*, bearing diagnostic bifurcated peripheral pseudopodia. (**d**) *Saccamoeba lucens*, a monopodial amoeba with prominent uroid. (**e**) *Amoeba proteus*, a polypoidal species with several lateral lobose pseudopodia. (**f**) *Mayorella limacis* in locomotion. (**g**) *Vexillifera lemani*, with characteristic of a triangular body and long tapered anterior pseudopodia. (**h**) *Vannella miroides*, a flattened

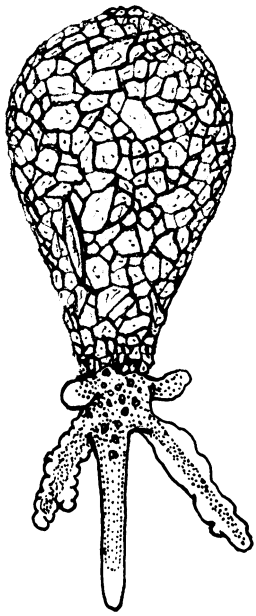

Fig. 2 Diagram of the lobose testate amoeba *Difflugia pyriformis*, with extended pseudopodia (Adapted from Bovee (1985a) with permission (International Society of Protistologists))

The morphology of the test is species specific and its composition is of diagnostic value. In some species it is composed of organic subunits cemented together. In others it is simply an enclosing leathery coat, or a more complex matrix with mineral components embedded within it (Bovee 1985a, b; Clarke 2003; Ogden and Hedley 1980). In some cases, the mineral components such as sand grains, diatom shell fragments, or other mineral particles are collected from the environment and attached to the organic matrix of the test. Typically, a single opening in the test (oral aperture) provides continuity between the internal cytoplasm and the protruding pseudopodia that extend into the surrounding environment (Fig. 2). There are two major groups: the lobose testate amoebae with lobopodia (e.g., Bovee 1985a; Smirnov 2008) and the filose testate amoebae with filopodia (e.g., Bovee 1985b). The latter are now included in the Cercozoa, within the subgroup Rhizaria, and are not considered here (see above).

Occurrence: Habitat, Distribution, and Abundance

Amoeboid protists are found in most habitats where other protists have been observed, including all major terrestrial habitats at low and high latitudes, freshwater

Fig. 1 (continued) fan-shaped amoeba. (**i**) *Thecamoeba sphaeronucleolus*, exhibiting characteristic of longitudinal surface ridges. Illustrations are not to scale; some are enlarged relative to others to display significant morphological features (Adapted from Bovee (1985a) with permission (International Society of Protistologists))

ponds and bogs, brackish marshes and estuaries, and open ocean at near surface or great depth. Typically, distinctions are made during research between soil-dwelling, freshwater, and marine species. This distinction may be more a matter of convenience, as a way to focus and delimit a research agenda, rather than being a necessary restriction of habitat diversity. In general, however, there is good evidence that many marine species are stenohaline and dwell only in marine environments. Estuaries are of particular interest because the periodic tidal fluxes create markedly varied salinity gradients, thus subjecting microbiota to strong selection pressures and leading to wide salinity tolerances. Some species collected from extreme environments, including extreme cold as in arctic and Antarctic locales, often are obligate cryophiles. They exhibit rapid evidence of distress and soon die when introduced to more moderate temperatures. Some amoeboid protists are extremophiles that are found in highly polluted environments with low pH and/or high levels of potentially toxic minerals or industrial waste products (e.g., Amaral Zettler et al. 2003). Their mechanisms of survival are of increasing interest as evidence of the remarkable adaptive capacity of some protists and perhaps as guides to the properties of lifeforms that may be found on other planets with more extreme environments ("exobiology").

Earlier research on amoeboid protists has provided substantial information on their habitats and distribution (e.g., Bovee 1979, 1985a; Kudo 1966; Leidy 1879; Loeblich and Tappan 1964; Page 1988). The distribution and adaptation of terrestrial naked and testate amoebae have been reviewed by Cowling (1994) and more recently for testate amoebae by Smith et al. (2008). Naked amoebae abundances, expressed as number per g soil dry weight, have been reported in the range of 10^5–2×10^6 g^{-1} for pine forest soil (Clarholm 1981), 10^2–5×10^3 g^{-1} in upland grassy plots in the USA (Anderson 2000), and with similar richness in grassland soils and the UK (Brown and Smirnov 2004). However, lower numbers (79–585 g^{-1}) were observed in sandy beach soil (Cowling 1994). Anderson (2009) reported data on the abundance of naked amoebae associated with major groups of plants, including moss (3.5×10^3–3.6×10^4 g^{-1}), ferns (2×10^3–4×10^6 g^{-1}), and seed plants (2×10^3–2×10^6 g^{-1}). He also reported similar data for testate amoebae, i.e., moss (3×10^2–6×10^3 g^{-1}), ferns (90–300 g^{-1}), and seed plants (10^4–4×10^5 g^{-1}). More recently, robust amoeba communities have been reported to be associated with terrestrial lichens (e.g., Anderson 2014), including other reports of the possible importance of testate amoebae (particularly the filose testate amoebae) in the silica biogeochemical cycle within lichen communities (Wilkinson et al. 2015). The distribution and abundance of terrestrial testate amoebae have been substantially investigated, in part because their tests persist for some time in the soil, especially in water-saturated sediments of peat bogs and marshes. Their diversity and abundance in soil strata provide evidence of their ecological and soil environmental histories (e.g., Smith and Coupe 2002). The abundance of testate amoebae of all kinds varies substantially within and across terrestrial sites but is generally in the range of 10^6–10^7 m^{-2} for

forest and sphagnum-rich soils (e.g., Cowling 1994; Foissner 1987; Lousier 1982; Miesterfeld 1977).

Recently, abundances of naked amoebae in freshwater and marine habitats have been more extensively recorded, e.g., Rogerson and Laybourn Parry (1992) reported an annual mean abundance in the Clyde Estuary (Scotland) of 8300 amoebae L^{-1}. Similarly, Anderson and Rogerson (1995) examined the annual abundances of naked amoebae in the Clyde, a more productive estuary, and the Hudson, a more turbid and less productive estuary. They found that maximum summer abundances in the Clyde were approx. 16,000 L^{-1}, while only 7000 L^{-1} were found in the Hudson. Moreover, increasing evidence indicates that naked amoebae in the Hudson may be major predators on bacteria, sometimes competing significantly with other bacteria-consuming protists in the food webs (e.g., Lesen et al. 2010). Naked amoebae can be particularly abundant in freshwater biofilms (Anderson 2013). In a freshwater pond in northern New York, biofilm amoeba densities ranged from 109 to 136 cm^{-2} biofilm surface area and 285 to 550 mg^{-1} biofilm dry weight. Sizes ranged from 13 to 200 μm. C-biomass ranged from 64 to 543 ng C cm^{-2} and 125 to 1700 μg C g^{-1} dry weight. Thirty morphospecies were identified, including very large amoebae in the range of 100–200 μm. Large amoebae (>50 μm) accounted for the largest proportion of the C-biomass.

With increasing interest in high-latitude biota, Mayes et al. (1998) examined naked amoeba abundances in the water column of two coastal sites off Eastern Antarctica. In general, numbers in the water column were highly variable (below detection to 2000 amoebae L^{-1}). There were no clear seasonal trends. Highest abundances, up to 2626 amoebae L^{-1}, were recorded at the ice-water interface. Abundance and diversity of amoebae in Alaskan tundra soils and their relationships to other terrestrial microbes in the carbon cycle and respiration of organic-rich, high-latitude soils have been reported by Anderson (e.g., Anderson 2012). Highly productive freshwater ponds support substantial numbers of naked amoebae, reaching densities close to 2000 mL^{-1} during the most productive periods in spring and early autumn when water temperatures are more favorable for growth (e.g., Anderson 1997). Organic-rich sediments are also highly favorable habitats for naked amoeba growth. The abundance and diversity have been reported in a variety of locales including brackish sediments of Niva Bay on the Baltic Sea (Smirnov 2002; Smirnov and Thar 2003, 2004) and calcareous sand sediments of coastal bays at Bermuda (Anderson 1998). Algal mats, fronds of thallose algae, and suspended floc are also favorable surfaces supporting diverse and/or abundant communities of naked amoebae (e.g., Armstrong et al. 2000; Rogerson 1991; Rogerson et al. 2003). The colony-forming cyanobacterium *Trichodesmium* supports a rich community of microbes, including naked amoebae (Anderson 1977), and as much as 50% of sampled colonies in the Sargasso Sea contained naked amoebae, among other eukaryotic microbes (Sheridan et al. 2002). Suspended floc in Antarctic lakes (e.g., Crooked Lake, Antarctica) may also support rich microbial communities that include attached amoebae and other eukaryotic microbes (Laybourn-Parry et al. 1992).

Practical Importance

Although most naked amoebae are free-living, some have also become pathogenic in humans and other primates. The amoeba *Entamoeba histolytica* (which is, phylogenetically speaking, a member of Archamoebae) invades the gut and causes amebic dysentery (a serious diarrhea), and in more pronounced morbid pathologies, it invades other organs and can be fatal. It is estimated to infect about 50 million people worldwide. More information on the biology of *Entamoeba* is included in the treatment of ▶ Archamoebae. *Balamuthia mandrillaris*, *Acanthamoeba* sp., and *Sappinia* sp. can invade the central nervous system, causing serious amoebic encephalitis, particularly in individuals with compromised immune systems (Visvesvara et al. 2007). *Acanthamoeba* also causes a local serious infection of the eye (*Acanthamoeba* keratitis; e.g., Auran et al. 1987).

Morphology and Taxonomy

Light Microscopic and Fine Structural Morphology

The classification of naked amoebae, based on light-microscopic morphology, relies largely on their shape, size, mode of locomotion, and rate of movement (e.g., Jepps 1956; Page 1976, 1983; Patterson et al. 2002; Rogerson and Patterson 2002; Sawyer 1980; Smirnov et al. 2011). One of the defining morphological features of the Amoebozoa is their shape and pattern of locomotion. Some amoebae that are fan-shaped with a broad anterior lobe often lack subpseudopodia extending from the anterior margin and move largely by differences in cytoplasmic pressure from posterior to anterior that propels the amoeba forward by constantly expanding the anterior margin and retracting the posterior portion. Likewise, anterior extension of the lobopodia occurs through forward flow of the cytoplasm that expands the tip of the pseudopodium in the direction of motion, as the main body of the amoeba is drawn forward. In some species, the subpseudopodia extending from the anterior surface can become quite long and tapered relative to the body of the amoeba (e.g., Fig. 1g). In addition to the overall shape of the amoeba and its pattern of locomotion, other defining features include the presence or absence of a uroid. A uroid is a posterior projection of the amoeba cell and may be rather rounded, sometimes smooth, or with fine posterior cytoplasmic extensions (Fig. 1a); it may exhibit small surface pustules (Fig. 1d) or be decorated with larger surface protrusions (Fig. 1f) which can become quite elaborate in certain species (Fig. 1e). In some species the uroids are adhesive, that is, they become momentarily attached to the substratum as the amoeba moves forward.

Identification of naked amoebae based on their morphology and mode of locomotion requires expert knowledge. In some cases, the subtle distinctions among some species make clear identification difficult. Moreover, broad and overlapping variations in morphology sometimes make discrimination difficult among closely related species, especially for differences in testate amoebae based on shell

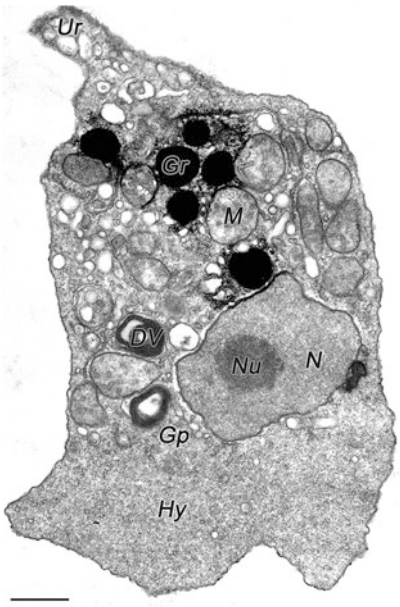

Fig. 3 Transmission electron microscopic image of a section through the nuclear region of a small naked amoeba showing the nucleus (*N*) with a denser nucleolus (*Nu*). The surrounding granular cytoplasm exhibits prominent vacuoles, including a digestive vacuole (*DV*) containing the non-digestible wall remains of a prey organism. Scale bar = 1 μm

morphology (Lahr and Lopes 2006). Consequently, in some cases, morphotypic categories are used, when appropriate for the research objectives. For example, Anderson and Rogerson (1995) used a typology with four types: Type 1, amoebae with lobose or filose protruding pseudopodia and/or locomotion by cytoplasmic streaming; Type 2, limax (worm-shaped) amoebae with steady, noneruptive locomotion; Type 3, limax amoebae with anterolateral bulging pseudopodia and eruptive locomotion; and Type 4, discoid or fan-shaped flattened amoebae. Additionally, identified genera and species were included as subcategories of each morphotype. Subsequently, a refined typology with 16 morphotypes based on more detailed features was published by Smirnov and Brown (2004).

Fine structure features shown by electron microscopy (e.g., Fig. 3) are typical of eukaryotic cells, including a prominent nucleus (N, Fig. 3) surrounded by a nuclear envelope, sometimes including a denser nucleolus (Nu, Fig. 3). The cytoplasm contains membrane-enclosed organelles, including mitochondria (M, Fig. 3), digestive vacuoles (DV, Fig. 3), and a variety of smaller vacuoles. Mitochondria in most species have branched tubular internal cristae, but some variations occur, including more flattened cristae; however, the mitochondria are not enclosed by rough endoplasmic reticulum as found in most Heterolobosea. In some cases food reserves are present as electron-dense granular deposits (Gr, Fig. 3). In species with a broad anterior region, the cytoplasm is largely composed of very fine contractile filaments and is designated as hyaloplasm (Hy, Fig. 3) compared to the more granular cytoplasm (Gp, Fig. 3) that contains most of the membrane-bounded organelles. The hyaloplasm is the region of the cell that is continuously expanding as the amoebae move forward. Amoebozoa dwelling in freshwater also have contractile

vacuoles that accumulate excess water from the cytoplasm and undergo rhythmic contractions to expel the water through a surface pore and into the surrounding environment.

Fine structure evidence has substantially improved our understanding of the cellular basis for making distinctions among taxa. For example, the amoeba's surface coat, if present, has been used to distinguish among genera. A full account is beyond the scope of this chapter, but some examples are given. The surface coat of *Mayorella* spp. is a multilayered organic lamina and differentiates them from the morphologically similar *Korotnevella* (syn.: *Dactylamoeba*) spp. that possesses organic oval to "boat-shaped" complex surface scales. *Vexillifera* has distinctive hexagonal peg-like surface glycostyles, while the members of the "vannellid group" bear either pentagonal towerlike glycostyles (*Vannella*) or less-prominent hexagonal prismatic projections (previously, *Platyamoeba*). Currently, however, molecular genetic evidence indicates that the fine structure of the scales is not a valid basis for distinguishing between species of *Vannella* and *Platyamoeba*. Therefore, it has been recommended that *Platyamoeba* species should be merged into the genus *Vannella* (Smirnov et al. 2007). In some cases, the surface coat is uniformly electron dense (e.g., *Thecamoeba* spp.) or thicker with chevron-like internal electron-dense structures (e.g., *Dermamoeba* spp.). The organization of the nucleus and the structure of mitochondrial cristae (tubular or flattened) are also important distinguishing characteristics (e.g., Page 1976, 1983, 1988). Internal inclusions such as crystals are also of significance, as are the arrangements of fibrillar substances and of microtubules.

The fine structure of the organic matrix and composition of surface components in the tests of testate amoebae have substantially enhanced our understanding of their morphology and systematics (e.g., Ogden and Hedley 1980), particularly in clarifying differences between surface components produced from within the cytoplasm (idiosomes) versus surface components gathered from the natural environment (xenosomes) (e.g., Anderson 1987, 1988a; Lahr and Lopes 2007; Miesterfeld 2002a, b).

Taxonomy

Modern taxonomy, based increasingly on fine structural and molecular phylogenetic evidence, is firmly rooted in the earlier systematics based largely on light microscopy. The literature base is substantial. Only some representative examples can be referenced here (e.g., Bovee 1985a, b; Cash et al. 1905/1909/1915; Chatton 1953; Deflandre 1953; De Saedeleer 1932; Page 1976, 1983; Penard 1902; Schaeffer 1926; Schaudinn 1899). Schaeffer's seminal publication (Schaeffer 1926) contains exquisite black ink-rendered illustrations produced by his own hand and, as he declared, with such attention to detail and lifelike features that they should look as though they could crawl off of the page. Our understanding of amoeboid protist systematics is still rapidly expanding, particularly with increasing insights from molecular genetics. Rogerson and Patterson (2002) identified 55 genera within 14 families in their

survey of naked amoebae (gymnamoebae). In the same publication, 71 genera of lobose testate amoebae were reported (Miesterfeld 2002a, b). In addition to those genera, further discoveries have been made including new naked amoebae: *Vermistella* (Moran et al. 2007) isolated from Antarctica, morphologically similar to *Stygamoeba*, but presently not grouping with it in molecular phylogenetic analyses; *Pellita*, an amoeba with an unusual thickened surface coat (Smirnov and Kudryavtsev 2005; Kudryavtsev et al. 2014); *Squamamoeba*, a small scale-bearing species (Kudryavtsev and Pawlowski 2013); *Cunea*, with two species of small triangular marine amoebae (Kudryavtsev and Pawlowski 2015); and new species of *Cochliopodium* (e.g., Tekle et al. 2013). A novel, filose pseudopod-bearing, multinucleated amoeba (*Telaepolella tubasferens*) assigned to the Gracilipodida (Amoebozoa), a taxonomic group that also includes the genus *Flamella* (see Adl et al. 2012), has been described by Lahr et al. (2012), and more recently its molecular phylogenetic position has been further clarified (Berney et al. 2015; Kudryavtsev et al. 2009).

A number of recent publications have addressed improved classification schemes using modern evidence (e.g., Adl et al. 2005, 2012; Lee et al. 2002; Smirnov et al. 2005, 2007, 2011). The classification of Adl et al. (2005), published by the International Society of Protistologists, is used here with modifications. However, for a more detailed updated hierarchical classification, especially for higher-level groups of amoebae, see Smirnov et al. (2011) and Adl et al. (2012). Within the following text, relevant categories included in the Adl et al. (2012) classification are also cited. Only the naked amoebae (without stages producing flagella or fruiting bodies) and the lobose testate amoebae are considered here. In this scheme, the lobose naked and testate amoebae are included in the supergroup Amoebozoa (and placed in turn in the higher-order group Amorphea by Adl et al. (2012)). However, further research is needed to validate the phylogenetic validity of the supergroups (e.g., Pawlowski 2009; Yoon et al. 2008).

Taxonomic Outline

Some examples of taxa included in major subcategories of Amoebozoa within the classification scheme listed prior to the introduction are briefly described, including illustrative genera.

Tubulinea. Amoebae with tubular or finger-shaped pseudopodia. The major morphological features and some illustrative genera are presented.

Euamoebida. Naked amoebae with subcylindrical pseudopodia in locomotion (or the entire cell is monopodial and subcylindrical); without alteration of the locomotive form to a flattened expanded and branched one; no adhesive uroid. *Amoeba*, *Cashia*, *Chaos*, *Deuteramoeba*, *Hartmannella*, *Hydramoeba*, *Saccamoeba*, and *Trichamoeba*

Leptomyxida. Naked, locomotive that forms a flattened expanded or reticulate one, becoming subcylindrically monopodial when in rapid movement or under

specific conditions; adhesive uroid; uninucleate, tending to have more, or always multinucleate in *Leptomyxa*. *Flabellula*, *Gephyramoeba*, *Leptomyxa*, *Paraflabellula*, and *Rhizamoeba*

Arcellinida. Testate amoebae with an organic or mineral extracellular test composed of either internally secreted components or mineral particles gathered from the natural environment and bounded together. Test with a single main opening. *Arcella*, *Cryptodifflugia*, *Difflugia*, *Nebela*, and *Pharynugula*

Disocosea. Flattened naked amoebae, never with tubular or subcylindrical pseudopodia and never altering the locomotive form, and cytoplasmic flow polyaxial (protruding outward around the periphery) or without a pronounced axis; subpseudopodia short or absent.

Flabellinia. Flattened, generally fan shaped, and discoid or irregularly triangular, never with pointed subpseudopodia; no centrosomes. *Korotnevella*, *Gocevia*, *Pellita*, *Trichosphaerium*, *Paramoeba*, *Vannella*, and *Vexillifera*

Himatismenida. Dorsal surface containing a rigid coat without a defined aperture, ventral surface naked. *Cochliopodium*

Stygamoebida. Flattened, elongate amoebae resembling slender toothpicks or splinters, temporarily with a forked or branched form; extended area of anterior hyaloplasm. *Stygamoeba*

Longamoebia. Flattened and elongated amoeba with pointed subpseudopodia and cytoplasmic centrosomes in one lineage. *Acanthamoeba*, *Balamuthia*, *Dermamoeba*, *Mayorella*, *Sappinia*, *Stenamoeba*, and *Thecamoeba*

Gracilipodida. Amoebae without cilium or centrosomes; flattened, fan shaped, or irregularly branched, with short conical subpseudopodia or fine hyaline, hair-like subpseudopodia; cysts with smooth single-layered enclosing wall. *Arachnula*, *Filamoeba*, *Flamella*

Comment

There are a number of taxa previously included in earlier published treatises on the naked and testate amoebae that are not accommodated in the current classification scheme, largely due to uncertainties about their molecular phylogenetic affinities, lack of clear evidence whether they produce stages with flagella or not, and other issues pertaining to the fine structural characteristics such as the presence or absence of identifiable mitochondria versus their possibly derived organelles such as hydrogenosomes (Yarlett and Hackstein 2005). Moreover, until recently the Amoebozoa have been relatively undersampled in molecular phylogenetic studies, and with increasing attention to their phylogeny, classification systems will undoubtedly undergo significant revisions to better accommodate the emerging evidence of their natural affinities. Hence, the classification scheme outlined here will undoubtedly be modified as additional evidence is available.

Life Histories and Ecology

Most lobose Amoebozoa are free-living amoebae inhabiting aquatic and terrestrial environments. Reproduction is by mitosis. Nuclear division (karyokinesis) precedes cytoplasmic division (cytokinesis). Sexual reproduction has not been documented in naked lobose amoebae but is reported in the testate amoebae. More recently, a form of parasexual activity (cell fusion followed by nuclear fusion and subsequent cell division without a meiosis stage) has been reported in *Cochliopodium* spp. (Tekle et al. 2014). In general, the organization of the nucleus and its transformation during mitosis can be a taxonomic diagnostic feature. Vesicular nuclei have a single central nucleolus (e.g., Fig. 3) or two or more portions (often, but not always, joined) in a parietal (lateral) position. The other principal type is the ovular or granular nucleus with many nucleoli, typically but not always in a parietal layer. Intermediate conditions exist including a moderate number of rather small nucleolar bodies. Mitotic patterns include open mitosis where the nuclear membrane disintegrates during metaphase, or closed mitosis where the nuclear membrane persists and may assist in the separation of the chromosomes during nuclear division.

Most of the amoeboid protists included here are exclusively heterotrophic, consuming bacteria, algae, or other small eukaryotes as prey. During ingestion, the prey is surrounded by the anterior pseudopodia and engulfed in intracytoplasmic digestive vacuoles (e.g., Fig. 3, DV). Some amoeba species contain intracellular algal symbionts (e.g., *Mayorella viridis*), but their role in host nutrition has not been established (Cann 1981). Bacterial endobionts are also present in some species, but their role also has not been described. However, an interesting example of co-adaptation has been reported in *Amoeba* by Jeon and Jeon (1976) that progressed from pathogenic bacterial infection (Jeon and Lorch 1967) to a mutually dependent status within several years, where the bacteria were required for the survival of the amoeba host. This relatively rapid evolution from a destructive to a mutually dependent relationship can be used as a model for the endosymbiotic origin of cellular organelles such as mitochondria (Margulis 1981).

Many terrestrial free-living Amoebozoan species are not obligate soil-dwelling biota and also are found in freshwater habitats. Some aquatic species are euryhaline, with a broad salinity tolerance. Others are strictly marine, or dwell in strong brackish water. Some species are cryophilic and grow only in cold temperatures, sometimes near the freezing point. Others require more moderate temperatures, and some thermophiles tolerate remarkably elevated temperatures, including those found in warm springs or shallow ponds subjected to elevated summer temperatures (e.g., Kyle and Noblet 1986, 1987). The capacity to form walled cysts, which resist desiccation, during unfavorable growth conditions (e.g., drought or insufficient food), especially for terrestrial and freshwater species, has enhanced the survival value of many amoeboid species and permitted widespread dispersal by wind or other transport mechanisms. Under favorable growth conditions, the encysted individuals excyst and emerge as actively feeding trophonts.

Earlier investigations on the habitats, feeding behavior, population growth dynamics, and life histories of pseudopodial-bearing protists (e.g., Bamforth 1985;

Bovee 1985a, b; Chatton 1953; Heal 1964; Sandon 1927) established a firm foundation for modern research on their life histories and ecology (e.g., Anderson 1988b; Fenchel 1985; Rodriguez-Zaragoza 1994; Smirnov 2008). Major advances have been made in our understanding of the significant ecological role of amoebae. Some recent representative studies on the life histories and ecology of amoeboid protists from aquatic and terrestrial environments are reviewed here within three broad ecological themes: (i) environmental variables, (ii) successions and seasonal abundances, and (iii) interactions with algae or plants, including biofilms.

Aquatic Ecology

Environmental variables. Temperature is a major variable determining the species composition and biogeographic distribution of Amoebozoa (e.g., Bonilla-Lemus et al. 2014). More generally, among other significant physicochemical variables, salinity is a major forcing function, segregating strictly freshwater amoebae (Page 1988) from marine species (Page 1983). In marine coastal marshes and estuaries, however, there are substantial populations of euryhaline amoebae (e.g., *Acanthamoeba Cochliopodium*, *Hartmannella*, *Mayorella*, *Vannella*, and *Vexillifera*) that have adapted to the diel cycles of tidal flushing where salinities may vary seasonally from 0 to 12 parts per thousand (e.g., Anderson and Rogerson 1995). The salinity tolerances of naked amoebae collected from widely different geographic sites, ranging from approximately 0 parts per thousand to 160 parts per thousand, were compared in laboratory experiments by Hauer and Rogerson (2005). Seven species were identified with remarkably wide tolerances in a range of 0 to 127 parts per thousand and six marine isolates that grew in the range of 2 to 127 parts per thousand. Further evidence of wide salinity adaptive tolerances of marine naked amoebae was reported by Cowie and Hannah (2006) who found substantial resilience to rapid salinity changes, including survival down to seven parts per thousand for the most resilient species.

Among other factors supporting naked amoeba population growth, the size, composition, and amount of suspended organic particles and floc in the water column are important variables. Naked amoebae must attach to surfaces while feeding on bacteria and other prey. Hence, suspended floc may be essential to support substantial planktonic populations of amoebae (e.g., Rogerson et al. 2003). Flocs may be "hot spots" for surface-dwelling eukaryotic microbes, especially amoebae (e.g., Anderson 2011), and represent significant centers for remineralization of nutrients through predation on bacteria (Arndt 1993; Zimmermann-Timm et al. 1998; Juhl and Anderson 2014).

Aquatic successions and seasonal abundance. The abundance of naked amoebae during seasonal successions is positively correlated with water temperature as exemplified by annual variation in abundances in some estuaries and ponds (Anderson and Rogerson 1995; Anderson 1997) with correlation values in the range of $r = 0.8$. Rivers and tidal estuaries offer unique environments to examine the effects of seasonal and tidal forcing functions on protists. Kiss et al. (2009) reported

maximum abundances of 3300 individuals L^{-1} in the Danube, particularly in April to July, with a secondary peak in October and November. Similar evidence of spring/summer and autumn blooms of naked amoebae was reported by Anderson and Rogerson (1995) for the Hudson Estuary and also in a shallow freshwater pond on the palisades above the Hudson Estuary (Anderson 1997, 2007). At maximum values, the amoeba carbon accounted for approximately 75% of the combined total carbon in the amoebae and ciliate fractions. Significant differences, however, may exist in the amoeba densities in sediments compared to the water column of some river systems, with amoebae dominating abundances in the sediment and ciliates in the water column (e.g., Gu et al. 1988). Weisse and Müller (1998), summarizing a 10-year analysis of seasonal standing stock of plankton in Lake Constance, reported that ciliates were found to be the single most important group, but naked amoebae were found in relatively high numbers and biomasses during phytoplankton peaks. A successional study of biofilms in a less-hospitable environment (the highly polluted Rio Tinto river, pH approx. 2) during 1 year by Aguilera et al. (2007) showed that amoebae and small flagellates were among the major eukaryotes after 1 month of biofilm development. Overall, the results suggest that some amoeboid eukaryotes are remarkably resilient, with potentials to adapt to highly mineral-polluted and low-pH environments.

Interactions within biofilms and with submerged phytobiota. Relatively little is known about the interactions of naked amoebae with prey bacteria in aquatic biofilms, but recent evidence suggests that naked amoebae may exert major top-down controls on biofilm bacteria (e.g., Anderson 2013; Zhang et al. 2014). Although ciliates are the most efficient predators in reducing bacterial biomass in the open water, amoebae can have a significant long-term negative effect on bacterial biomass both in the open-water phase and biofilms. Alga lamina and submerged stems and roots of plants, as well as floating colonies of algae (Anderson 1977), provide organically rich surfaces to support communities of naked amoebae, with surfaces of seaweeds supporting especially robust growth of potential bacterial prey (Armstrong et al. 2000). Additional studies of microbial populations on the surfaces of mangrove plant prop roots covered in epibiont film were reported by Maybruck and Rogerson (2004). No clearly discernible temporal pattern was detected throughout a 1-year sampling program, although naked amoebae were the second-most abundant group after flagellates. Some experimental trials comparing the growth of protozoa on tightly and loosely associated bacteria indicate that amoebae are more capable of removing tightly associated bacteria than are other micrograzers. Attached bacteria are likely to be significantly involved in the degradation of mangrove carbon; hence, predatory amoebae may serve an important ecological role in the film community.

Sediment and Soil Ecology

Environmental variables. The wide variation in the size and composition of organic and mineral particles in sediments and soils, as well as the intricate pore spaces,

produces a highly complex environment of microbial microniches, especially for amoeboid protists that typically attach to, or locomote upon, the elaborate surfaces of the solid substratum. Microniches have been characterized in sediments from Niva Bay (Baltic Sea) by Smirnov (2002) and subsequently extended to include oxygen analyses of the microenvironments within the microniches by Smirnov and Thar (2003). Naked amoebae were most abundant and diverse in the upper 1 cm of sediment. Their number and diversity decreased with increasing depth in the sediment. Species composition and abundance were highly heterogeneous, even at spatial scales of several centimeters, indicating the presence of microhabitats selectively occupied by particular suites of species. Amoebae were recovered from oxygenated upper layers as well as deeper anoxic layers. Some of the small sediment samples contained "hot spots" of amoebae biodiversity, with up to four species co-occurring in the same area. These may be loci of particularly favorable environmental growth conditions.

The distributions and biomass of amoebae and other protists in marine, brackish, and freshwater sediments were also examined by Lei et al. (2014) at 15 littoral stations across a relatively wide range of latitudes (arctic to European and North American sites). Amoeba abundance ranged from 0 to 937 cells mL^{-1} and biomass from 0 to 4.71 μg C mL^{-1}. Some of the highest naked amoebae densities were observed at marine tidal flats and contained only naked forms, whereas in a freshwater lake, only testate amoebae were observed. On an arctic ice floe, only naked amoeba forms were observed, and they contributed an average of more than 96% of the total protozoan abundance or biomass. At the other stations, both naked and testate amoebae were found.

Similar evidence of microhabitats (microbiocoenoses) in temperate forest soil has been reported by Anderson (2002). Samples of soil from four sites of varying soil porosity were analyzed in the laboratory, either unamended (NN) or amended (NE) with glucose solution to increase the organic content. Generally, the abundance of naked amoebae tended to increase with increasing soil particle size for both NN and NE treatments, possibly indicating that abundances increase with increasing porosity of the soil and the concurrent differences in physical and chemical properties that characterized the soil types. The NE cultures, moreover, showed consistently higher abundances and diversity of naked amoebae compared to the NN cultures. There also was evidence of growth "hot spots" where localized environmental conditions, such as sporadic nutrient loading or other favorable conditions, may have fostered proliferation of the amoebae.

Further evidence of the complexity of small-scale patchiness was obtained in a study carefully documenting the variation in numbers of amoeba morphotypes in small soil samples (Anderson 2003) to yield a mathematical model of biocomplexity using Euclidean spatial analysis. Three indices of amoeba abundance and distribution in the small volume samples were plotted as a three-dimensional graph: morphospecies richness (mean number of morphospecies counted in each small soil subsample), morphospecies diversity (number of morphospecies occurring in only one of the small soil subsamples but in no others), and morphospecies patchiness (the degree of aggregation or nonuniform distribution of morphospecies among

the soil subsamples). Soil samples were obtained from a freshwater bog, freshwater marsh, salt marsh, stream margin, and deciduous forest floor. Samples from the marsh rhizosphere were the most biocomplex, followed in decreasing order by the stream edge, salt marsh, and bog. Finally, forest soil samples and those from a nearby ravine were least complex.

In general, there is evidence that amoeba abundance decreases with depth in sediments (e.g., Decamp et al. 1999; Smirnov 2002), probably due to increasing anoxia and reducing conditions. However, there may be less stratification in soils, at least in the uppermost organically rich layers, especially if they are sufficiently hydrated (e.g., Bischoff 2002). Nonetheless, abundance usually declines within deeper layers of most stratified soils (Cowling 1994). Moisture content is seldom a major environmental variable in sediments, which are water-saturated in many cases. However, moisture is a major factor in determining naked amoeba abundance in terrestrial environments, as well as the proportion that is active versus encysted (e.g., Anderson 2000; Bischoff 2002).

Further evidence of the effects of soil water availability on terrestrial protists, including amoebae, was obtained by Geisen et al. (2014) using soil cores maintained under controlled environmental conditions in the laboratory. Total protist abundance differed eightfold between the two most extreme moisture treatments, and the higher number of total individuals was mainly attributed to an increased abundance of amoebae, which was 7.2-fold higher in the most moist treatment compared to the most dry. Some taxa reached highest numbers only in fully water-saturated soils and readily decreased when the habitable pore spaces became smaller, whereas other taxa were more resistant to decreasing water and only decreased at a later stage of water stress when the maximum size of water-filled pores (Pmax) was <60 μm. Overall, as the authors hypothesized, the largest protist species decreased with increasing soil dryness, but in particular nanoamoebae dominated in the dry soil, not flagellates as was initially predicted.

Successions and seasonal abundance. Abundances of terrestrial naked amoebae are typically lowest in winter and increase during early spring and summer, but precipitation and available moisture are much more significant factors than season (e.g., Anderson 2000; Bischoff 2002). Precipitation accounts for more variance in abundance than local organic content of the soil or its temperature at time of sampling, at least in a study of a temperate upland grassy site (Anderson 2000). Abundances of amoebae during mild winters with substantial precipitation may be comparable to those during warmer seasons of the year (Anderson 2000). Available water and water table depth in swamp and bogs may also be more important factors than is season in accounting for abundances of sphagnum-dwelling testate amoebae (Warner et al. 2007). Likewise, biological and microscale environmental factors may be important in explaining seasonal changes in testate amoebae, as documented above for soil-dwelling naked amoebae.

Testate amoebae serve an important role at the inception of succession on land. Wanner et al. (2008) examined the succession of testate amoebae in litter bags in four different soils that varied in nitrogen and phosphorous nutrients to document the early colonization (within less than 55 days) and establishment of testate amoebae

communities. Substrates at the nutrient-poor sites were colonized more rapidly than reference sites where colonization was later and in lower densities. Both small-sized (r-strategist) and larger (K-strategist) species occurred in remarkably high densities on all sites. During later stages of colonization, the influencing environmental factors became more complex, and the composition of the testate communities changed from variability to stability.

The ability of amoebae to encyst and excyst relatively rapidly has contributed to their survival capacity, especially in temperate terrestrial environments where soils are subjected to intervals of drying and protracted periods of freezing during winter. However, the dynamics of encystment and excystment have not been extensively investigated during the development of successions following recovery from winter conditions. Anderson (2010) obtained winter soil samples from an organically rich swamp site and a less-moist mineral soil beneath a stand of pine and observed the dynamics of excystment in laboratory microcosms during warming simulating spring temperatures. The proportion of active and encysted naked amoebae was documented for 10 days during the ensuing succession (Fig. 4). The pine stand sample (ambient 18% moisture and organic content 6%) overall had lower initial total densities of naked amoebae and proliferated to lower total levels after 10 days compared to the swamp sample (ambient 47% moisture and organic content 15%). However, the proportion of encysted to total amoebae was more informative. In the drier pine stand sample, the proportion of encysted relative to total amoebae increased markedly during the 10-day rising from an initial 60% to a final 100% (Fig. 4a), whereas, the proportion of encysted to total amoebae in the swamp sample,

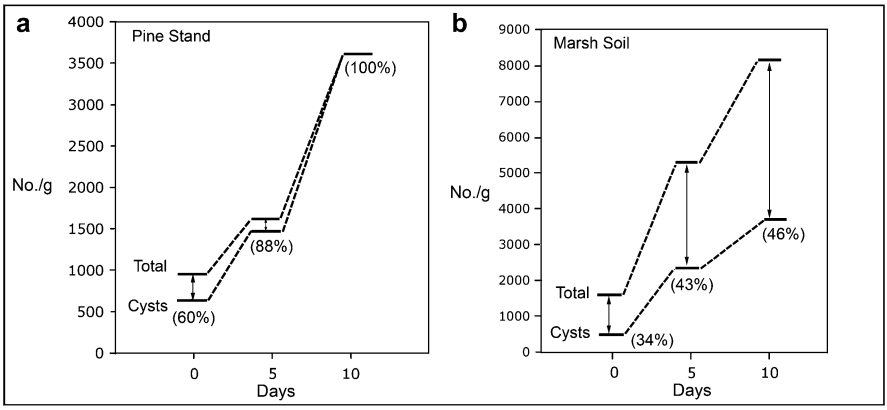

Fig. 4 Comparative plot of the densities of total amoebae (*upper graph*) and cysts (*lower graph*) including (percent encysted) at 0, 5, and 10 days in a laboratory microcosm study of a succession when winter soil was warmed to simulate spring temperatures. Plot of relative densities of total amoebae and encysted stages for a pine soil sample (**a**) and marsh soil sample (**b**) showing the gradual progression toward total encystment in the pine soil preparation and a more steady-state lesser ratio of encysted to total amoebae in the marsh soil preparation (Reproduced from Anderson (2010) with permission of the publisher (*Acta Protozoologica*))

though increasing moderately from 34% to 46% over 10 days, was much more stable (Fig. 4b). The increase between day 5 and day 10 for the swamp sample was 43–46%, which is probably near a constant carrying-state value.

Overall, in both samples there is clearly a dynamic relationship between active and encysted stages, with evidence of substantial interconversion of active and encysted stages during the succession. More recently Anderson (2016) showed that, in addition to encysted stages, amoebae in temperate soil environments are capable of forming freeze-resistant resting stages without forming cysts. These "resting cells" are able to rapidly resume active feeding and metabolism when the soil unfreezes, either intermittently during winter or with the onset of spring, thus providing a more rapid exploitation of the environment than can be achieved if the amoebae had encysted. However, soil moisture must be sufficient at the time of freezing to support active amoebae; otherwise, they will encyst rather than forming resting stages.

In general, the typical circular cycle of alternation between encysted and active stages portrayed in textbooks, and some scientific treatises, should be expanded to include recognition of the dynamic balance in the alternation of the two stages during early succession. Moreover, further refinement is needed to include winter freeze-resistant resting stages that may provide more rapid resumed growth compared to cysts, requiring a more prolonged time for excystment in response to favorable growth conditions.

Given an increasing interest in high-latitude environments and climate change, Anderson (2008) examined the seasonal abundance of naked and testate amoebae during a succession from spring (June) to summer (August) at a tundra site (Toolik Lake, Alaska). Naked amoebae abundance (number per g of soil dry weight) increased from 2×10^4 to 3×10^4, and testate amoebae abundance increased more markedly from 1000 to 6000 during the seasonal succession. Interestingly, in terms of carbon content, the testate amoebae accounted for a larger part of the biotic carbon fraction than naked amoebae. Testate amoebae comprise a significant part of the microbial communities in moss-rich, high-latitude environments.

With evidence of global warming, what is the likely effect on these significant microbial communities? Beyens et al. (2009) examined the potential effects of global warming on the structure of testate communities by experimentally simulating a heat wave in Greenland arctic soils. Although the experimental heating of the soil was sufficiently severe to induce significant leaf mortality in the aboveground vegetation, overall there was no detectable effect on testate amoebae abundance. However, transient shifts in species populations occurred in the heated plots during the acute exposure, followed by increases in species richness weeks after the experimental heat wave had ended. Lobose pseudopod-bearing testate amoebae were more resistant to the heating and its associated desiccation than filose amoebae.

Interactions with plants. In general, substantially more information has been gathered on the interaction of testate amoebae with a wide variety of plant types, especially mosses, largely because their tests are more easily preserved and counted in samples (e.g., Cowling 1994). Naked amoebae are known to be abundant in the rhizosphere (root zone) of plants (e.g., Clarholm 1981), and there is increasing

evidence that naked amoeba abundance is higher in the rhizosphere and soil beneath plants compared to surrounding bare soil in a variety of ecosystems, including agricultural soils (Cowling 1994; Zwart et al. 1994, p. 102), arid lands (Robinson et al. 2002), and deserts (Rodriguez-Zaragoza and Mayzlish 2005; Rodriguez-Zaragoza et al. 2005). There is some variation, depending on the precipitation patterns and time of year. Within the limitations of methodological error, the ratio of protozoan biomass in the rhizosphere to that in bulk soil is in the range of 4–6 (Zwart et al. 1994). This is attributed in part to the organic exudates released from plant roots and possibly also the higher moisture content of soil immediately surrounding the roots. The complex interactions of protists, including amoebae, with the plant rhizosphere have attracted considerable experimental research attention (e.g., Zwart et al. 1994) including a spatial analysis of the number of active and encysted amoebae in relation to the distance along the root axis (e.g., Coûteaux et al. 1988).

With evidence of increasing atmospheric carbon dioxide concentrations, there has been an interest in documenting how atmospheric CO_2 affects plants, and, in turn, what effects (if any) there may be on rhizosphere microbial communities. Anderson and Griffin (2001) grew wheat plants in containers in controlled climate chambers with ambient and elevated carbon dioxide concentrations. Plant dry biomass was higher in the elevated CO_2 treatment (4.4 g/plant) compared to the ambient treatment (2.8 g/plant). The rhizosphere mean abundance of flagellates, ciliates, and amoebae, expressed as number/g dry weight, was greater in the elevated CO_2 treatment compared to the ambient treatment, with an approximate twofold difference in amoeba abundances. Comparable results using pot-grown wheat plants were reported by Rønn et al. (2003), who found that soil from pots with plants grown in elevated CO_2 had higher abundances of protozoa (especially bacterivorous amoebae) but similar abundances of bacteria. The bacteria may have been under grazing pressure by the predators, thus controlling their numbers.

The interactions of the protozoan and bacterial communities with mycorrhizal fungi in the soil may be complex (Rønn et al. 2002). In the absence of fungi, protozoan abundance was enhanced under elevated CO_2 treatments, but when fungi were present, the abundance of protozoa was reduced, possibly by adverse competitive effects of the fungi on the growth of food bacteria. Similar results were found in the natural environment for soil microbiota in grasslands exposed to elevated CO_2 (Hungate et al. 2000). Although the biomass of active fungi and flagellates increased, there was no difference in the abundance of ciliates and naked amoebae between the ambient and elevated treatments. In sum, there appear to be at least short-term effects of elevated atmospheric CO_2 concentrations on plant growth and root proliferation, and consequently increased sources of organic nutrients to support microbial communities, including an increased abundance of amoebae. However, complex interactions in the microbial communities, especially with fungi, may moderate these effects. Moreover, in some cases the relative peak in protozoan abundance during the first several weeks in the elevated CO_2 treatment was not sustained for longer time intervals. The reasons are not clear, but changes in trophodynamics, including increased top-down predation on the protozoa, may account for their decline in abundance with time.

Increasing evidence that rhizosphere eukaryotic microbes enhance plant growth has led to some interesting experimental studies to better understand the synergistic interactions. Bonkowski et al. (2001) examined the effects of amoebae on growth of Norway spruce seedlings in experimental cultivation. Spruce seedlings, cultivated with or without an ectomycorrhizal fungus, were grown for 10 months in microcosm chambers with defaunated forest soil, either supplemented with naked amoebae or without amoebae. The presence of amoebae resulted in the development of a more complex root system by increasing root length (51%), length of fine roots (64%), and number of root tips (43%). The effects of the amoebae were more pronounced in the absence of mycorrhizae. The explanation for enhanced growth of plants in the presence of protozoa is not fully determined, although the most direct effect is likely the remineralization of nutrients by predation on bacteria and perhaps by activation of bacteria that break down complex molecules into smaller, more available sources of plant nutrition.

In a more novel perspective, Bonkowski and Brandt (2002) evaluated the hypothesis that rhizosphere protozoa enhance plant growth by a grazing-induced stimulation of plant growth-promoting rhizobacteria that release plant growth substances (phytohormones). They investigated changes in root morphology of watercress seedlings and effects on the composition of the rhizosphere bacterial community, by adding *Acanthamoeba* sp. to the experimental treatments. They found that the presence of *Acanthamoeba* sp. induced changes in root morphology of watercress seedlings as soon as the root protruded from the seed, i.e., it was greater and more branched. These changes resembled hormonal effects and were accompanied by an increase in the proportion of auxin-producing rhizosphere bacteria. Evidence showed that the auxin (indole-3-acetic acid, IAA) did not originate from amoebal metabolism but resulted from changes in the composition and activity of the prokaryotic microbial community. They proposed a new mechanism based on hormonal effects of protozoa on root growth: protozoa function as "bacteria-mediated mutualists" promoting plant growth by hormonal feedback mechanisms and, as previously proposed, also due to nutrient effects based on nutrient release from grazed bacterial biomass, i.e., the microbial loop. There are undoubtedly multiple synergistic effects in the plant-protozoan association, but the preponderance of evidence, both experimental and from field studies, indicates that there is a mutual enhancing effect through the association of these two very diverse biotas.

Maintenance and Cultivation

Detailed instructions for collecting and laboratory cultivation of amoebae have been published by Page (1988). Some general information is presented here. A good source for collecting amoebae is the organic debris and decaying plant material usually present in the sediment of shallow ponds. Collect some of the debris from the pond using any convenient container such as a small plastic pitcher with a handle, or a large cup. Gently suspend the debris in the water and pour small portions into shallow culture dishes (e.g., 9 cm plastic or Pyrex Petri dishes). Keep the dishes

covered to prevent excessive evaporation and possible increase in solute and nutrient concentrations. Maintain a temperature in the range of 25°C. Avoid direct sunlight to prevent overheating. After several days, when the preparation has become more stable, add a small segment of a heat-killed wheat seed or a small rice grain to serve as a source of nutrients for food bacteria for the amoebae (wheat seeds and contaminant-free rice grains are available from organic food stores or from biological supply houses). After about 1–2 weeks, withdraw some water from the bottom of each dish and examine it with a microscope. Phase-contrast microscopes are preferred for visualization of smaller flattened amoebae. A 40x objective is usually necessary. If you find that there are sufficient amoebae to be visualized within a few milliliters of water, you can transfer aliquots into new culture dishes. Try to include some of the organic debris when making the transfer so there will be an initial source of food for the amoebae, and add a freshly prepared portion of a wheat seed, or rice grain, to the new dish. Usually, within a week to 2 weeks, you should obtain a fairly robust culture that can be maintained by periodic transfer of aliquots to new culture dishes prepared as above. Sometimes, a better yield of amoeba growth is obtained if you use a cube of nutrient-enriched agar to promote bacterial growth, instead of, or in combination with, wheat seed. Prepare the agar as follows: fully dissolve 0.1 g of malt extract and 0.1 g of yeast extract in 1 L of water from the culture site, or a good grade of noncarbonated bottled springwater may also suffice. For convenience, take a 100 mL portion and add 1.5 g of non-nutrient agar. Gently heat until the agar becomes a sol (a microwave oven is often preferable to prevent overheating the agar). Care must be taken not to allow the agar to froth and boil over. The agar sol is poured into a clean or preferably sterile Petri dish to about ¼ depth and solidified. The Petri dish can be wrapped in plastic film and kept in the refrigerator until needed. Portions about 1 cm square are cut from the solidified malt/yeast agar preparation and added to your culture dishes as a source of nutrients for food bacteria. You may increase the concentration of the malt and yeast extract twofold if you want a slightly more robust source of nutrients.

An improved yield of amoeba growth may be obtained by using one of several mineral media (Page 1988) such as modified Neff's amoeba saline. Prepare each of the following stock solutions by dissolving in 100 mL of glass-distilled water.

NaCl	1.20 g
$MgSO_4 \cdot 7H_2O$	0.04 g
$CaCl_2 \cdot 2H_2O$	0.04 g
Na_2HPO_4	1.42 g
KH_2PO_4	1.36 g

Prepare the final dilution by adding 10 mL of each stock solution to enough glass-distilled water to make 1 L. The very slightly saline solution reduces osmotic stress for some amoebae, but the culture medium must be prepared exactly as prescribed. You may be able to obtain a high quality of bottled distilled water at a local pharmacy or food store, but caution must be exercised to ensure that the water is as pure as possible.

Living amoeba cultures are available from biological supply houses and some culture collections. If you prefer to pursue your own collections, a key to success is to try collecting from a variety of sites to ensure as much diversity as possible. Avoid contaminating the cultures with toxic substances introduced in unclean containers or from impure water used to make the culture media. Persistence often leads to success if a good natural source of sample material is located. If you choose to sample brackish or marine sites, prepare your culture media using water from the source, again trying to find samples from rich organic sediments or where you see organic floc or plant debris. In general, whatever your source for samples, do not put too much debris in your culture dishes when you transfer your suspension; otherwise, an overgrowth of bacteria may make the culture medium too acidic and/or too anoxic for good amoeba growth.

Evolutionary History: In Light of Molecular Phylogenetics

The naked amoebae, without a substantial enclosing test or shell, leave no trace in the microfossil record, and therefore their evolutionary history must be inferred from other evidence, including interpretations based on comparative morphology, fine structure, life histories (e.g., Schönborn 1989; Schuster 1979, 1990), and, more recently, the significant insights obtained from molecular phylogenetics (e.g., Minge et al. 2009; Tekle et al. 2008). Testate amoeba tests are well preserved in some environments and provide a fairly robust microfossil record (Deflandre 1953). Classical evidence (e.g., Bradley 1931; Loeblich and Tappan 1964) has also been augmented by modern molecular phylogenetic analyses. Some of the most ancient microfossil specimens are from the middle Eocene epoch and are similar to extant species, including approximately 24 species (e.g., Schuster 1990). Moreover, fossils resembling the tests of lobose testate amoebae have been reported from the 740 MYA Chuar formation (Porter and Knoll 2000; Porter et al. 2003).

Although the evolutionary roots of the naked amoebae remain obscure, there is emerging strong molecular genetic evidence that they arose from flagellated ancestors (Cavalier-Smith et al. 2014, 2015; Minge et al. 2009; Paps et al. 2013), as previously inferred in earlier treatises (e.g., Bovee and Jahn 1973; Schuster 1990). Whether the naked amoebae (Amoebozoa) are monophyletic or polyphyletic has been a topic of considerable debate (e.g., Bovee and Jahn 1973; Chatton 1953; Page 1976). Currently, there is increasing evidence that the Amoebozoa are monophyletic (e.g., Cavalier-Smith et al. 2015; Lahr et al. 2011; Tekle et al. 2008). The order of evolutionary emergence of the major Amoebozoan groups is not fully resolved, but Tekle et al. (2008) position the Tubulinea at a deeper level in the phylogenetic tree than Flabellinea, and more recently, Cavalier-Smith et al. (2015) place the Discosea near the base of the Amoebozoa.

The Arcellinida (lobose testate amoebae) are grouped within the Tubulinea, with fairly good evidence of monophyly based on ribosomal RNA analyses, but not on actin analyses. The tree of Tekle et al. (2008) places *Echinamoeba* in the Tubulinea,

basal to Leptomyxida, followed by Arcellinida, Hartmannellidae, Amoebidae, and Thecamoebidae. Acanthamoebidae is basal relative to Dactylopodida and Vannellidae. However, this is a rapidly developing field, and further refinements and adjustments are to be expected. Although our knowledge of phylogeny of testate amoebae is advancing, the origin of the test during evolution remains unclear.

Abstract

Protosteloid amoebozoans, formerly called protostelids, are a non-monophyletic assemblage of Amoebozoa where, at one point in their development, an amoeba rounds up on the surface of a substrate and develops into a subaerial fruiting body, or sporocarp. The sporocarp consists of a noncellular, microscopic stalk bearing one to a few terminal spores. Amoeboid states of protosteloid amoebae vary considerably in morphology, and many species have life cycles that include both amoeboflagellates, a cell type that can reversibly transform from amoeba to flagellate, and obligate amoebae, a cell type that exists only as an amoeba. Protosteloid development was first recognized in *Protostelium mycophaga* and has been observed in perhaps 100 species, roughly 40 of which are formally named. Protosteloid amoebae are predators of decomposer bacteria and fungi in terrestrial ecosystems. They are global in distribution. Most are quite easy to isolate and to bring into culture, thus facilitating developmental studies. Sporocarpy, as a mode of development, is found in protosteloid amoebae and in myxogastrids; it is exclusive to Amoebozoa. This raises the question whether it is

a homologous process or whether it has arisen independently multiple times within Amoebozoa. If the former proves to be the case, it would suggest that the last common ancestor of Amoebozoa must have had a sporocarp in its life cycle.

Introduction

General Characteristics

Protosteloid amoebozoans, formerly called protostelids (see Shadwick et al. 2009b), are a non-monophyletic assemblage of terrestrial protists found in both major subgroups of Amoebozoa, Conosa, and Lobosa (sensu Smirnov et al. 2011; Cavalier-Smith et al. 2015). They are considered together in this chapter because of their morphological and ecological similarity. All have an amoeboid trophic stage, or stages, that live primarily as predators of decomposer microorganisms in terrestrial habitats, and one of those amoeboid stages can develop into a stalked, spore-dispersal structure, or fruiting body, called a "sporocarp" in the terminology of Olive (1975). Sporocarps of protosteloid amoebae typically are morphologically similar, consisting of a microscopic stalk bearing a single spore or a few spores, while the amoebae are quite morphologically variable from taxon to taxon (Figs. 1, 2, 3, and 4). Sporocarpy, where a fruiting body develops from a single amoeboid cell, is a form of development that is only seen in Amoebozoa.

The taxon Eumycetozoa (sensu Olive 1975, Adl et al. 2012) was established to include the monophyletic and sporocarpic plasmodial slime molds, Myxogastria or myxomycetes (see ▶ Myxomycetes), the monophyletic and sorocarpic dictyostelid cellular slime molds, Dictyostelia (see ▶ Dictyostelia), and what Olive described as a paraphyletic assemblage of sporocarpic mycetozoans that he called Protostelia, or protostelids. The unifying characters of Eumycetozoa according to Olive were (1) amoeboid trophic cells with acutely pointed subpseudopodia, (2) mitochondria with tubular cristae (Olive 1975; Dykstra 1977), and (3) the ability to fruit by producing stalked, spore-bearing structures (though stalks are absent in some myxomycetes). Of the Eumycetozoa, sensu Olive, protostelids have the simplest fruiting bodies, or sporocarps (Olive 1975; Spiegel 1990; Spiegel et al. 2004; Shadwick et al. 2009). They develop from single amoebae or from nucleated fragments of

(**f)** Amoeba of *P. mycophaga* showing morphology typical of Protosteliida. (**g)** Biflagellated amoeboflagellate of *Pl. aurantium*. (**h–l)** Protosteloid Fractovitelliida. (**h**, **i)** Two views of sporocarps of *Soliformovum expulsum* showing bipartite stalk. (**j)** Sporocarp of *S. irregularis*. (**k)** Locomoting amoeba of *S. irregularis* showing morphology typical of genus. (**l)** Early prespore cell of *S. irregularis* showing morphology diagnostic of genus. (**m–v)** Schizoplasmodiida. (**m)** Sporocarp of *Ceratiomyxella tahitiensis*. Sporocarps of this species and *Nematostelium gracile* are indistinguishable from each other. (**n)** Sporocarps of *N. ovatum*. (**o)** Plasmodial obligate amoeba of *C. tahitiensis* cleaving into three prespore cells (*top*) and three rising sporogens (*below*). This mode of development is characteristic of all Schizoplasmodiida.

multinucleate amoebae and consist of a microscopic stalk that supports one or a few walled spores (Figs. 3 and 4). In the last edition of this Handbook, Spiegel (1990) suggested that most protostelids were members of a paraphyletic assemblage in a monophyletic Eumycetozoa but held out the possibility that some purported protostelids were not closely related to other fruiting amoebae at all. Initial molecular phylogenies, which included only single species of protostelids, gave some support to the taxon Eumycetozoa that contained protosteloid amoebae, myxomycetes, and dicytostelids (Spiegel et al. 1995a; Baldauf and Doolittle 1997; Baldauf et al. 2000). However, phylogenetic work with more species of purported protosteloid amoebae and a large set of other amoebozoans shows that organisms that had been called protostelids appear in several lineages of the taxon Amoebozoa (Shadwick et al. 2009b; Fiore-Donno et al. 2010; Lahr et al. 2011b; Kudryavtsev et al. 2014). For that reason it is now preferred to designate sporocarpic amoeboid organisms that have simple, microscopic, stalked sporocarps as "protosteloid amoebae" (Shadwick et al. 2009b). Regardless of their phylogenetic affinities, all protosteloid amoebae occur in

Fig. 1 (continued) When large plasmodia cleave, gregarious fruiting occurs. (**p**) Complete sporocarp of *Schizoplasmodium cavostelioides* with spore expulsion droplet on right side. Stalks from which spores have been expelled are visible to top right and lower left of intact sporocarp. All species of *Schizoplasmodium,* as used in this chapter, have the droplet-mediated forceful expulsion of spores. (**q**) Sporocarp of *S. seychellarum* with spore expulsion droplet on upper left of spore. (**r, s**) Expelled spore of *S. obovatum* on agar surface. Stalks are identical to those of *S. cavostelioides*. (**t**) Shed spore of *S. cavostelioides* is oriented such that the annular hilum associated with the spore/stalk articulation is visible. This hilum is characteristic of all schizoplasmodiids. Sporocarps of all schizoplasmodiids have highly deciduous spores such that they are often first recognized by shed spores such as these. (**u**) Amoeboflagellate of *C. tahitiensis.* (**v**) Plasmodial amoeba of *S. seychellarum*, as typical of all schizoplasmodiids. Upper flabellate portion is free of bacteria, and highly reticulate veins are immersed in colony of bacteria. This is the only trophic stage reported in *Schizoplasmodium* spp. and *Nematostelium* spp. as here defined. It represents the obligate amoeba stage in the life cycle of *C. tahitiensis.* (**w–aj**) Cavostellida. (**w**) Sporocarps of *Cavostelium apophysatum.* (**x**) Triflagellate amoeboflagellate of *C. apophysatum*. (**y**) Obligate amoebae of *C. apophysatum.* (**z**) Sporocarps of *Schizoplasmodiopsis pseudoendospora.* (**aa**) Highly reticulate plasmodial amoeba of *S. pseudoendospora.* This can be distinguished from schizoplasmodiid plasmodia because it is always reticulate and never flabellate. (**ab**) Sporocarp of *S. vulgare.* (**ac**) Sporocarp of *S. reticulata.* (**ad**) Amoeba of *S. vulgaris*, typical also of *S. reticulata*, showing highly branched pseudopodia that may form reticulations. Amoebae may have less extended pseudopodia under some conditions. (**ae**) Sporocarp of *Schizoplasmodiopsis micropunctata*. (**af**) Sporocarps of *Tychosporium acutostipes.* (**ag**) Spore of *T. acutostipes* showing craterlike hilum, typical also of *S. micropunctata*. (**ah**) Amoeba of *T. acutostipes*, also typical of *S. micropunctata.* (**ai**) Sporocarp of *Schizoplasmodiopsis amoeboidea*. (**aj**) Amoeba of *S.* amoeboidea. Note diffuse nucleolus. (**ak–aq**). Protosporangiida, Protosporangiidae. (**ak**) Two-spored sporocarp of *Protosporangium articulatum* with two spherical spores. (**al**) Two-spored sporocarp of *P. bisporum* with two hemispherical spores. (**am**) Four-spored sporocarp of *P. conicum*. (**an**) Four-spored sporocarps of *P. fragile.* (**ao**) Amoeboflagellate of *P. articulatum*, typical of morphology of all members of Protosporangiidae. This example has two apical kinetids with the long flagellum two of each one apparent. Supernumerary kinetids are common in this group. (**ap**) Obligate amoeba of *P. articulatum*, typical for the Protosporangiidae. (**aq**) Sporocarps of *Clastostelium recurvatum*

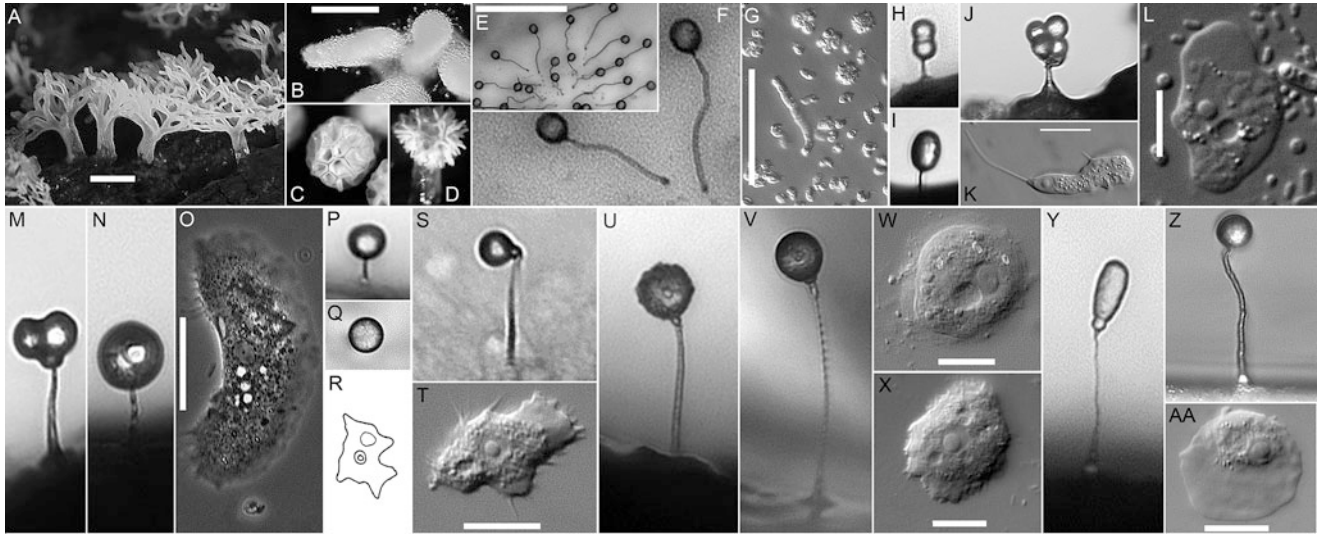

Fig. 2 All presently described species of *Ceratiomyxa*, Protosporangiida, Macromycetozoa (**a–g**), protosteloid and protosteloid-like Myxoagastria, Macromycetozoa (**h–l**), protosteloid Amoebozoa incertae sedis (**m–r**), and protosteloid Discosea (except *Luapeleamoeba hula*) (**s–aa**). (**a–g**) Protosporangiida, *Ceratiomyxa*. (**a**) Macrophotograph of fructification of *C. fruticulosa* showing multiple, arborescent slime columns. (**b**) Detail of slime columns of *C. fruticulosa* showing silhouettes of individual protosteloid sporocarps. (**c**) Fructification of *C. morchella*. (**d**) Fructification of *C. sphaerocephalum*. (**e**) Portion of simple fructification of *C. hemisphaerica* showing gregarious sporocarps on small, subtle slime mound. (**f**) Two individual sporocarps of *C. hemisphaerica*. (**g**) Low power overview of stages of spore germination and amoeboflagellate development in *C. fruticulosa*. In this developmental process, typical of the genus, the tetranucleate germling emerges from the spore as a vermiform cell, rounds up, undergoes a round of mitosis, and then forms eight lobes that separate as individual amoeboflagellates. (**h–l**) Protosteloid Myxogastria, *Echinostelium*. (**h**) Sporocarp of *E. bisporum* with the sheath (peridium) dehydrated showing two spores of sporangium in linear array. (**i**) Sporocarp of *E. bisporum* with hydrated sheath making it difficult to see the spores of the sporangium. (**j**) Sporocarp of the nonprotosteloid myxogastrid, *E. lunatum*, for comparison. (**k**) Flagellated amoeboflagellate of *E. bisporum*. (**l**) Amoeboflagellate of *E. bisporum* in the nonflagellate condition. (**m–r**) Incertae sedis protosteloid amoebozoans. (**m–o**) *Echinosteliopsis oligospora*. (**m**) Four-spored sporocarp with dehydrated sheath. (**n**) Sporocarp with hydrated sheath. (**o**) Amoeba. (**p–r**) *Microglomus paxillus*. (**p**) Sporocarp. Note faint vertical line delimiting spores in the sporangium.

similar habitats and fruit with sporocarps that are morphologically quite simple when compared with most myxogastrids or dictyostelids. However (see below), because being protosteloid is a morphological state and not a taxonomically significant designation, there are some myxogastrids that are also protosteloid, and they are thus included in this chapter (Fig. 2h, i, k, l).

Because species of protosteloid amoebae are difficult to identify with any certainty in the trophic, i.e., amoeboid, stage of the life cycle, the most effective way to find a protosteloid amoeba is to observe its sporocarps on natural substrates under a microscope (Spiegel et al. 2005). The sporocarp develops as follows: a trophic cell rounds up to become one or more prespore cells (Figs. 3d and 4m), rises at the tip of a delicate stalk during the culminating sporogen stage (Figs. 3e and 4n), and

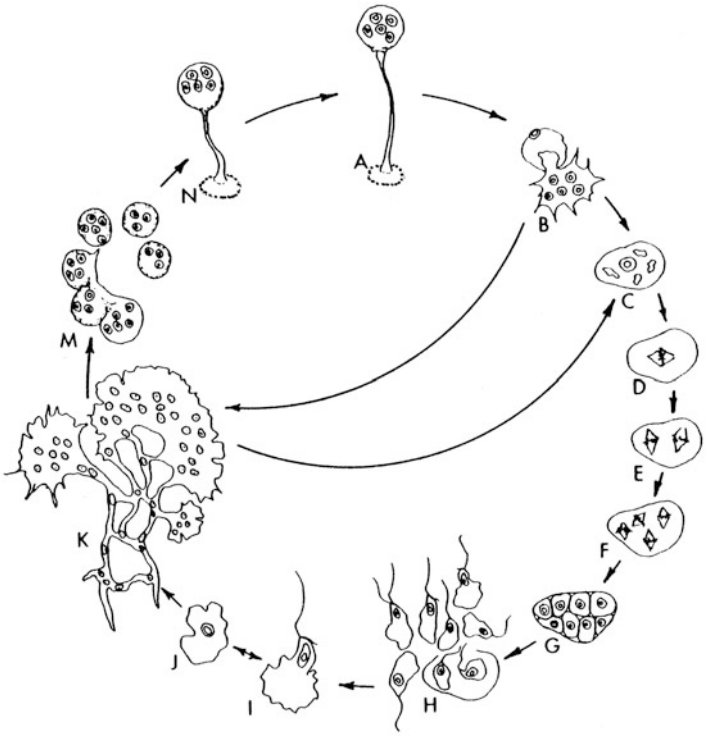

Fig. 4 Complex life cycle of *Ceratiomyxella tahitiensis*: (**a**) sporocarp; (**b**) germinating protoplast; (**c**) all but one of the nuclei degenerating in protoplast, or portion of plasmodium, which is converting into zoocyst; (**d–f**) three nuclear divisions in zoocyst; (**g–h**) eight or fewer flagellate cells cleaving and germinating from zoocyst; (**i–j**) amoeboflagellate stage; (**k**) plasmodium; (**m**) plasmodium cleaving into prespore cells; (**n**) rising sporogen. (**n, b**) the simple life cycle of *Nematostelium gracile* and all other schizoplasmodiids would jump from stage c to stage k with no development of an amoeboflagellate

develops a cell wall to form one or more spores at the apex of the mature stalk (Figs. 1, 2, 3a, and 4a). As stated above, sporocarps alternate in the life cycle with an amoeboid trophic stage, and the life cycle may be simple, with only one type of trophic cell (Fig. 3), or complex, with several types of trophic cells (Fig. 4). In complex life cycles, there is alternation between an amoeboflagellate (amoebomastigote) state and an "obligate amoeba" state (see Spiegel et al. 1995a), with the former associated with spore germination and the latter developing from the amoeboflagellate and subsequently producing the prespore cells. Such a life cycle is consistent with sexuality. Sex is confirmed (sensu, Lahr et al. 2011a; Spiegel 2011) in myxogastrids but has yet to be fully confirmed in other sporocarpic amoebozoans. However, synaptonemal complexes, structures associated with meiosis, have been reported in *Ceratiomyxa* (Furtado and Olive 1971) and *Protosporangium* (Bennett 1986a). Possible syngamy has been reported in *Ceratiomyxa* (Olive 1975; Spiegel 1981a). *Cavostelium* and *Ceratiomyxella* appear likely to be sexual, but direct

evidence has yet to be found. In simple life cycles with a single type of amoeba, that amoeboid state may be derived from an amoeboflagellate or from an obligate amoeba (see Spiegel et al. 1995). Most protosteloid amoebae with simple life cycles appear to be asexual, but one taxon with a simple life cycle, *Microglomus*, has been reported to have synaptonemal complexes in its developing sporocarp, indicative of meiosis and a possible sexual life cycle (Olive et al. 1983).

As of this moment, there are 37 morphologically defined species of protosteloid amoebae that have been described formally. Of these 37, 33 are microscopic species (Figs. 1 and 2), i.e., their fruiting bodies can only be adequately resolved with the compound microscope (Spiegel et al. 2007). There are 19 genera, and protosteloid species are found among nine well-supported clades of Amoebozoa (Table 1). Five of these clades are exclusively sporocarpic, while the remaining four contain both sporocarpic and non-fruiting taxa. Two protosteloid species are incertae sedis. Revisionary work still underway suggests that several species may be complexes of cryptic species and that several genera are non-monophyletic as originally conceived. In addition, there are new protosteloid amoebae constantly being found that need formal descriptions. Therefore, the taxonomy of these organisms is still fluid, and it is likely that over 100 species will eventually be described.

Occurrence

Protosteloid amoebae occur as predators of bacteria and fungi on decaying plants in both terrestrial (see Spiegel et al. 2004) and freshwater (Lindley et al. 2007; Tesmer and Schnittler 2009) ecosystems, though they are only known to fruit subaerially, i.e., at the substrate/air interface. They have been found in all habitats where there are decaying plants, ranging from the Antarctic Peninsula to the subarctic (Fig. 5), and they appear to be most abundant in North Temperate to tropical latitudes. Microhabitats in which they occur include aerial, dead primary tissues of plants (i.e., dead pieces still attached to a standing plant), similar tissues in the ground litter, bark of

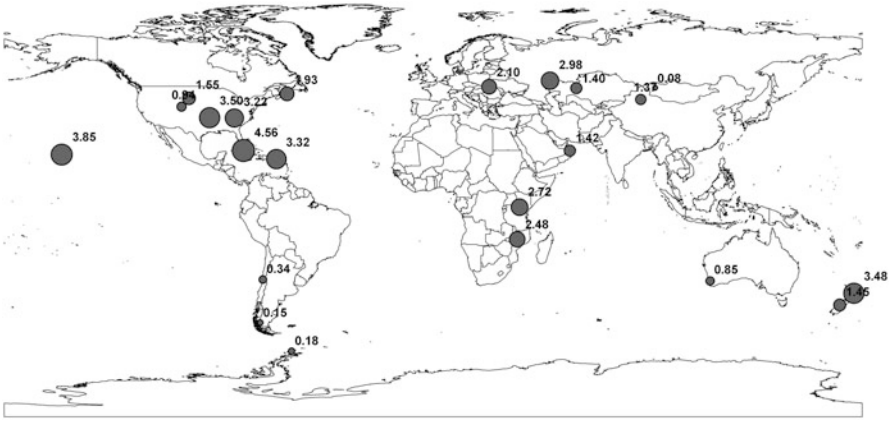

Fig. 5 Map of global collections showing mean number of species of protosteloid amoebae per collection. Though collection effort per country or state varied, there are enough collections associated with each to give at least a qualitative impression that protosteloid amoebae are ubiquitous and that they are more common in some parts of the world than in others

living trees, bark on decaying logs, decaying wood on both standing and fallen trees, herbivore dung, decaying plant parts submerged in freshwater, occasionally the surfaces of living leaves, and occasionally soil.

The most extensive collections of protosteloid amoebae are housed in the F.W. Spiegel lab at the University of Arkansas and the M.W. Brown lab at Mississippi State University, where both active and liquid nitrogen-frozen cultures are maintained. In addition, a number of species are available at the American Type Culture Collection's Eumycetozoan Special Collection, and others are available at the Culture Centre for Algae and Protozoa in the United Kingdom. There are plans to submit additional cultures to CCAP.

Literature

Most of the literature on the taxonomy and systematics of protosteloid amoebae is from the lab of the late L.S. Olive (see Olive 1967, 1970, 1975, 1982) and the lab of F.W. Spiegel (see Spiegel 1984, 1991; Spiegel et al. 1994, 1995a, b, 2004, 2006; Shadwick et al. 2009b, 2016; Adl et al. 2012; Schnittler et al. 2012; Tice et al. 2016). Prior to 1975 most work on the development and ultrastructure of protosteloid amoebae was done by Olive's group (see Olive 1975). After 1975, important publications on ultrastructure and development were carried out by M.J. Dykstra, K.D. Whitney, and members of the Spiegel lab, which are all cited in Spiegel et al. (1995a) and Shadwick et al. (2009b). Ecological research on protosteloid amoebae was pioneered by D.L. Moore, and this work is summarized in Spiegel et al. (2004). After 2004, most work on ecology has been done in association with the Spiegel lab and collaborators (Tesmer et al. 2005; Aguilar et al. 2007, 2011; Lindley et al. 2007;

Ndiritu et al. 2009; Shadwick et al. 2009a; Zahn et al. 2014). No work has been published on the physiology, biochemistry, or genetics of protosteloid amoebae. The best web resource for protosteloid amoebae is the *Eumycetozoan Project* (http://slimemold.uark.edu). It includes identification guides, guides to literature, culturing guides, and interactive maps.

History of Knowledge

The protosteloid amoebae were first recognized by L.S. Olive and C. Stoianovitch in 1959 when they discovered *Protostelium mycophaga*, along with the heterolobosean sorocarpic amoeba *Acrasis rosea* (Olive and Stoianovitch 1960). This was the beginning of a collaboration that lasted almost 25 years, during which the protosteloid amoebae were recognized to be morphologically diverse and ubiquitous members of the decomposer community. Most work on protosteloid amoebae that was not carried out by Olive and Stoianovitch has been done by his students, M.J. Dykstra, K.D. Whitney, W.E. Bennett, and F.W. Spiegel. Since the early 1980s, much work has involved Spiegel's students S.C. Gecks, L.D. Smith, R.N. Bortnick, D.L. Moore, J.D. Shadwick, L.L. Shadwick, G. Ndiritu, and M.W. Brown and collaborators, J. Feldman, D.E. Hemmes, S.L. Stephenson, J. Tesmer, M. Schnittler, C. Lado, and M. Aguilar. Recently, M.W. Brown has set up a lab at Mississippi State University that has become an important site of research on protosteloid amoebae, as well as Amoebozoa in general.

Practical Importance

To date, protosteloid amoebae have been treated as a somewhat esoteric group of relatively little importance because none are known to be pathogens of plants or animals. However, protosteloid amoebae are ideal organisms for studying cell motility and the evolution of cell motility systems (Spiegel, 1981b, 1982a, b; Spiegel et al. 1979, 1986). The actin-myosin-driven process of sporocarp culmination (Spiegel et al. 1979) is a useful model for contractile systems in non-muscle cells, and the variations in kinetid (i.e., flagellar apparatus) structure provide a model for relating rootlet structure to function (Spiegel 1981a, b, 1982a; Spiegel et al. 1986; Spiegel and Feldman 1989). Variations in nuclear division may be useful in understanding structure/function relationships in the mitotic spindle (Spiegel 1982a; Spiegel et al. 1986; Spiegel and Feldman 1986). They are also potentially useful for studying the evolution of amoeba morphology (Spiegel and Feldman 1985; Spiegel et al. 1995a). These organisms appear to make up a major portion of the amoeboid component of the decomposer community, where they feed upon bacteria and fungi (see Spiegel et al. 2004). It is quite possible that they may be involved in controlling populations of bacteria (Olive and Whitney 1982) and fungi (Feest 1987), some of which may be pathogenic. Certainly, much more work is needed to determine the practical ecological importance of protosteloid amoebae. The wide

distribution of amoebozoans with protosteloid fruiting is particularly interesting to understand. If protosteloid fruiting, a phenomenon found only in Amoebozoa, were to be demonstrated to be homologous, that would suggest that this developmental process was found in the last common ancestor of extant amoebozoans (Shadwick et al. 2009; Adl et al. 2012; Spiegel 2016).

Habitats and Ecology

A great deal has been learned about several aspects of the ecology of protosteloid amoebae since the last version of this Handbook (Spiegel 1990). There is still much to learn, however.

Protosteloid amoebae typically are found by bringing potential substrates into the laboratory, keeping them in moist chambers, and examining them under the microscope for the presence of sporocarps (Olive 1975; Spiegel et al. 2004, 2005, 2007). This technique is necessary because all species are microscopic, with the exception of the three larger species of *Ceratiomyxa*. However, Olive (1975) and Olive and Stoianovitch (1972) reported seeing blooms on rotting wood that microscopic examination showed to be large numbers of sporocarps of *Protosporangium* spp.

Substrates that have proven to yield protosteloid amoebae consistently include aerial portions of dead or dying plants that have begun to decay but have not fallen to the ground, decaying plants in the litter, herbivore dung, bark of living and dead trees, and rotting wood. In such substrates, there are large numbers of bacteria and fungi present to serve as a food source. The vast majority of described species of protosteloid amoebae have been found on dead plant parts made up of primary tissues, in both the aerial litter and ground litter microhabitats (see Spiegel et al. 2004). However, in some habitats the assemblages of species occurring in the two microhabitats may differ considerably (see Spiegel et al. 2004; Shadwick et al. 2009). Another source of protosteloid amoebae is the bark of living trees (Olive 1975; Best and Spiegel 1984; Spiegel et al. 2004). Pieces of bark from trees with coarse bark from North Temperate regions kept in a moist chamber for several days will almost always have one or more species present. However, smooth-barked trees, trees from the tropics, and trees from South Temperate regions appear to be much less likely to support protosteloid amoebae. Species of *Protosporangium* are most commonly found on bark. Unfortunately, bark-inhabiting protosteloid amoebae are very difficult to isolate and maintain in cultures; this is true even for species that are easy to isolate when they occur on other substrates (Olive 1975). Of the other substrates, one species, *Protosteliopsis fimicola* (which will shortly be reassigned to *Vannella*; see Shadwick et al. 2009b), is relatively common on herbivore dung. *Protosporangium fragile* and *Ceratiomyxa* spp. occur on rotting wood. In fact, the macroscopic *Ceratiomyxa fruticulosa*, which occurs on rotting wood, is probably the most commonly encountered slime mold (in the broad sense) on earth (see ▶ Myxomycetes). Protosteloid amoebae are rarely reported in humus and soil (Olive 1975; Feest 1987).

Protosteloid amoebae have been recorded from all major types of terrestrial biomes and from all continents (Fig. 5). Early collecting by Olive focused primarily on the Eastern United States and the tropical Pacific, with various additional collections in Australia, New Zealand, Southeastern Asia, Africa, and Western Europe. Other than mention of the detailed locations for nomenclatural types, most discussion of distribution of these early collections is very general. More detail is available in Olive's unpublished collecting notes at the Southern Collection of the Library at the University of North Carolina at Chapel Hill, though there are no truly quantitative data. The first quantitative data on protosteloid amoebae were presented by Best and Spiegel (1984) for temperate habitats in southwestern Ohio, followed by the work of Moore and several coworkers (see Spiegel et al. 2004) who studied the rates at which sterilized substrates were colonized by protosteloid amoebae when introduced to the environment. At present the Spiegel lab is in the process of a global biodiversity inventory of all purportedly eumycetozoan organisms, including all the protosteloid amoebae. Records of several thousand observations from around the world are available with interactive maps at the *Eumycetozoan Project* website (http://slimemold.uark.edu).

As large collection databases are being developed, it is becoming possible to discern some information about the biogeography of protosteloid amoebae in general (Fig. 5 and see Table 2 in Ndiritu et al. 2009):

1. In essentially all latitudes where dead, decaying vegetation occurs in terrestrial (and freshwater) habitats, at least some species of protosteloid amoebae can be found (Fig. 5).
2. Geographic isolation seems to be no barrier to their potential dispersal, since all described microscopic species have been found in high abundance in the Hawaiian Islands (Fig. 5), the most remote archipelago on earth. They have also been collected throughout Polynesia and Micronesia (Olive 1975) and in subantarctic islands (Spiegel and Stephenson 2000).
3. In general, species richness appears to be highest at tropical and temperate latitudes (Fig. 5), with lower species richness at high latitudes. However, species richness is lower than might be expected in southern South America. It is also low in parts of Central Asia.
4. Though species richness seems relatively uniform, the abundance of protostelids appears to be quite variable (Ndiritu et al. 2009). The average number of species per collection is highest in the moist tropics and forested, mesic habitats in North America, relatively high in western Eurasia, lower in drier to arid parts of the Northern Hemisphere, and lowest in southern South America. Until careful ecological analyses of these collections are completed, these patterns cannot be confidently explained.
5. Collections taken from around the world from above an altitude of 3000 m almost never yield protosteloid amoebae. There is presently no explanation for this phenomenon.

Table 2 Media useful for isolating and cultivating protostelids

Medium	Ingredients added to 1 L distilled water
wMY[a, b]	0.002 g malt extract, 0.002 g yeast extract, 0.75 g K_2HPO_4, 15–20 g Difco Bacto agar (Either the malt extract or yeast extract or both may be left out to little effect. Too much of either is more of a problem than too little.)
HI[b, c]	2.5 g hay infused in water, remove hay, adjust volume back to 1 L, add 15–20 g Difco Bacto agar
OB[b,c]	2.5 g white oak bark infused in water, treat as above
CM+	17.5 g Difco cornmeal agar, 2.0 g glucose, 2.25 g yeast extract
Liquid medium[d]	2.5 g peptone, 0.5 g yeast extract, 1.0 g glucose, 2.25 g KH_2PO_4, 0.5 g K_2HOP_4, 0.2 g $MgSO_4 \cdot H_2O$

[a]The standard medium in the Spiegel lab
[b]pH may be adjusted as desired, usually with lactic acid and NaOH
[c]Infusions may be made of other plants and types of bark
[d]The salts from this medium make a useful buffer

Olive (1975) stated that some species were abundant, others common, others occasional, and some rare. However, until the work of Best and Spiegel (1984), there were no quantitative data to support these conclusions. Even examination of Olive's unpublished collection records suggests that his group did not keep detailed information on the frequency with which species were observed; rather, they recorded only the occurrences that had particular interest to them. With the advent of the ecological studies of Moore (see Spiegel et al. 2004), a standard for describing species as abundant, common, occasional, or rare was established. An abundant species is one in which at least 10% of collections support the species, common >5–<10%, occasional >1–<5%, and rare <1%. From the set of 3535 collections used to generate Fig. 5, the two most abundant morphological species, globally speaking, are *Protostelium mycophaga* (39%) and *Schizoplasmodiopsis pseudoendospora* (34%). Other globally abundant species are *Schizoplasmodiopsis amoeboidea* (24%), *Soliformovum irregularis* (22%), *Nematostelium gracile* (including *Ceratiomyxella tahitiensis*) (22%), *Cavostelium apophysatum* (13%), *Schizoplasmodiopsis vulgare* (11%), *Luapeleamoeba* (as *Protostelium*) *arachisporum* (11%), and *Nematostelium ovatum* (10%). Globally, common species are *Protostelium nocturnum*, *Soliformovum expulsum*, *Echinosteliopsis oligospora*, *Schizoplasmodium cavostelioides*, *Tychosporium acutostipes*, *Endostelium zonatum*, *Acanthamoeba* (as *Protostelium*) *pyriformis*, and the myxogastroid *Echinostelium bisporum*. Because the vast majority of these collections consist of primary plant tissues from the aerial and litter microhabitats, bark specialists and dung specialists are underrepresented. Of the bark-preferring species, *Protosporangium articulatum* is the most common, while *Protosteliopsis fimicola* is the most common species found on herbivore dung.

However, although the ability of protosteloid amoebae to be dispersed to isolated archipelagoes is established, and although it is possible to make global generalizations about the abundance of particular species of protosteloid amoebae (Ndiritu et al. 2009), it is becoming clear that many species show biogeographic patterns. For

instance, even though *Protostelium mycophaga* (Figs. 1b and 3) is the most common species of protosteloid amoebae globally, it is not equally common everywhere. It occurs with high frequency in temperate North America and western Eurasia, Hawaii, East Africa, and New Zealand; however, it occurs at much lower frequency in southern South America, Western Australia, Oman, and Central Asia. Where it is uncommon, it is likely that there is no single explanation. For instance, in southern South America, all protosteloid amoebae are very uncommon, yet *P. mycophaga* is the most frequently found species, while in Oman and Central Asia, *P. mycophaga* is found much less frequently than other species. Another example of an abundant species with a distinct biogeographic pattern is *Nematostelium ovatum* (Fig. 1n). This species is most frequently found in Northern Hemisphere sites, especially in temperate forested areas and tropical sites. The only major habitat where it is not found abundantly is open grassland (see also Moore and Spiegel 2000c), though it is not uncommon in some deserts. However, with the exception of the North Island of New Zealand, *N. ovatum* is rare or absent from high southern latitudes, with the southern end of the North Island of New Zealand being the southernmost point where it is found. Our collecting efforts are reaching a level where it is possible to identify the biogeographic patterns of at least the abundant and common protosteloid amoebae even if we do not yet have any explanation for these patterns. Other information on other species is covered below in the section "Characterization and Recognition."

On a finer scale, Olive's work (see Olive 1975) suggested that various species were likely to be found in some microhabitats more than others. This was first borne out quantitatively in the work of Best and Spiegel (1984) which showed that some species were much more likely to occur on aerial dead plant parts than on bark, while others, such as species of *Protosporangium*, almost exclusively inhabit bark, as had been suggested by Olive's work. Moore (see Spiegel et al. 2004) was first to show that aerial and ground litter microhabitats from the same habitat could yield consistently different assemblages of protosteloid amoebae. As a rule, work over the last 20 years has shown general patterns for at least the common and abundant species that are covered below in section "Characterization and Recognition."

Spores of protosteloid amoebae are readily dispersed. Work by Moore and Spiegel (see Spiegel et al. 2004), which monitored colonization of sterilized wheat straws placed in the field, showed that dead, primary plant tissues could be colonized by protosteloid amoebae and their prey microorganisms in as little as 1 week (see Spiegel et al. 2004), and it has been noticed subsequently that some substrates can be colonized within 24 h (J. Shadwick, unpublished). Spores of protosteloid amoebae may be deciduous or nondeciduous. It is likely that the deciduous species are air-dispersed, at least in part. Tesmer et al. (2005) present evidence that strongly suggests that air dispersal is sufficient to account for the colonization of European beech leaves by *Protostelium mycophaga*. Many species of protosteloid amoebae produce forcibly ejected and dispersed spores, using a number of different mechanisms (see Spiegel et al. 1994, 2006). It is likely that these dispersal mechanisms serve to lift spores above the boundary layer of the substrate. In fact, all deciduous species with sporocarps under 40 μm tall appear to have forcible spore discharge.

Sporocarps of nondeciduous species, and perhaps spores and sporocarps of some deciduous species, may be dispersed by small arthropods and other invertebrates, by myxomycete plasmodia, or by water dispersal. All these mechanisms have been seen in culture plates and "primary isolation plates" (see section "Maintenance and Cultivation", below). Small invertebrates moving about on plates often become covered with spores and sporocarps and deposit them as they move about. During a bad mite infestation in working cultures that occurred in the Spiegel lab, the mites carried species from one plate to another. In one case, a millipede captured in the field and allowed to walk across an agar plate was found to be carrying *Schizoplasmodiopsis vulgare* (M.W. Brown, unpublished). Myxomycete-facilitated dispersal occurs when sporocarps of protosteloid amoebae float up upon the outer surface of plasmodia that migrate into them and then are carried some distance until they are deposited in the slime trail the plasmodium leaves behind (Spiegel, unpublished). Water dispersal is effected by sporocarps floating on their hydrophobic basal disks and being carried along by the flow (Spiegel, unpublished).

If one collects substrates throughout the year, it is possible to find species of protosteloid amoebae on them. However, if one introduces sterile substrates into the environment, then one finds that their dispersal is seasonal. Moore and Spiegel (see Spiegel et al. 2004) found that sterilized wheat straws were colonized about four times as frequently during the summer as the winter in Northwest Arkansas. This suggests that although protosteloid amoebae are present in winter, they are most likely to be in dormant states and that they are active and producing dispersal states, presumably fresh spores, only in warmer months.

Future work should include environmental sequencing because it may yield additional detail on the ecology of protostelids that cannot be discovered if they are not observed to be fruiting.

Characterization and Recognition

The *sine qua non* of protosteloid amoebae is the sporocarp, consisting of a delicate stalk that bears one to four spores or sometimes more (Figs. 1 and 2). These organisms are found by direct observation of their sporocarps that have developed on bits of natural substrate on primary isolation plates (see section "Maintenance and Cultivation"). Although sporocarps are superficially similar to the simple sporangia and conidiophores of some fungi, they may be easily distinguished because the fungal structures arise from hyphae and protosteloid sporocarps rest upon basal disks (Olive 1975; Spiegel et al. 2004, 2007). Their appearance is distinct enough that one can quickly learn to recognize protosteloid fruiting bodies on natural substrates. With a few weeks' practice, one can recognize almost all species of protosteloid amoebae by their sporocarps (Figs. 1 and 2; see also Spiegel et al. 2007). This makes it relatively easy to survey the biota of these organisms (see Spiegel et al. 2004; Tesmer et al. 2005; Aguilar et al. 2007).

However, though most species can be identified by fruiting body morphology, life histories must be taken into account both when confirming that an apparent

sporocarp is a protosteloid amoeba and when classifying species into higher groups (see Spiegel et al. 1995a).

For confirmation, especially with apparently undescribed species, spores must be germinated and/or an amoeba must be observed to fruit to confirm that what looks like a sporocarp is actually the fruiting stage of a protosteloid amoeba. Several microfungi produce sporulating structures similar to protosteloid sporocarps (see Olive 1975; Spiegel et al. 2007). Though culturing from spore to spore is ideal, these observations may still be made if culture proves difficult. Often, it is possible to identify the amoebae that produce sporocarps or to recognize the amoebae that germinate from spores on primary isolation plates. In other cases, spore germination can be observed on culture slides or culture plates, even if the whole life cycle cannot be completed in culture. In the latter case, great care must be taken to make frequent observations to be certain that any amoebae observed on a slide or plate actually germinated from the spores in question (Spiegel et al. 2005).

As our knowledge of the molecular signatures of protosteloid amoebae increases, and as our ability to acquire sequences from single spores improves, it will become possible to confirm that fruiting bodies belong to amoebozoans even if amoebae are never seen. For example, it was confirmed that *Endostelium amerosporum* is indeed congeneric with other species of culturable *Endostelium* spp. by acquiring sequence data from single spores (Kudryavtsev et al. 2014). Recent work in M.W. Brown's lab indicates that single-spore sequencing from primary isolation plates has great promise for expanding the ability to identify/confirm new species of protosteloid amoebae from sporocarp observations alone.

At present we accept 37 validly described species of protosteloid amoebae. Most are microscopic in all stages of the life cycle. Thirty-five of the described species fall into well-supported monophyletic groups of amoebozoans that have both morphological and molecular identities (Shadwick et al. 2009b; Lahr et al. 2011a; Adl et al. 2012), and two are considered Amoebozoa of the taxon Conosa, incertae sedis. These are listed below, and their places in the amoebozoan phylogeny-based classification are shown in Table 1:

1. Conosa/Variosea/Protosteliida (Fig. 1a–g) has four species, three in the genus *Protostelium* and one in the genus *Planoprotostelium* that are formally named, and three more that are being described (J. D. Shadwick et al., unpublished). All known species fruit. It corresponds to Group I of Spiegel (1990), minus *Acanthamoeba* (*Protostelium*) *pyriformis*.
2. Conosa/Variosea/Fractovitelliida (Fig. 1h–l) has two named protosteloid species in the genus *Soliformovum*, with one being described (J.D. Shadwick, unpublished). This group also includes the non-fruiting taxon *Grellamoeba* (not covered here). *Soliformovum* corresponds to Group III of Spiegel (1990).
3. Conosa/Variosea/Schizoplasmodiida (Fig. 1m–v) has six named protosteloid species in three genera, *Schizoplasmodium*, *Nematostelium*, and *Ceratiomyxella*. It corresponds to Group II of Spiegel (1990). All known members of the taxon fruit.

4. Conosa/Variosea/Cavosteliida (Fig. 1w–aj) has seven named species and at least two needing to be described. It presently consists of three genera, *Cavostelium*, *Schizoplasmodiopsis*, and *Tychosporium*. It corresponds to Group IV of Spiegel (1990), with the addition of *Tychosporium acutostipes*. All known species fruit.
5. Conosa/Macromycetozoa/Protosporangiida (Figs. 1ak–2g) has nine named species, all of which fruit. It is divided into two clades, Protosporangiidae (Fig. 1ak–aq), with five species, and *Ceratiomyxa*, with four (Fig. 2a–g). It corresponds to Group Va of Spiegel (1990). All known species fruit. The three macroscopic species of *Ceratiomyxa* were traditionally considered to be unusual members of the myxogastrids prior to the discovery of protosteloid amoebae and the careful observations of L.S. Olive (see Olive 1975; Olive and Stoianovitch 1979), and they are also discussed briefly in the chapter on ► Myxomycetes.
6. Conosa/Macromycetozoa/Myxogastria (Fig. 2h, i, k, l) has one protosteloid member, *Echinostelium bisporum*. The whole of the myxogastrids are covered in a separate chapter (► Myxomycetes). It corresponds to Group Vb of Spiegel (1990). Some preliminary evidence suggests that *Echinoseliopsis* (see 7 below) may also belong here.
7. Conosa (incertae sedis) includes two protosteloid species for which there are not yet adequate molecular data, *Echinosteliopsis oligospora* (Fig. 2m–o) and *Microglomus paxillus* (Fig. 2p–r). Ultrastructure (Lindley et al. 2006; Olive et al. 1983) does not suggest an obvious affinity for either species. The few preliminary molecular data for *E. oligospora* suggest it may belong in Myxogastria, and there are no molecular data for *M. paxillus.*
8. Lobosa/Discosea/Centramoebida (Fig. 2s, t, x, y), a taxon known mainly for its non-fruiting members, also contains the protosteloid species *Acanthamoeba* (*Protostelium*) *pyriformis* (Tice et al. 2016; Fig. 2s, t), *Luapeleamoeba hula* (illustrated in Shadwick et al. 2009b, 2016), and *Luapeleamoeba* (*Protostelium*) *arachispora* (Fig. 2x, y; Tice et al. 2016). The first was included in Group I of Spiegel (1990), and the last in Group VII, Eumycetozoa incertae sedis, of Spiegel (1990). *Acanthamoeba pyriformis* is the first confirmed sporocarpic species in this genus (Tice et al. 2016), and *Luapeleamoeba* is sister to the non-fruiting genus *Protacanthamoeba* (Shadwick et al. 2009b, 2016; Tice et al. 2016).
9. Lobosa/Discosea/Pellitida (Fig. 2u–w) has two protosteloid species in the genus *Endostelium*. One new member of this genus has not been observed to fruit (Kudryavtsev et al. 2014). *Endostelium* (*Protostelium*) *zonatum* was included in Group VII of Spiegel (1990). Pellitida also includes the non-fruiting amoebozoan genera *Pellita* and *Gocevia* (Kudryavtsev et al. 2014; Adl et al. 2012; see also Lahr et al. 2011a).
10. Lobosa/Discosea/Vannellida (Fig. 2z, aa). *Protosteliopsis fimicola* was shown to be a vannellid by Shadwick et al. (2009b). Spiegel (1990) included it in Group VI. It must still formally be transferred to *Vannella.* No other members of *Vannella* have ever been reported to fruit.

The described species are listed below and illustrated in Figs. 1 and 2 with kinetids for the appropriate groups diagrammed in Figs. 6 and 7. The groups to which they belong are based, in most cases, on the taxa listed in Adl et al. (2012). Earlier classifications are summarized in Shadwick et al. (2009b) and Spiegel (1990). Taxonomic revision is underway in several of the groups and will be published elsewhere; however, there will be some comments on the directions the revisions will be going. Those species that are in need of revision at the generic level have genus names in quotation marks. Sporocarps, except for the macroscopic *Ceratiomyxa* spp., are all illustrated at the same scale in Figs. 1 and 2. *Luapeleamoeba hula* is not illustrated here but is illustrated in Shadwick et al. (2009b, 2016), and Tice et al. (2016). It should be remembered that the overall proportions of sporocarps tend to remain the same but that size can vary within a species by at *least* twofold (and sometimes more). Amoeboid and prespore cells are shown for their salient characteristics, not for their details. "Amoeba" will be used for cells that never become flagellated, and "amoeboflagellate" (synonym "amoebomastigote") will be reserved for cells that can reversibly produce flagella (referred to as cilia in Spiegel 1990; Adl et al. 2012), consistent with Spiegel (1990).

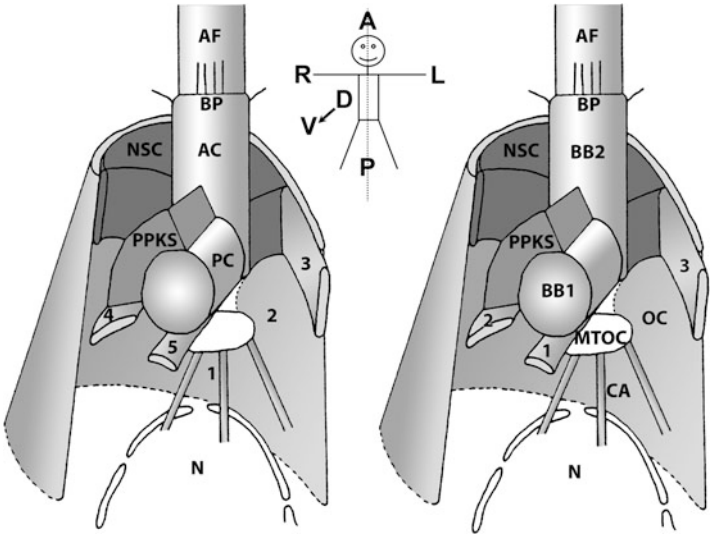

Fig. 6 Cartoon of ventral view of kinetid of *Echinostelium bisporum* (and all *Myxogastria*). comparing elements using the nomenclature of Spiegel (1990) (*left*) and the "universal" nomenclature for the eukaryote kinetid (e.g., Yabuki and Leander 2013; Heiss et al. 2013) (*right*). Abbreviations: *AC* anterior centriole, *BB2* basal body 2, *PC* posterior centriole, BB1 *basal body 1*, *BP* (*both*) basal plate, *N* (*both*) nucleus, *MTOC* (*both*) microtubule-organizing center, *PPKS* (*both*) posterior parakinetosomal structure, *NSC* (*both*) nonstriated connective; microtubular elements: 1 *(left)*, MTA-1 = CA, conical array (note this is attached by an unlabeled stalk to the proximal end of BB2); 2 (*left*), MTA-2 = OC (*right*), outer cone of microtubules (designated as F in Heiss et al. 2013); 3 (*left*), MTA-3 = 3 (*right*) microtubular root 3; 4 (*left*) MTA-4 = 2 (*right*), microtubular rootlet 2; 5 (*left*), MTA-5 = 1 (*right*), microtubular rootlet 1 (Redrawn from Spiegel (1990))

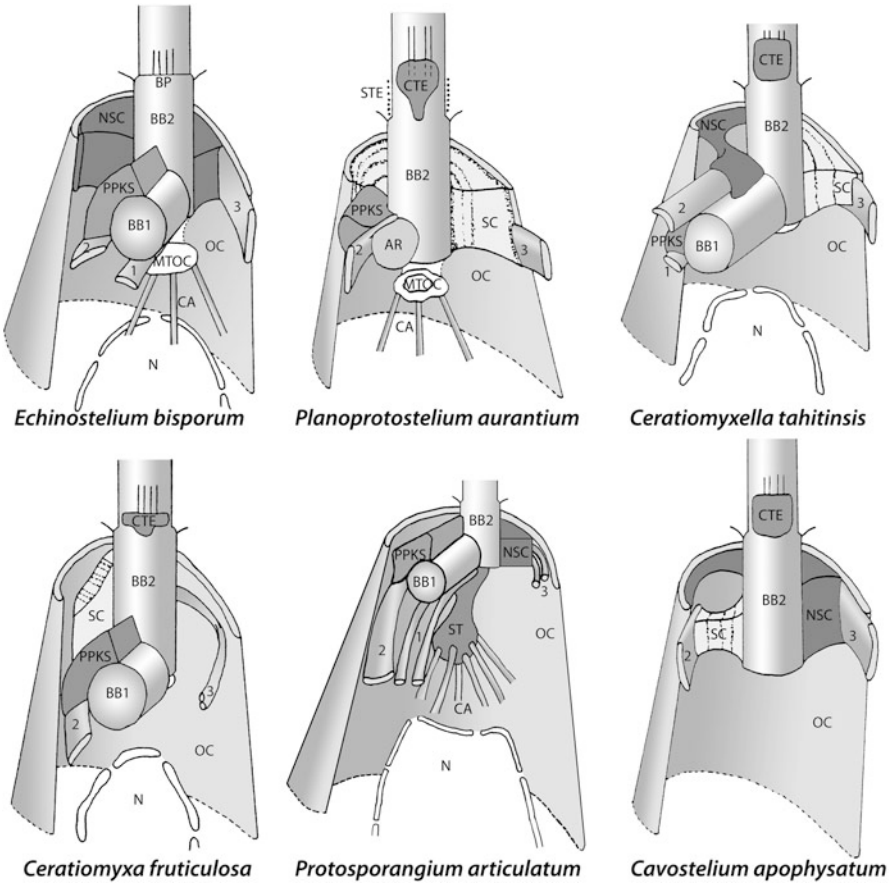

Fig. 7 Cartoons of ventral views of kinetids of all known amoeboflagellates of sporocarpic amoebozoans. Abbreviations: Same as Fig. 6 plus *STE* spiral transitional element, *CTE* cylindrical transitional element, *SC* striated connective, *ST*, stalk connecting proximal end of BB2 to CA. All redrawn from Spiegel (1990) except *P. articulatum* adapted from Spiegel et al. (1986)

Cyst stages have not been illustrated. References are provided for taxa that have been described since 1990. Readers are referred to the first edition of this Handbook for earlier references (Spiegel 1990). For more illustrations of sporocarps, see also Spiegel et al. (2007). Statements concerning the occurrence of these species are based on information from Spiegel et al. (2007) and Ndiritu et al. (2009).

Protosteliida

This clade contains the genus *Protostelium* s.s. and the monotypic *Planoprotostelium aurantium* (Spiegel et al. 1994, 2006) (Figs. 1a–g, 3, and 7). All species

have single spores; they may be deciduous or nondeciduous. The prespore cell of all species, when viewed from above, starts out lozenge-shaped before becoming circular in outline (Fig. 1c). *Protostelium okumukumu* (Spiegel et al. 2006) and *P. nocturnum* have forcibly discharged spores, the former through bursting of the swollen stalk apex (Spiegel et al. 2006) and the latter through the sudden disappearance of the entire stalk. *Protostelium mycophaga*, a probable species complex, is under revision. Most members of this nominal species have spores that fall passively from the stalk, though the degree of deciduousness can vary from strain to strain. "*Planoprotostelium aurantium*" belongs in this complex (see Shadwick et al. 2009) and typically has nondeciduous spores. All have uninucleate amoebae with lamellopodia that bear acutely pointed subpseudopodia (Figs. 1f and 3b) and contain orange-pigmented lipid droplets. The trophic cell of "*P.*" *aurantium* is an amoeboflagellate (Fig. 1g) that can reversibly transform from the amoeba typical of the group to a flagellate with one to several unikont kinetids, one of which is diagrammed in Fig. 7. "*Planoprotostelium aurantium*" nests within the *Protostelium* complex in molecular phylogenies and will have to be reassigned as a species of *Protostelium* (Shadwick et al. 2009). Trophic cells can either encyst as microcysts (not shown) or develop into ellipsoid prespore cells. On a global scale, *P. mycophaga* s.l. is the most abundant microscopic protosteloid amoeba; *P. nocturnum* is common to occasional, and the other species are rare. All tend to be found more often on aerial litter than any other microhabitat.

Fractovitelliida

One sporocarpic taxon, *Soliformovum*, and one non-fruiting taxon, *Grellamoeba* (Lahr et al. 2011a), make up this clade (Fig. 1h–l). *Soliformovum* was segregated from *Protostelium* by Spiegel et al. (1994) as had been suggested in Spiegel (1990). It has two described species, but at least two other rare, undescribed protosteloid amoebae probably belong to the genus based on prespore cell morphology. *Soliformovum irregularis* (Fig. 1m) has long straight, persistent stalks with a hastate tip and a single, spherical, deciduous spore, while *S. expulsum* (Fig. 1h, i) has a bipartite, reflexed stalk that bursts to forcibly discharge the single, spherical spore. The uninucleate amoebae of all species are broad and thin, and often flabellate, with lamellopodia bearing numerous short, acutely pointed subpseudopodia (Fig. 1k). The nucleus has a diffuse nucleolus consisting of several nucleolar bodies (Spiegel et al. 1994). An amoeba may either encyst (not shown) or develop into a rounded prespore cell that in its earliest stages has a raised refractile mound in the center (Fig. 1l). The "fried egg" appearance of the prespore cell is the basis for the genus name (Spiegel et al. 1994). *Soliformovum irregularis* is one of the most abundant species globally, preferring the aerial litter microhabitat over ground litter, while the common-to-occasional *S. expulsum*, though widespread, seems more likely to be found in the tropics on both aerial and ground litter.

Schizoplasmodiida

The schizoplasmodiids presently contain three described genera with a total of six species, all of which have an amoeba that is a large, multinucleate plasmodium that fragments into multinucleate prespore cells (Fig. 1o) (Figs. 1m–v, 4, and 7). The sporocarps of all species consist of a stalk that is topped with a cuplike swelling, or apophysis, on which sits a single spore with a ringlike hilum that fits like a socket over the apophysis (Fig. 1m, n, p–t). All species have deciduous spores. In *Schizoplasmodium* (Fig. 1p–t), the spores are forcibly discharged when a droplet is produced laterally and then bursts (Fig. 1p, q). *Schizoplasmodium cavostelioides* has a short stalk with a large, spherical spore, while *S. obovatum* has an obovate spore, and *S. seychellarum* has a moderately long stalk with a spherical spore. The other two genera, *Nematostelium* and *Ceratiomyxella*, have very long stalks (Fig. 1l, m). In *Schizoplasmodium* spp. and the two *Nematostelium* spp., the plasmodium (Fig. 1v) is the sole amoeboid state. In *Ceratiomyxella tahitiensis*, there is a complex, potentially sexual life cycle (Fig. 4) where amoeboflagellates (Figs. 1u and 4) can alternate with the plasmodium. The bikont flagellar apparatus of *C. tahitiensis* is diagrammed in Fig. 7. The sporocarps of *N. gracile* and *C. tahitiensis* are morphologically identical, so identification of these species from collections requires observation of spore germination. Once a more complete molecular phylogenetic study is available, a decision may be made to include all species in the genus *Schizoplasmodium*, the name that has nomenclatural priority. This is because of the homogeneity of the plasmodial obligate amoeboid stage and the very similar sporocarp topology. *Nematostelium gracile/C. tahitiensis* is abundant to common in tropical and midlatitudes and less common at higher latitudes. This complex is found on aerial and ground litter and on bark in the tropics, more commonly on the latter two microhabitats at mid-to-high latitudes. *Nematostelium ovatum* (see above) is abundant to common in the tropics, northern mid latitudes, and occasional in northern high latitudes. It is occasional in southern midlatitudes and absent in southern high latitudes. Its microhabitat preferences are similar to *N. gracile*. *Schizoplasmodium cavostelioides* is common to occasional in the tropics, abundant to occasional in midlatitudes, and rare at high latitudes. It is found most commonly on aerial litter. *Schizoplasmodium seychellarum* and *S. obovatum* are both very rare.

Cavosteliida

The cavosteliids are a morphologically diverse group, but the traits that appear to be universal among them are sporocarps with uninucleate, nondeciduous spores (Fig. 1w, z, ab, ac, ae–ag, ai); the spores bear some type of ornamentation that may or may not be visible with light microscopy (see Spiegel 1990) (Figs. 1w–ah and 7). All have amoebae that are flat and relatively transparent, and these amoebae often display long, thin subpseudopodia. *Cavostelium apophysatum* (Fig. 1w–y) has very short stalks with goblet-like apophyses and spherical spores with warty and micropunctate sculpturing that is easily visible with light microscopy (Fig. 1w).

It has a complex, potentially sexual life cycle where an amoeboflagellate, with one to several unikont kinetids (Figs. 1x and 7), alternates with a flat, transparent obligate amoeba with branched pseudopodia (Fig. 1y). *Schizoplasmodiopsis pseudoendospora* (Fig. 1z, aa) has short to very short delicate stalks with small, spherical spores (Fig. 1z). The spores are covered with minute spines that are seen clearly only with transmission electron microscopy (Dykstra 1978). The sporocarps often are gregarious when they have developed from a large plasmodium (Fig. 1aa). *Schizoplasmodiopsis vulgare* (Fig. 1ac, ae) and *S. reticulata* (Fig. 1ad) both have relatively long stalks when seen in primary isolation plates. The stalks are somewhat thick and coarse at the base and taper markedly to a relatively blunt apex where the stalk and spore are connected. Relative stalk length can be variable in *S. vulgare*, ranging from about two times the spore diameter to more than four times the spore diameter, especially in culture. The spores of *S. vulgare* and *S. reticulata* are both covered with a reticulum of raised ridges (Dykstra 1978; Spiegel and Feldman 1993). This is readily apparent in the light microscope with *S. reticulata*, even at low magnifications, but is only apparent under higher magnifications in *S. vulgare*. The three species, *S. pseudoendospora*, *S. vulgare*, and *S. reticulata*, make up the genus *Schizoplasmodiopsis* s.s. They all have amoebae that branch, which possess long, thin subpseudopodia that anastomose and become reticulate. These amoebae do not round up during mitosis, and they produce uninucleate prespore cells that are circular in outline. In *S. pseudoendospora* the uninucleate amoeba that germinates from a spore develops into a multinucleate, highly reticulate plasmodium (Fig. 1aa) that may exceed 1 cm in its longest dimension. In *S. vulgare* and *S reticulata*, the amoebae (Fig. 1ad) tend to stay uninucleate to plurinucleate, though large multinucleate masses that we interpret as culture artifacts are reported (Olive and Stoianovitch 1975). "*Schizoplasmodiopsis*" *micropunctata* (Fig. 1ae) and *Tychosporium acutostipes* Spiegel et al. (1995b) (Fig. 1a f, a g) are very similar, and we are currently investigating if they might be the same species (see also Spiegel et al. 1995a). Both have long, thin stalks that suddenly taper to a fine point and support turbinate-to-spherical spores that have a craterlike hilum at the point where they attach to the stalk (Fig. 1ag). Under oil immersion optics, the spores of both species can be seen to have numerous micropunctate markings. We usually assign a protosteloid organism to "*S.*" *micropunctata*, when its stalk length is more than five times its spore diameter and the thinning of the stalk apex is very pronounced, or to *T. acutostipes* when the stalk length is less than five times the spore diameter and the thinning of the stalk apex is more gradual. These two species typically have uninucleate amoebae with lamellopodia bearing short, narrow, acutely pointed subpseudopodia (Fig. 1ah) though some large, multinucleate forms may appear in cultures (Spiegel et al. 1995b). The prespore cells (not illustrated, but see Spiegel et al. 1995b) are similar in their development to those of Protosteliida. In fact, *Tychosporium* was originally hypothesized to be a member of the Protosteliida because of its prespore cells (Spiegel et al. 1995b); however, molecular systematics places it in the cavosteliids (Shadwick et al. 2009b). "*Schizoplasmodiopsis*" *amoeboidea* has a sporocarp (Fig. 1ai) that, at first, appears to be a larger version of *S. pseudoendospora*. Its spore has minute spines visible with TEM (Olive and

Whitney 1982), but its stalk is usually more tapered and has a more noticeably narrowed apex than *S. pseudoendospora* when viewed directly from the side. Its amoebae (Fig. 1ah) are broad and flat and may branch, but it does not have anastomosing subpseudopodia. In addition, the nucleus of the amoeba has a more diffuse-looking nucleolus than is seen in other members of this group, which have the typical, dense central nucleolus seen in most protosteloid amoebae. On a global scale, *S. pseudoendospora*, "*S.*" *amoeboidea*, *and S. vulgare* are among the most abundant species. Both *S. pseudoendospora* and *S. vulgare* are more likely to be found on ground litter, and *S. amoeboidea* is common on all both aerial and ground litter. Bark is also a common substrate for *S. pseudoendospora* and "*S.*" *amoeboidea.* Ground litter from cool, moist habitats is where *S. vulgare* is often the most commonly found species. *Cavostelium apophysatum* is often abundant in the tropics and common to occasional at mid-to-high latitudes. It occurs on aerial and ground litter and on bark. *Tychosporium acutostipes* morphotypes are common to occasional worldwide on aerial and ground litter. The other two species in the cavosteliids, *S. reticulata* and the "*S.*" *micropunctata* morphotype, are both rare.

Protosporangiida

The protosprorangiids fall into two groups, the Protosporangiidae that includes the genera *Protosporangium* and *Clastostelium* and its sister group, the genus *Ceratiomyxa* (see Spiegel 1991; Adl et al. 2012) (Figs. 1ak–2g and 7). Shadwick et al. (2009b) demonstrated the close relationships among the genera of Protosporangiidae, and subsequent unpublished analyses in our lab show its fully supported position as sister to *Ceratiomyxa.* All species have a complex, sexual or potentially sexual life cycle where the spore set contains more than one nucleus, usually two or four; the germling of the spore divides to produce additional amoeboflagellates (see Fig. 2g for the extreme example) which appear not to divide further. Microtubular rootlet 3 of the flagellar apparatus consists of only two microtubules (Fig. 7), and the amoeboflagellates are covered with a cell coat that consists of fine hairs that are branched at the apex. Also, when it has been observed, meiotic prophase is seen in the prespore cell and presumptive meiosis is completed during spore formation (Furtado and Olive 1971; Bennett 1986a). The genus *Protosporangium* consists of four species, *P. articulatum* (Fig. 1ak), *P. bisporum* (Fig. 1al), *P. conicum* (Fig. 1am), and *P. fragile* (Fig. 1an), which all have long, delicate stalks. The first two species most often have two spores, though *P. articulatum* may have four or even eight. The spores are nearly spherical and usually uninucleate in *P. articulatum*, and hemispherical and binucleate in *P. bisporum*. The stalk of *P. articulatum* typically has a distinct joint and bend about 1/2–2 spore diameters from its apex, while the stalk of *P. bisporum* is flexuous along its length. The latter two species typically have four uninucleate spores; *P. conicum* has three apical, spherical spores subtended by an obconic spore that articulates with the stalk, and *P. fragile* has a spore mass where the spores are compressed to each other to form quarter-spheres, or they may bulge out slightly

to give the spore mass a subtly lobed appearance. The stalk of *P. conicum* is fairly straight to moderately bent, and on the short end of length for the genus, while the stalk of *P. fragile* is long and bent at several articulations along its length, such that the stalk often looks collapsed. *Clastostelium recurvatum* (Fig. 1aq) has a bipartite stalk with a short conic base and an inflated, banana-shaped apical portion that supports two hemispherical to subspherical, uninucleate spores, usually in a side-by-side configuration. The fluid-filled apical portion of the stalk slowly begins to straighten and then suddenly bursts, propelling the spore mass away while leaving the base intact. The spores of both *Protosporangium* ssp. and *C. recurvatum* germinate as amoeboflagellates that divide shortly after germination to produce more amoeboflagellates (Fig. 1aq), which all have an essentially identical kinetid (Fig. 7). Then, with little or no division to produce further amoeboflagellates, they develop into obligate amoebae by a process that has not yet been observed (Fig. 1ar). The obligate amoebae are uni- to plurinucleate and have essentially identical morphology and microtubular cytoskeletons (see Spiegel 1991). The species of *Protosporangium* are most common on bark of living trees, though they may also be found on rotting wood. *Protosporangium articulatum* also can be found occasionally on dead primary plant tissues. *Clastostelium recurvatum* is most often found on aerial or ground litter. *Protosporangium articulatum* and *P. conicum* may be rare to common depending upon the habitat and are often among the few species found in arid habitats worldwide. The other two species of *Protosporangium* are rare, as is *C. recurvatum*. *Ceratiomyxa* spp. all produce fructifications where several to several thousands of individual sporocarps arise on a microscopic pad or on macroscopic columns of extracellular slime that is deposited by the plasmodium prior to its division into uninucleate prespore cells. A series of nuclear divisions, which is interpreted as meiosis, starts with prophase in the prespore cell and ends in the spore, with all nuclei surviving (Furtado and Olive 1971). The deciduous, tetranucleate spore germinates as a worm-shaped cell that eventually rounds up into a tetrad with one nucleus in each of its four lobes. Usually, each nucleus divides and the tetrad develops into an octet of eight lobes, and then each lobe differentiates into an amoeboflagellate (Fig. 2g). The amoeboflagellates never subsequently divide, though they have been observed to fuse, similarly to the plasmogamy seen between gametic amoeboflagellates of myxogastrids (Spiegel 1981b). Somehow, the amoeboflagellates or zygotes are involved in plasmodial development; however, this has never been observed. The few observations of plasmodia in the genus suggest that it is small (<1 mm) to extensive (>1 m), reticulate, and lacks regular shuttle streaming (Olive 1982; Olive and Stoianovitch 1979). Three species produce macroscopic fructifications: *C. fruticulosa* (Fig. 2a, b), *C. morchella* (Fig. 2c), and *C. sphaerosperma* (Fig. 2d). By contrast, *C. hemisphaerica* (Fig. 2e, f) has microscopic fructifications. Species are recognized on the basis of fructification morphology and spore shape. All species have single ellipsoidal spores except *C. sphaerosperma*, which has spherical spores. *Ceratiomyxa fruticulosa* has extensive, columnar to branched, white to brightly colored fructifications; *C. morchella* and *C. sphaerosperma* have white fructifications with colorless stipes and white, sporocarp-bearing heads, the former being pitted and the latter having radiating

columns; and *C. hemisphaerica* has small, clear, microscopic slime mounds. The macroscopic species of *Ceratiomyxa* fruit mainly on decaying woody substrates (including shells of tropical nuts in the case of *C. sphaerosperma* (A. Rollins, personal communication)), while *C. hemisphaerica* has also been found on aerial and ground litter. *Ceratiomyxa fruticulosa* may be the most commonly encountered macroscopic slime mold in moist to mesic forests worldwide. The other two macroscopic species are less common and mostly restricted to the tropics. *Ceratiomyxa hemisphaerica* is very rare and has been found exclusively in forests on various substrates.

Because the macroscopic species of *Ceratiomyxa* are easily seen and similar in size to myxogastrids, they were known well before it was recognized that there were other protosteloid amoebae. Therefore, until the 1970s (see Olive 1975), they were considered to be a morphologically unusual order-level taxon in the myxogastrids (Ceratiomyxales – see ▶ Myxomycetes). However, though their amoeboflagellates are superficially similar to myxogastrids, they differ considerably with respect to cell coats and kinetid structure (Figs. 6, and 7, see Spiegel 1991). Their plasmodia do not show the shuttle streaming typical of myxogastrid plasmodia (see Olive and Stoianovitch 1979). Their fructifications are macroscopic because of extracellular, secreted slime columns, not because of macroscopic spore-containing structures typical of the macroscopic myxogastrids. There is no equivalent to the slime columns among any other amoebozoans. They are unique to *Ceratiomyxa* and are one synapomorphy that distinguishes the genus from the rest of the protosporangiids. The individual sporocarps are protosteloid, and the spores are smooth-walled and not sculptured as in the myxogastrids, and meiosis appears to be completed before spore wall maturation (rather than after, as is the case in myxogastrids; see Olive 1975; Olive and Stoianovitch 1979; Spiegel 1991). Thus, the inclusion of the genus in the myxogastrids is no longer tenable with the discovery and understanding of the other protosteloid amoebozoans.

Myxogastria

The two-spored myxogastrid *Echinostelium bisporum* (Figs. 2h, i, k, l, 6, and 7) was originally described as a protosteloid amoeba and is most often found by workers looking for protosteloid amoebae. Because "protosteloid" refers to sporocarp appearance, rather than to a phylogenetic affinity, *E. bisporum* is treated here as a protosteloid amoeba (Figs. 2h–l, 6, and 7). Its sporocarp (Fig. 2h and see Spiegel and Feldman 1989) consists of a short, nearly solid stalk with a flared apophysis that articulates with a ring-shaped hilum on the bottom spore. There are matching hila on each of the spores at their point of articulation. The spores are covered with minute, hollow spines, and the slime sheath (= peridium) may become hydrated such that the spores appear to be suspended in a drop of liquid (Fig. 2i). The spores of *E. bisporum* germinate as amoeboflagellates (Fig. 2k, l) that are identical in general morphology and kinetid structure (Figs. 6 and 7) to other myxogastrids. Unlike all other myxogastrids, the only free-living amoeboid state is the amoeboflagellate (Fig. 2k, l);

the transition to anything similar to a plasmodial ultrastructure does not occur until well after fruiting is underway (Spiegel and Feldman 1989). Though never treated as a protosteloid amoeba, *E. lunatum* (Fig. 2j), with a sporangium of four to eight spores and a columella shaped like a half cup, may be encountered when collecting for protosteloid amoebae and be mistaken for a four- to eight-spored *E. bisporum.* Since *E. lunatum* has a complete myxogastrid life cycle that includes a plasmodium and a more complex sporocarp, we choose not to consider it to be protosteloid. *Echinostelium bisporum* is occasional to common in the tropics and midlatitudes and may be found on aerial or ground litter or occasionally on bark; *E. lunatum* is rare and almost always found on bark.

Conosa, Incertae Sedis

All of the above protosteloid organisms are sporocarpic amoebozoans that are members of molecularly and morphologically supported groups that are known best from their fruiting members (Fig. 2m–r). The following two taxa are accepted as amoebozoans, and probably conosans, because their sporocarps and amoebae show some similarity to the conosan protosteloid amoebae listed above. However, their morphology does not readily suggest any affinities to other amoebozoans.

Echinosteliopsis oligospora

This species has a sporocarp with a moderately long stalk and four (to eight) nearly spherical, smooth-walled spores that may not all be of equal size (Fig. 2m) (Fig. 2m–o). They are usually arranged such that one is attached to the stalk and the others form a group that sits around the basal spore's apex. As a result, only three of the four spores are usually visible in one view. The sheath is hygroscopic, such that the spores may appear suspended in a drop (Fig. 2n). The amoeba may have one to several nuclei. In overall appearance, the amoeba (Fig. 2o) is similar to the small protoplasmodia found in some myxomycetes; however, the nucleus is unique in that it has several discrete nucleoli (Lindley et al. 2006). It occurs most frequently on aerial or ground litter and is abundant to common in the tropics and common to occasional in midlatitudes and rare at high latitudes. There is no amoeboflagellate state. Phylogenies of elongation factor 1α and β-tubulin genes (L. Shadwick unpublished) and preliminary phylogenomic analyses performed in M.W. Brown's lab suggest that this taxon may be an unusual myxogastrid.

Microglomus paxillus

This small, short-stalked species has varieties that may be four-spored or two-spored (Fig. 2p, q). While it may look superficially like *S. pseudoendospora*, careful examination shows that it is sporangial and that the sporangium is often slightly

ellipsoid (Fig. 2p) (Figs. 2p–r). High magnifications reveal the demarcation between the tightly packed spores (Fig. 2q). The short stalk supports the spores within a wall (= peridium?) that has minute spines visible with TEM. Olive et al. (1983) interpreted the fruiting body to have a single two- to four-celled spore rather than multiple spores in a sporangium. Each sporocarp has nuclei in meiotic prophase during early development, and meiosis is thought to be completed during sporogenesis. This is the only protosteloid amoeba with a simple life cycle that shows evidence of sexuality. Germination results in the release of amoebae that eventually become uninucleate. The amoebae have conic pseudopodia that may have long acutely pointed subpseudopodia (Fig. 2r). No cultures of this species are currently available, and we have not been able to examine amoebae directly. This species is occasional to rare worldwide and is most commonly encountered on bark in arid regions but is also present on aerial and ground litter. It has recently been seen in primary isolation plates in M.W. Brown's lab, and there is hope to have some sequence data for it in the near future.

Protosteloid Amoebozoans from Taxa Known Primarily for Their Non-fruiting Members

The following protosteloid amoebae have been found to be members of groups of amoebozoans that are classically thought of as "naked" amoebae (Fig. 2s–aa). Two described species, *Acanthamoeba pyriformis* and "*Protosteliopsis*" *fimicola*, are placed in existing genera of "naked" amoebae, and the remaining species are placed in more inclusive taxa. All are found within the amoebozoan clade with the taxon name Discosea.

Centramoebida: *Acanthamoeba* (*Protostelium*) *pyriformis*

This species was tentatively treated as a member of the genus *Protostelium* by Spiegel (1990) (Fig. 2s, t). However, recent sequence data (Tice et al. 2016), as well as its morphology and ultrastructure (Bennett 1986b, Spiegel, unpublished), clearly demonstrate that it is a sporocarpic member of the genus *Acanthamoeba.* It has an obpyriform, uninucleate spore with a basal invagination that fits over the apex of the stalk (Fig. 2s). This allows the spore to flag (wave back and forth) easily in air currents. The apex of the stalk has a small, knob-like swelling, the apophysis, which is visible when the spore is shed. The stalk is relatively long and slightly tapered. During development, the apical portion of the forming stalk is enclosed in a sheathlike invagination of the rising sporogen. The amoeba stage is identical in appearance to non-fruiting species of *Acanthamoeba*, with respect to acanthopodia (Fig. 2t), cysts (Bennett 1986b), and the microtubule-organizing center (Bennett 1986b). Also, like some other species of *Acanthamoeba*, cells in late prophase to early anaphase display short, radiating pseudopodia (Spiegel, unpublished). Different strains that have been cultured have sporocarps that differ in size and cyst

morphology. This suggests that *A. pyriformis* may be a species complex. Until recently no viable cultures were available, but one isolate has recently been cultured and sequenced. Further success at isolation of other strains will make it possible to see if indeed there are other similar, cryptic species. This species is occasional worldwide and found about equally commonly on ground and aerial litter and sometimes on bark.

Centramoebida: *Luapeleamoeba*

Shadwick et al. (2009b) studied a protosteloid amoeba designated LHI05M5g-1 that has recently been described as a new species in a new genus, *Luapeleamoeba hula* (species not illustrated, see Shadwick et al. 2016; Tice et al. 2016) (Fig. 2x, y). Subsequent study (Tice et al. 2016) shows that *Protostelium arachisporum* should also be included in the same new genus, as *Luapeleamoeba arachispora*. It was something of a surprise that this taxon is not closely related to *Endostelium*, as hypothesized by Spiegel (1990). *Luapeleamoeba hula* has a sporocarp with a short stalk and obpyriform spore. The stalk apex has a knob-like apophysis that is inserted into an invagination at the base of the spore. It becomes visible when the deciduous spore is shed. While the spore is supported by the stalk, it constantly changes shape, suggesting that it either has a very thin, flexible spore wall or possibly no wall at all. Sporocarp development is similar to that seen in *Endostelium* spp. and *A. pyriformis*. As in these two taxa, the stalk develops inside an invagination of the rising sporogen (Shadwick et al. 2016). *Luapeleamoeba arachispora* is somewhat variable in many respects and probably will be segregated into several species. Nonetheless, it is fairly easy to recognize (Fig. 2y). Its stalk may range from less than the length of the spore to more than two times the spore's length. It always has a small, knob-like apophysis, and the base flares out noticeably just above the basal disk. The spore is usually elongate, often with one or more constrictions along its length such that it looks like a peanut, but it may be only slightly elongate and ellipsoid. The deciduous spores flag readily while attached to the stalk. We have noticed that spores can slowly change shape while attached to the stalk. This may be because the spore wall is very thin. The uninucleate amoeba of both species is relatively thick from top to bottom and round to elongate in outline (Fig. 2x). The pseudopodium is often broad and supports numerous short subpseudopodia which are blunt or pointed, with broad bases. *Luapeleamoeba arachispora* is abundant to common in the tropics and common at midlatitudes on both aerial and ground litter, while *L. hula* is rare.

Pellitida: *Endostelium*

Recent work by Kudryavtsev and others (Kudryavtsev et al. 2014) and Lahr et al. (2011a) has shown that *Endostelium* is closely related to the non-fruiting taxa *Gocevia* and *Pellita* (Fig. 2u–w). There are two fruiting species in the genus and one species that has not been reported to fruit. Both fruiting species, *E. amerosporum* (Fig. 2u) and

E. zonatum (Fig. 2n), have large, coarse sporocarps with large deciduous spores. The former has a smooth stalk with a knob-like apophysis, upon which sits a spherical or subspherical spore that is often covered with irregularities which appear to be bacteria adhering to its surface. The spores do not flag noticeably in air currents. *Endostelium zonatum* has a series of regularly spaced swellings along the length of the stalk, and the apex of the stalk is inserted into an invagination in an extension of the obpyriform-to-turbinate spore. The spore in this species flags readily in air currents. Both species have large, thick, amoebae that are round to slightly flabellate in outline, and they have a thick slime sheath. The pseudopodia are broad and have short, peg-like subpseudopodia extending forward and projecting downward from the ventral surface when the amoeba is locomoting (Kudryavtsev et al. 2014). The rising sporogens, analogous to *A. pyriformis* and *L. hula*, form an invagination in which the developing stalk is inserted. There appears to be a lot of variation in the morphology of different fruitings of *E. zonatum* with respect to overall size, spore shape, and the degree to which the regular swellings appear on the stalk. Sometimes, they even appear to have smooth stalks. With further work, it is likely that *E. zonatum* will eventually be split into several species. *Endostelium zonatum* is common in tropical and midlatitudes and equally common on both aerial and ground litter, and occasionally found on bark, while *E. amerosporum* is rare enough that no microhabitat preference has been determined.

Vannellida: "*Protosteliopsis*" *fimicola*

The long stalk of this species is relatively wide, somewhat contorted and appears waterlogged or gelatinous (Fig. 2z) (Fig. 2z, aa). Its base is noticeably broader than the rest of the shaft. It supports a single, nondeciduous, uninucleate spore (Fig. 2z). The amoeba may be elongate or flabellate with a broad, hyaline pseudopodium. Its amoeba (Fig. 2aa) is indistinguishable from other species of *Vannella*, and molecular data place it deep within the tree of *Vannella* (Shadwick et al. 2009b). It has yet to be formally renamed but will be reassigned soon. It is occasional worldwide and represents the protosteloid amoeba most likely to be found on herbivore dung, though it may also present in rich ground litter or even aerial litter.

Maintenance and Cultivation

Protosteloid amoebae are relatively easy to find on natural substrates (Spiegel et al. 2004, 2005, 2007). Substrates include pieces of dead plant parts from standing plants or litter, rotting wood, bark, herbivore dung, or humus/soil. Substrates are collected in the field and placed in paper bags, and location and ecological data are recorded. If the substrates are to be stored before plating, they must be air-dried. In this condition they can be stored for up to 18 months at room temperature. In the laboratory, the substrates are cut into small pieces and placed on plates of weakly nutrient agar such as wMY, HI, or OB (Table 2; this is the same as Table 3 in the first edition of this

Handbook, except that the recipe for wMY agar has been changed to **0.002 g malt extract** and **0.002 g yeast extract**. We have begun to leave malt extract and/or yeast extract out of the wMY medium with no ill effect. Our standard practice is to lay bits of substrate in eight radiating lines on wMY agar and then to wet them with sterile distilled water. We refer to these as "primary isolation plates." Other preparative methods include suspending substrates in water and then spreading them on an agar plate, a method that works with ground litter and soil, or placing substrates on moistened absorptive paper in a dish as a moist chamber.

After 2–3 days, microscopic examination of the sample with either a compound or dissecting microscope should reveal the first sporocarps of protosteloid amoebae. The first sporocarps will most likely be found directly on the dead plant material, but after several days, more should be seen on the surrounding agar. Primary isolation plates may be examined daily for 2–4 weeks because the species composition will change during this period. Species such as *Protostelium mycophaga*, *Soliformovum irregularis*, and *Cavostelium apophysatum* will appear within the first few days, while species of schizoplasmodiids may take well up to a week to appear. Macroscopic *Ceratiomyxa* spp. are best collected as showy white "fructifications" on rotting logs, as they rarely appear in primary isolation plates of substrate collections (Olive and Stoianovitch 1979).

In many cases it is necessary to culture a protosteloid amoeba that appears on a primary isolation plate. Most protosteloid amoebae are relatively easy to isolate and culture from nature (Spiegel et al. 2005). Exceptions, which will be discussed below, are species from bark and *Ceratiomyxa* spp.

Plates of weakly nutrient media should be spotted with several yeasts and bacteria to serve as possible food sources; then spores or other cells of the protosteloid amoeba to be isolated should be picked off the substrate plate with a fine, sterile metal or glass needle or an eyelash glued to a stick (W.E. Bennett, personal communication) and transferred to each spot of food organisms on the isolation plate. Single-spore isolation should be avoided until the culture is established. Spores may be picked off free of contaminants most easily; cysts and trophic cells will carry a number of other organisms. The use of a handheld needle or eyelash takes some practice, and, if available, a micromanipulator may be used instead (Olive 1975). An effort should be made to include one spot of bacteria and/or yeast from the primary isolation plate near the species being isolated, to serve as food on the initial culture plate. A researcher should try several types of tools and settle on the method that works best in his/her particular case.

Protosteloid amoebae should be allowed to grow for several days on the initial culture plate. They should then be transferred to culture plates of one of the agar media listed in Table 2, though we find that wMY works almost universally. The plate should be streaked with the food organism(s) on which the protosteloid amoeba has grown most vigorously (and formed sporocarps), and an inoculum of the species should be placed at one end of the streak. It is often difficult to get a protosteloid amoeba isolated cleanly on the first attempt; patience and several transfers are usually necessary. Species with ballistospores and deciduous spores may be cleaned up quite easily by inverting an agar block containing sporocarps on the lid of a

culture plate and letting the spores drop onto the agar below (Olive 1975). Some species grow very slowly when first isolated. These must be watched carefully and transferred quickly if contaminants appear on the plate. If one carefully observes the amoeboid cells that germinate from a spore and follows their development, a trustworthy culture may be established even if a strain will not fruit.

Bark-inhabiting protosteloid amoebae are usually very difficult to culture (Olive 1975). Much experimentation with agar hardness and pH and food organism combinations may be necessary to get a "barkie" to grow. Often, pieces of sterile bark must be scattered on the agar to get the protosteloid amoeba to form sporocarps, even if amoebae have grown (C. Stoianovitch, personal communication). No species of *Ceratiomyxa* has been grown in culture, but spores can be germinated by sprinkling them onto a plate of agar flooded with water (see Fig. 2g).

Once a protosteloid amoeba is in culture, it should be maintained with its food organism(s) on one of the weakly nutrient agars listed in Table 2; CM+ may be used for hardy species such as *Protostelium mycophaga* and *Planoprotostelium aurantium*. Liquid medium can be used to culture large numbers of trophic cells of some species (Spiegel 1982a). We have also found that any medium can be converted to a liquid medium by leaving out the agar. We find it easiest to keep cultures in plastic Petri dishes that allow microscopic inspection of the unopened culture at low power. Cultures are maintained at a room temperature below 25 °C (because some species are quite heat sensitive) and transferred once a month, although transfers may be made successfully from cultures that are over 6 months old. Most species can be frozen in liquid nitrogen and stored indefinitely.

Established cultures of most species are kept in the University of Arkansas and Mississippi State culture collections, and several species are available in the Eumycetozoan Special Collection at the American Type Culture Collection and the Culture Centre for Algae and Protozoa.

Evolutionary History

The fossil record for potential amoebozoans is best for arcellinids and appears to extend back at least 740 mya (Porter and Knoll 2000). Arcellinids are tubulinids, a highly derived group that contains no sporocarpic members. Their fossil record, therefore, serves only to place the last common ancestor of amoebozoans, as a whole, at some time earlier than about three quarters of a billion years ago. There are no known fossils that can be assigned to protosteloid amoebozoans. Therefore, their history, and that of amoebozoans in general, must be inferred from comparative morphology and comparative molecular studies.

Molecular work supports Amoebozoa as a major monophyletic lineage among eukaryotes (see Adl et al. 2012). This lineage contains several well-supported clades (see Adl et al. 2012; Lahr et al. 2011a; Shadwick et al. 2009b), but the deeper relationships among these clades have yet to be discovered. There are no data that support a monophyletic subclade that contains all, or even most, of the sporocarpic taxa to the exclusion of most non-fruiting amoebozoans, as espoused in the concept

of Eumycetozoa by Olive (1975, 1982) and by Spiegel (1990, 1991; Spiegel et al. 1995a). Rather, there are several independent, well-supported lineages that contain sporocarpic, protosteloid members (Table 1). One study has suggested, with weak support, uniting the protosporangiid taxon *Ceratiomyxa*, the myxogastrids, and the dictyostelids into the taxon Macromycetozoa (Fiore-Donno et al. 2010). This clade was not recovered in other studies (Lahr et al. 2011a); however, preliminary unpublished molecular work from the labs of M.W. Brown and F.W. Spiegel, based on a greater sample of amoebozoans, suggests more support for Macromycetozoa, and we have chosen to accept it in this chapter. Many protosteloid amoebae are not located in Macromycetozoa but instead in its apparent sister group, Variosea (Shadwick et al. 2009b; Fiore-Donno et al. 2010; Lahr et al. 2011a; Cavalier-Smith et al. 2015; Berney et al. 2015). Further, Berney et al. (2015) illustrated several new taxa of non-fruiting variosean amoebozoans with trophic cells that are very similar to schizoplasmodiids, fractoviteliids, and cavosteliids. There are also several discosean protosteloid amoebae.

Given that simple sporocarpy is the classical hallmark of protosteloid amoebozoans, the question to be asked is: How many times has sporocarpy arisen? Ultrastructure of mature and developing protosteloid sporocarps (see Spiegel 1990; Spiegel et al. 1995a; Spiegel, unpublished data) is consistent with the hypothesis that protosteliids, fractoviteliids, schizoplasmodiids, cavosteliids, protosporangiids, myxogastids, *Endostelium*, *A. pyriformis*, and perhaps the sorocarpic dictyostelids all had a common sporocarpic ancestor. However, not enough work has been done to rule out several origins of sporocarpy, with convergence upon a similar morphology. The lack of sporocarpy outside of Amoebozoa compared to the wide range of sorocarpy among eukaryotes (see Adl et al. 2012; Brown et al. 2011) tempts one to lean toward a single origin of sporocarpy.

We are at the beginning of a transcriptomic study of amoebozoans which may yield results that can help determine whether the underlying genetic basis for sporocarp development is the same, or different, across the wide phylogenetic range of protosteloid amoebozoans. Should the results indicate considerable homology for the fruiting process, this would lend support to a single origin of sporocarpy. Thus, it would suggest that sporocarpy was a trait of the last common ancestor of amoebozoans and that it has been independently lost several times in several lineages. A corollary of that would be the conclusion that all extant amoebozoans are the descendants of a terrestrial ancestor and that exclusively freshwater-aquatic and marine lineages of amoebozoans are derived.

Sporocarpy is not the only character protosteloid amoebae have in common; there is also the rest of the life cycle to consider. When one looks at life cycles with respect to amoebozoans as a whole, the history of the entire "supergroup" appears to reflect a loss of characters that were present in a morphologically and developmentally complex last common ancestor.

Because amoeboid cells of the different groups of protosteloid amoebae are so variable (see Spiegel 1990; Spiegel et al. 1995a), Spiegel was skeptical that sporocarpy had a common origin and was unwilling to accept it as a potentially apomorphic character of the protosteloid amoebae. However, many protosteloid

amoebae have a life cycle that includes an amoeboflagellate stage – there are flagellated members in the protosteliids, schizoplasmodiids, cavosteliids, protosporangiids, and myxogastrids. While the morphology and swimming behavior of amoeboflagellate cells is variable among these groups (Figs. 1g, u, x, ao and 2k; see also Spiegel 1991; Spiegel et al. 1995a); flagellar apparatus ultrastructure (Figs. 6 and 7; see Spiegel 1991; Spiegel et al. 1995a) is very consistent, suggesting a common ancestry for all these organisms. In addition, the morphology of amoeboflagellates when they are not flagellated (see Spiegel et al. 1995a) and the details of mitosis in amoeboflagellates (see Spiegel 1991; Spiegel et al. 1995a) all point to the conclusion that all of these organisms share a common ancestry. It was more the characters of amoeboflagellates than the characters of sporocarpy that led Spiegel (1990, 1991) and Spiegel et al. (1995a) to conclude that the protosteliids, schizoplasmodiids, cavosteliids, protosporangiids, and myxogastrids (at least; of the sporocarpic organisms) form a monophyletic group. Spiegel (1990, 1991) was one of the first protistologists to suggest that complex flagellar apparatuses within a purported clade were probably more primitive than simpler ones because the different groups with simple flagellar apparatuses lacked different elements that were present in groups with complex ones. Spiegel (1991) was also one of the first protistologists to suggest that the elements of the complex flagellar apparatus of one major lineage were homologous with topologically similar elements in another major lineage of eukaryotes, thus implying that the early ancestors shared by the major lineages had a complex flagellar apparatus. This is a view that is more widely held today (see Spiegel 2012, 2016; Yubuki and Leander 2013; Heiss et al. 2013). Other features of the amoeboflagellates of the sporocarpic amoebozoans, such as a ventral groove for the posterior flagellum, also appear to be widespread among eukaryotes (Spiegel 2012).

Sex is a symplesiomorphy of amoebozoans (Lahr et al. 2011b; Spiegel 2011) since it is a synapomorphy of extant eukaryotes. Thus, the last common ancestor of amoebozoans must have been sexual. Sex is present or suspected in the schizoplasmodiids, cavosteliids, protosporangiids, and myxogastids, all of which have complex life cycles with amoeboflagellates and obligate amoebae (Lahr et al. 2011b). *Microglomus* is the only suspected sexual sporocarpic amoeba that has a simple life cycle.

The presence of sporocarpy, the characters of amoeboflagellates, and similar potentially sexual life cycles suggested that organisms that share these characters should be closely related (see Spiegel et al. 1995a), but in-depth molecular phylogenetic studies clearly imply that there is no support for a single clade that includes all sporocarpic amoebozoans nor support for a single, exclusive subclade that includes all flagellated amoebozoans. Nonetheless, these characters strongly suggest that the organisms that express them are closely related. Therefore, the hypothesis must be considered that the last common ancestor of extant amoebozoans was sexual, had an amoeboflagellate stage with a ventral groove and a complex bikont kinetid, and was sporocarpic. Since sporocarps appear to be adaptations for dispersing propagules of terrestrial amoebozoans, it is likely that this ancestor was terrestrial. This hypothesis is offered so that it can be tested. More comparative light

microscopy and ultrastructural work combined with comparative genomics and comparative developmental genetics should provide the data to support or reject this hypothesis.

Acknowledgments We would like to thank Joyce Feldman for her assistance on some of the work reported here from the first edition of the Handbook. We would also like to thank Jeffrey Silberman for his participation in much of the molecular work reported in this update. Portions of the work were supported by the National Science Foundation grants BSR83-07376, BSR86-00639, BSR89-00190, DEB-039102, DEB-0316284, and DEB-1456054, a grant from the National Geographic Society, and a grant from the Arkansas Biosciences Institute.

Archamoebae

37

Giselle Walker, Eliška Zadrobílková, and Ivan Čepička

Abstract

Members of the Archamoebae comprise free-living and endobiotic amoeboid flagellates, amoeboflagellates, and amoebae, with distinctive hyaline cytoplasm and bulging pseudopodia. They live in anoxic or microoxic habitats and are anaerobes, lacking typical mitochondria, as well as Golgi stacks, plastids, and normal peroxisomal microbodies. They have a distinctive flagellar apparatus present in all flagellated members of the group. Life cycles of individual species can include flagellates, amoebae of various sizes, and cysts. In recent years, the group has been divided into five separate families, Mastigamoebidae, Entamoebidae, Pelomyxidae, Tricholimacidae, and Rhizomastixidae, whose interrelationships have not been completely resolved. Here, we clarify the composition of these groups and the circumscription of genera in the Archamoebae.

[Archamoebae incertae sedis: *Mastigina*, Tricholimacidae (*Tricholimax*), *Endamoeba*]

Introduction

General Characteristics

The Archamoebae is a group of amoebae, amoeboid flagellates, and amoeboflagellates (i.e., organisms with both flagellates and amoebae in their life cycle), with distinctive hyaline cytoplasm and bulging pseudopodia (Fig. 1). They comprise three

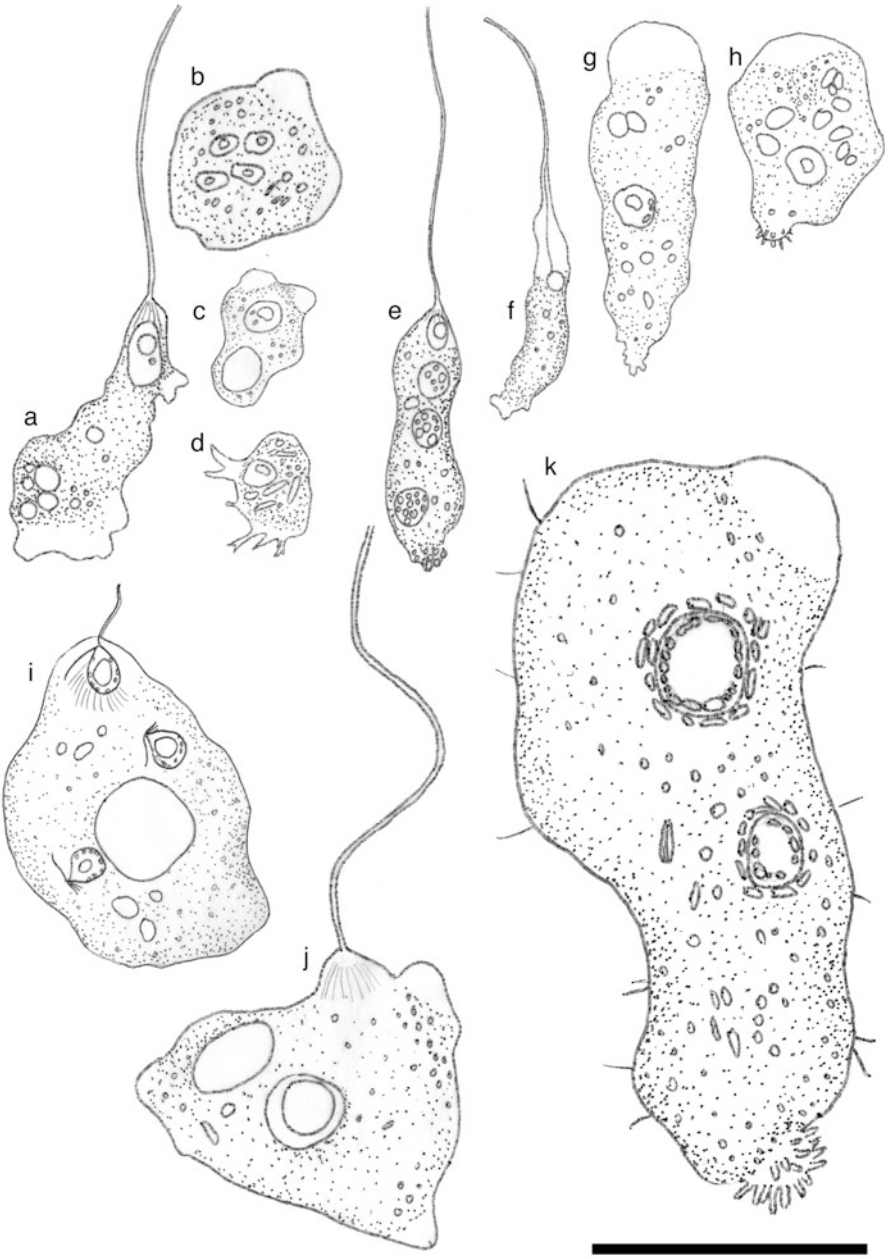

Fig. 1 General appearances of genera in the Archamoebae. (**a**) In the dominant flagellated trophic stage, ***Mastigamoeba*** has a microtubular cone that connects the flagellar base to the nucleus. (**b**) ***Mastigamoeba*** also typically has amoeboid stages, which may be multinucleate. (**c**) ***Iodamoeba*** contains small aflagellate amoebae with hyaline lobopodia. (**d**) ***Endolimax*** forms small aflagellate amoebae with variable pseudopodia similar to those in *Mastigamoeba*. (**e**) ***Mastigina*** contains

lineages that have collectively been referred to as pelobionts: mastigamoebids, pelomyxids, and *Tricholimax*, as well as *Rhizomastix* and entamoebids. All Archamoebae are anaerobic (some more aerotolerant than others) and lack normal mitochondria (which are reduced to remnants), Golgi stacks, plastids, and normal peroxisomal microbodies. Many contain endosymbiotic bacteria and archaea. Flagellated taxa have a distinctive cytoskeleton.

Mastigamoebids currently include *Mastigamoeba*, *Endolimax*, and *Iodamoeba*: these include mostly free-living amoeboflagellates as well as endobiotic amoebae; many have distinctively hyaline cytoplasm and move with pseudopodia when attached to a substrate. In flagellate mastigamoebids, the flagellum is functional and has a conventional 9 + 2 microtubular arrangement, but there is a distinctively "languid" or slow flagellar beat arising from the lack of outer dynein arms in the flagellar axoneme. The base of the flagellum gives rise to a cone of microtubules that connect to the nucleus. Molecular phylogenies divide mastigamoebids into two clades, "A," containing large species with a broad flagellar apparatus (e.g., *Mastigamoeba balamuthi*), and "B," containing small species with a narrow flagellar apparatus and trailing pseudopodia (e.g., *Mastigamoeba simplex*) as well as *Endolimax* and *Iodamoeba* (Ptáčková et al. 2013; Pánek et al. 2016). Members of *Endolimax* and *Iodamoeba* have entirely lost the flagellar apparatus and were historically classified within entamoebids. They have only recently been transferred to mastigamoebids on the basis of molecular-phylogenetic analyses (Cavalier-Smith et al. 2004; Ptáčková et al. 2013; Stensvold et al. 2012; Poulsen and Stensvold 2016). Historically, the flagellated *Mastigella* has usually been thought of as a mastigamoebid, but it is more closely affiliated with *Pelomyxa* (Zadrobílková et al. 2015).

Pelomyxids include members of *Mastigella* and *Pelomyxa*. *Mastigella* includes amoebae and flagellated amoebae where the base of the flagellum gives rise to a microtubular cone that is not connected to the nucleus. *Pelomyxa* includes large (up to several millimeters) amoebae, with nonfunctional, short flagella that have a disordered microtubular arrangement and a microtubular cone that is unconnected to the nucleus or nuclei. Recent phylogenetic analyses have shown that *Mastigella* is closely related to *Pelomyxa* (Zadrobílková et al. 2015).

Rhizomastix was recently placed in the Archamoebae (Čepička 2011; Ptáčková et al. 2013). It includes amoeboflagellates with a single anterior flagellum, which live

Fig. 1 (continued) amoeboid flagellates with a limax appearance and no lateral pseudopodia. (**f**) ***Rhizomastix*** contains small amoeboid flagellates that have a microtubular rhizostyle connecting the flagellar base to the nucleus. (**g**) ***Entamoeba*** contains amoebae with hyaline lobopodia and granular cytoplasm. (**h**) ***Endamoeba*** includes amoebae with a characteristic pattern of nuclear chromatin and no strong distinction between hyaline and granular areas of cytoplasm. (**i**) ***Tricholimax*** includes a single species of multinucleate amoeboid flagellate with a short, nonfunctional flagellum. (**j**) ***Mastigella*** contains amoeboid flagellates where the flagellar base is not connected to the nucleus by the cone of microtubules; the dominant trophic stage may be an aflagellate amoeba. (**k**) ***Pelomyxa*** contains large amoebae with multiple nuclei and very short, nonfunctional flagella. Scale bar = 20 μm

endobiotically in the intestines of insects and amphibians or are free-living in freshwater sediments. In *Rhizomastix* the cone of microtubules arising from the base of the flagellum has been modified into a tapering microtubular tube, the "rhizostyle."

Entamoebids are aflagellated, mostly endobiotic amoebae that were, until relatively recently, classified among other amoebae and taxonomically separated from the pelobionts. They currently formally include the genus *Entamoeba* (historically also *Endamoeba*, *Endolimax*, and *Iodamoeba*) and have in the past also included several genera of currently uncertain phylogenetic position, such as *Schizamoeba*, *Hydramoeba*, and *Malpighamoeba*. Their morphological similarities to pelobionts were recognized several decades ago (Cavalier-Smith 1983, 1987a, b) and since confirmed with molecular phylogenetics. Most entamoebids are probably harmless commensals of the digestive tract in invertebrates or vertebrates, including humans (e.g., *Entamoeba moshkovskii*; Heredia et al. 2012); a recent description reports a free-living or commensal marine species (Shiratori and Ishida 2016). The most important is the parasitic *Entamoeba histolytica*, which causes the dangerous amebic dysentery of humans.

Mastigina is a poorly known genus, with few sightings and no molecular data, currently classified as *incertae sedis* (Pánek et al. 2016) though likely to be a member of the mastigamoebids. It has many similarities to *Mastigamoeba* but has a limax body shape where pseudopodia emerge only at the anterior or posterior ends. Its identity has historically been confused with that of *Tricholimax* (see section "Systematics and Taxonomy", below).

Tricholimax hylae, a large multinucleate amoeba with a short, nonfunctional flagellum, is endobiotic in the hindgut of frog tadpoles. The phylogenetic placement of *Tricholimax* is unknown, in the absence of molecular data, so it is classified as Archamoebae incertae sedis (Pánek et al. 2016); nonetheless, it shows considerable similarity to *Mastigella* and *Pelomyxa*. Its identity has historically been confused with that of *Mastigina*.

Endamoeba is a poorly known genus; it includes aflagellate Archamoebae found in insects. Its morphological similarity to *Entamoeba* suggests it is likely to be a member of Entamoebidae, but it is currently classified as Archamoebae incertae sedis in the absence of molecular data (Pánek et al. 2016).

History of Knowledge and Literature

Taxonomic History of the Archamoebae as a Group

The name Archamoebae was introduced and used by Cavalier-Smith (1983, 1987a, b) and Cavalier-Smith et al. (2004) to group the pelomyxids, entamoebae, and mastigamoebids. The grouping of entamoebae, pelomyxids, and mastigamoebids was later supported by molecular phylogenetic analyses with complex evolutionary models (Cavalier-Smith et al. 2004; Edgcomb et al. 2002; Kudryavtsev et al. 2005; Milyutina et al. 2001; Nikolaev et al. 2006; Pánek et al. 2016; Ptáčková et al. 2013; Stensvold et al. 2012). The taxonomic concept of Archamoebae has been used at

ranks of infraphylum and class (Cavalier-Smith 1998, 2013; Cavalier-Smith et al. 2004) and has been compositionally unstable (Cavalier-Smith 1991, 1997; Cavalier-Smith and Chao 1995). It is currently ranked as a class, Archamoebae Cavalier-Smith, 1983 (Pánek et al. 2016).

In its recent incarnations (e.g., Cavalier-Smith 2013; Ptáčková et al. 2013; Zadrobílková et al. 2015, 2016), Archamoebae has included four main clades, the entamoebae, pelomyxids, mastigamoebids, and *Rhizomastix*, with *Tricholimax* sometimes treated as a fifth clade (Cavalier-Smith 2013) or regarded as incertae sedis but probably part of the pelomyxids, as discussed above (Frolov 2011; Pánek et al. 2016; Ptáčková et al. 2013; Zadrobílková et al. 2016). Relationships between clades have recently been resolved using multigene phylogenetics, dividing the group clearly into entamoebids (*Entamoeba*) and pelobionts (pelomyxids; mastigamoebids and *Rhizomastix*), and the high-level taxonomy has been updated to reflect this, as presented below here (Pánek et al. 2016).

Flagellated mastigamoebids and pelomyxids have historically been considered together as "pelobionts." The Order Pelobiontida was originally introduced to include only the genus *Pelomyxa* (Page 1976, 1987) and has occasionally been used at other ranks, e.g., Class Pelobionta (Krylov et al. 1980). Its trophic form being a large amoeba, *Pelomyxa* was until recently more usually classified with lobose amoebae (e.g., Bovee 1972; Bütschli 1880; Chatton 1925, 1953; Page 1976; Reichenow 1952; Siemensma 1987) but with increasing recognition that it was distinct from other large amoebae (Whatley and Chapman-Andresen 1990). Griffin (1988) revised the Order Pelobiontida to include *Mastigamoeba*, *Mastigella*, *Mastigina*, and *Dinamoeba*, on the basis of the ultrastructural evidence for flagella in *Pelomyxa* (Griffin 1979, 1988). Cavalier-Smith (1987a, b) created a different concept of pelobionts consisting of pelomyxids and entamoebids. However, this composition of the pelobionts has only rarely been used (e.g., Cavalier-Smith et al. 2004). The term "pelobiont" has since been used to encompass mastigamoebids and pelomyxids to the exclusion of entamoebae (Pánek et al. 2016).

The name Entamoebae was created to group aflagellate Archamoebae (*Entamoeba*, *Endamoeba*, *Endolimax*, and *Iodamoeba*). However, *Endolimax* and *Iodamoeba* have been removed from entamoebids, *Endamoeba* is currently regarded as Archamoebae incertae sedis, and the loss of the flagellum has occurred at least twice independently in Archamoebae. Thus, the name Entamoebae is confusing and should ideally only be used in the future with specific clarification as to its composition, noting that this is different from that of recent years.

History of Genera in the Archamoebae

Mastigamoeba was the first genus created to house species with a flagellum and an amoeboid body, with a hyaline cytoplasm unlike that of other superficially similar taxa such as the cercomonads (Kent 1880; Klebs 1892; Schulze 1875b; Stokes 1886, 1888, 1890). Frenzel (1897) then created *Mastigella* as a vehicle for species with similar characteristics but no (direct) connection between the nucleus and the

flagellum and *Mastigina* for flagellated species that had a limax shape and few lateral pseudopodia. These three genera have historically been described collectively as "mastigamoebids" (i.e., hyaline amoeboid flagellates), though the composition of this informal group has recently changed (see "General Characteristics", above). Subsequent revision of *Mastigina* from Goldschmidt (1907a) added an apical, spherical nucleus as a distinguishing criterion, as well as fountain-flow cytoplasm, though this is not present in all described species of *Mastigina* (Frenzel 1897) and is present in species of other genera that had already been described at that time, e.g., *Pelomyxa palustris*, *Mastigamoeba aspera*, and *Tricholimax hylae* (Frenzel 1897; Greeff 1874; Leidy 1879; Schulze 1875a, b). This had the effect of narrowing the circumscription of *Mastigamoeba* to include only hyaline amoeboid flagellates with a connection between the flagellum and the nucleus, with lateral pseudopodia, and with elongated nuclei. *Tricholimax hylae* (the sole species of *Tricholimax*) was then also treated as belonging to *Mastigina* (Brugerolle 1982; Brugerolle and Patterson 2000; Collin 1913; Goldschmidt 1907a; Wickerham and Page 1970), leading to some confusion about the distinguishing criteria of *Mastigina* (Frolov 2011).

Through the twentieth century, over 200 nominal species of *Mastigamoeba* and *Mastigella* were created on the basis of shape and size, pseudopodial form, and contractile vacuole number and location (e.g., Goldschmidt 1907a, Lemmermann 1914; see list of names in Ptáčková et al. 2013). Early studies of life cycles (Goldschmidt 1907a, b) and more recent culture-based studies (Bernard et al. 2000; Chystjakova et al. 2012; Ptáčková et al. 2013; Simpson et al. 1997; Walker et al. 2001; Zadrobílková et al. 2015) have shown that a single individual over time can express a very wide range of size, mode of amoeboid movement, gliding, swimming, and/or pseudopodial form, meaning that many previously described species are difficult to recognize with any confidence. However, recent molecular phylogenetic work has demonstrated that the ephemeral characteristics previously used to distinguish species can be used successfully as taxonomic characters, given a sufficiently detailed description (Ptáčková et al. 2013; Zadrobílková et al. 2015, 2016). Molecular phylogenetics has also shown that there are two main clades within *Mastigamoeba*, which have different ultrastructural characteristics (Pánek et al. 2016; see below).

What are now the type species of *Endolimax* and *Iodamoeba* were described in 1917 and 1912, respectively, as two *Entamoeba* species from humans (originally *Entamoeba nana* and *Entamoeba buetschlii*, respectively). *Endolimax* was created in 1917 (Kuenen and Swellengrebel 1917), and *Iodamoeba* in 1919 (Dobell 1919). Species have subsequently been assigned to each genus mostly based on morphology, with some debate about the degree of host specificity leading to fluctuating numbers of nominal species. Recent molecular phylogenetic studies suggest that the diversity encompassed by these descriptions is highly inconsistent from one nominal species to the next. Both genera are in need of revision (Stensvold et al. 2012; Poulsen and Stensvold 2016).

Species description in *Pelomyxa* has followed a similar pattern to that of *Mastigamoeba*. The amoeba now known as *Pelomyxa palustris* was first found by Greeff in 1870 and was named *Pelobius* (a name already occupied by an insect); it

was subsequently redescribed in more detail under its present name, *Pelomyxa palustris* (Greeff 1874). Greeff recognized that this "new, large freshwater rhizopod" was distinctively different from members of the genus *Amoeba* and emphasized the great morphological variability of the species. Leidy (1879) was also aware of this variability and suggested that the different forms of *Pelomyxa* might all be shown later to be different stages in the life cycle of the same species. During the twentieth century, various authors assigned numerous species to *Pelomyxa* (e.g., Penard 1902), but the prevailing view by the end of the twentieth century was that there was one or a few highly polymorphic species (Whatley and Chapman-Andresen 1990). Subsequently, as studies have employed light and electron microscopy and molecular phylogenetics, the number of species has begun to increase again (Berdieva et al. 2015; Chystjakova and Frolov 2011; Chystjakova et al. 2014; Frolov et al. 2004, 2005a, b, 2006, 2011; Ptáčková et al. 2013). The concept of *Pelomyxa* as a flagellated amoeba is relatively recent (Griffin 1979, 1988), but its similarities to mastigamoebids have long been noted (Bütschli 1880; Goldschmidt 1907a; Kudo 1939; Page 1970; Penard 1936; Schulze 1875b).

The genus *Endamoeba* was created in 1879 by Leidy for his newly described species, *Endamoeba blattae*, from cockroaches. Without noticing this, Casagrandi and Barbagallo (1895) created the genus *Entamoeba* and transferred into it the human parasitic species known previously as *Amoeba coli*. Since the names *Entamoeba* and *Endamoeba* are very similar, they were often confused, leading to their homonymization and the formal suppression of *Entamoeba* in 1928. The human pathogen *Entamoeba histolytica* can be, therefore, found under name *Endamoeba histolytica* in the older literature. This concept was, however, challenged by many authors (e.g., Kirby 1945) who argued that *E. blattae* and *E. coli* were not congeneric. The *Entamoeba*/*Endamoeba* problem was settled in 1954 when the International Commission on Zoological Nomenclature refuted the homonymization. Since that time, *Entamoeba* and *Endamoeba* have universally been considered distinct genera. The phylogenetic placement of *Endamoeba* remains unknown: although it is assumed to be related to *Entamoeba*, the cases of *Endolimax* and *Iodamoeba* now being placed in Mastigamoebidae suggest that *Endamoeba*'s position should be regarded as incertae sedis for now.

Since *Entamoeba histolytica* is an important human parasite, it is by far the best-known member of the Archamoebae. It was first reported by Lösch in 1875 and has since been intensively studied (see Martínez-Palomo (1993) and Wenyon (1926) for pertinent citations). The research into cell biology and biochemistry of *Entamoeba* was greatly facilitated when methods of its axenic culture became available (Diamond 1961). *Entamoeba histolytica* was one of the first putatively amitochondriate eukaryotes whose mitochondrial derivative (mitosome in this case) was discovered (Tovar et al. 1999). The genome sequence of *E. histolytica* was published more than 10 years ago (Loftus et al. 2005). Genome sequences of several other *Entamoeba* species are currently available (http://amoebadb.org/amoeba/). Several hundred papers on *E. histolytica* have been published annually during the last few years.

The genus *Rhizomastix* was described in 1911 by Alexeieff for his species *Rhizomastix gracilis* from the intestines of an axolotl. *Rhizomastix gracilis* was soon found also in larvae of crane flies (Mackinnon 1913), and its morphology was studied in detail by Ludwig (1946). Although a few additional *Rhizomastix* species have been described from insects and amphibians (see Čepička (2011) and Zadrobílková et al. (2016) for pertinent references), the phylogenetic position of this genus remained unclear until the recent molecular phylogenetic study of Ptáčková et al. (2013), which showed that *Rhizomastix* belongs to Archamoebae. The diversity of the genus has recently been studied using cultures and molecular phylogenetics (Zadrobílková et al. 2016; Pánek et al. 2016).

Practical Importance

Endobiotic Taxa Most described endobiotic Archamoebae are poorly known, and their relationships with their hosts have not been determined. Nevertheless, most species are probably harmless commensals.

The situation is much clearer in case of the few human symbionts. Several species have been reported from the intestine of humans (*Entamoeba histolytica*, *E. coli*, *E. dispar*, *E. polecki*, *E. hartmanni*, *E. moshkovskii*, *Endolimax nana*, and *Iodamoeba buetschlii*) and oral cavity (*Entamoeba gingivalis*). Although most of them are considered non-pathogenic, *Entamoeba histolytica* is an important human pathogen, which is responsible for 500 million new cases and 100,000 deaths annually. The disease caused by *E. histolytica* is called amebiasis or amebic dysentery and is distributed worldwide, though most cases are reported in developing countries. Amebiasis is also commonly diagnosed in travelers returning from tropical countries. The infection by *E. histolytica* usually occurs by ingestion of cysts with food or water. The primary site of infection is the large intestine where the amoebae may invade the mucosa and cause colitis that itself may be lethal. Occasionally, the amoebae spread via blood to various internal organs (usually the liver), and extra-intestinal amebiasis (with significant mortality) develops. For more information on amebiasis, see Martínez-Palomo (1993) and Haque et al. (2003).

Entamoeba dispar is morphologically indistinguishable from *E. histolytica* and was historically considered its non-pathogenic variant. It has been, however, shown that the two organisms represent separate species (see Diamond and Clark 1993). The pathogenity of *E. moshkovskii* is currently under debate (Heredia et al. 2012). *Entamoeba invadens* is known to cause severe reptilian amebiasis (see Reavill and Schmidt 2010).

Endolimax has been considered to be pathogenic by some authors, possibly causing diarrhea, intestinal inflammation, polyarthritis, or urticaria, but evidence for this is inconclusive (Poulsem and Stensvold 2016).

Free-Living Taxa Pelobionts and rhizomastixids are of unknown practical importance. While they have a worldwide distribution, they are not known to contribute to

any specific agricultural or pathogenic processes. They have historically been regarded as extremely "primitive" or deep-branching eukaryotes but are no longer regarded as such (see "Evolutionary History", below).

Habitats and Ecology

Occurrence/Distribution in Nature

Free-living pelobionts and rhizomastixids are found in the upper layers of mud or sand, mostly in freshwater rivers, lakes, bogs, or pits, and usually in stagnant or near-stagnant water, which creates a low-oxygen environment. The ideal place to find them is among undisturbed algal growth at the water-sediment interface, in shallow low-oxygen ponds (about 10–20% atmospheric oxygen) with relatively low pH (Bernard et al. 2000; Chystjakova et al. 2012; Frolov 2011; Ptáčková et al. 2013; Whatley and Chapman-Andresen 1990). Several papers have described them from sewage treatment works (e.g., Lackey 1923, 1932). Some taxa have been also described from low-oxygen intertidal marine sediments (Bernard et al. 2000; Bovee and Sawyer 1979; Larsen and Patterson 1990; Lee and Patterson 2000; Page 1983; Simpson et al. 1997; Shiratori and Ishida 2016; Zadrobílková et al. 2015).

Pelobionts have been described from all over the world (e.g., Larsen and Patterson 1990; Lee and Patterson 2000). The majority of reports in the literature are from temperate Europe and North America, due to the intensity of study in these locations in the last 200 years.

Endobiotic Archamoebae are widely distributed among various vertebrates and invertebrates. However, host specificity of particular species is only poorly understood and has been partially elucidated only in human parasites. For example, humans seem to be the primary host of *Entamoeba histolytica* though it has also been isolated from nonhuman primates and dogs. Similarly, *Entamoeba coli*, another species from the intestines of humans, can infect also nonhuman primates, dogs, and marsupials (see Thompson and Smith 2011). *Entamoeba moshkovskii* is most probably both endobiotic and free-living (Heredia et al. 2012; our observations).

Characterization and Recognition: Light-Microscopical Features

Recognizing Archamoebae

Most of the nominal species among Archamoebae have been described from a few cells seen on a single occasion (e.g., Calaway and Lackey 1962; Lackey 1923; Larsen and Patterson 1990; Penard 1902, 1909; Stokes 1886, 1888, 1890; Skvortzkov and Noda 1976). Many species can exist as flagellates, uninucleate amoebae, multinucleate amoebae, and cysts, a situation referred to as polymorphism.

Also, individual amoebae and flagellates change their appearance and are therefore pleomorphic. As most well-studied pelobionts are both polymorphic and pleomorphic, it would be tempting to assume that only static taxonomic characters that transcend any ephemeral changes can be used to distinguish species, such as the spines on the outside of *Mastigina setosa* (Goldschmidt 1907a), the extranucleolar "dot" in *Mastigamoeba punctachora* (Walker et al. 2001), or the doubled nucleus in *Mastigamoeba schizophrenia* (Simpson et al. 1997). But recent molecular work combined with observations of cultures (Ptáčková et al. 2013; Zadrobílková et al. 2015, 2016) confirms that – while transcendent characters make distinctions easier – ephemeral characters such as pseudopodial shape do correlate with molecular phylogenetic differences. Under these circumstances, it is important to not only observe variation in size and shape, flagellar length, speed of swimming, cytoplasmic movement, or separation into inner and outer layers but also to observe what percentage of the time characters are expressed.

General Appearance of the Cell

Archamoebae are chiefly recognized by being obviously amoeboid or amoeboid flagellates but are differentiable from other, similar taxa (e.g., myxomycete or protostelid swarmers, breviates, cercozoans, lobose amoebae) by having hyaline (clear) cytoplasm, which gives rise to "eruptive" or "bulging" hemispherical pseudopodia, usually at the anterior end of a moving cell (Fig. 1). The range of pseudopodial shapes reported in the literature also includes other morphologies – lateral or trailing pseudopodia may be rarely fine and filose or, more often, tapering finger shaped, broadly conical, or broadly lobate (e.g., Chystjakova et al. 2012; Frolov 2011; Frolov et al. 2004, 2006; Ptáčková et al. 2013; Zadrobílková et al. 2015, 2016). A uroid is frequently present at the posterior end of the cell; though in some taxa, particularly *Mastigamoeba simplex* and other members of the "Mastigamoebidae B" clade, and some *Mastigina* species, trailing pseudopodia are present instead (e.g., Goldschmidt 1907a; Pánek et al. 2016; Walker et al. 2001). *Rhizomastix* displays various pseudopodial shapes (Čepička 2011; Ptáčková et al. 2013; Zadrobílková et al. 2016). *Pelomyxa* has larger cells, and short flagella, but has many of the amoeboid characteristics seen in *Mastigamoeba*, as do members of *Mastigella* (Zadrobílková et al. 2015). Cells of *Entamoeba* spp. move by eruptive, clear lobopodia, though trailing filaments may be rarely formed. Although *Endolimax* is superficially similar to *Entamoeba*, its cells often form short tapering pseudopodia, similar to those seen in some species of *Mastigamoeba* (see Figs. 1, 3, and 4).

In some archamoebae, the cytoplasm is arranged in a distinct separation between "endoplasm" (interior of the cell body, where organelles are located) and the "ectoplasm" – a clear peripheral layer of cytoplasm, directly underneath the plasma membrane, which remains distinct from the agglomeration of nuclei, vacuoles, and endomembrane system in the center of the cell. This is the layer from which eruptive

pseudopodia form, into which the central cell contents then roll. The differentiation of ectoplasm has been described in mastigamoebids, including *Mastigamoeba scholaia* (Klug 1936), *Mastigella nitens* (Penard 1909), and *Mastigina setosa* (Goldschmidt 1907a; Skibbe and Zölffel 1991).

The ectoplasm may also be involved in "fountain flow" cytoplasmic streaming, as the outer part of the cytoplasm that runs backward, relative to the forward motion of the middle of the cell. Cytoplasmic streaming has mostly been described in *Pelomyxa* (Blochmann 1894; Hollande 1945; Rhumbler 1905; inter alia) but has also been reported in *Mastigamoeba aspera* (Chystjakova et al. 2012; Schulze 1875b), *Tricholimax hylae* (Becker 1928; Brugerolle 1982; Collin 1913; Frenzel 1897), and *Mastigina setosa* (Goldschmidt 1907a; Skibbe and Zölffel 1991).

Polymorphism and Life Cycle

Polymorphism is well-documented and a defining feature in pelobiont Archamoebae, as well as being necessary for completion of the life cycle in parasitic entamoebae. Life cycles have also been studied in several species. However, the actual cytological processes accompanying changes from one form to another remain mostly unknown, except in *Entamoeba* (Frolov 2011).

Recent descriptions of members of *Mastigamoeba*, *Rhizomastix*, and *Mastigella* have usually employed laboratory culture conditions that do not permit a study of the life cycle under normal environmental conditions. The general picture is that mastigamoebid Archamoebae can produce some or all of the following stages: amoeboid flagellates, aflagellate amoebae, large multinucleate amoebae, and cysts. All of these forms have been documented in detailed studies of *Mastigamoeba balamuthi* (Chavez et al. 1986; Pánek et al. 2016) and *M. schizophrenia* (Simpson et al. 1997), while flagellates and amoebae have been documented in *M. aspera* (Chystjakova et al. 2012), *M. simplex* (Bernard et al. 2000), *M. punctachora* (Bernard et al. 2000), *M. lenta*, *M. abducta*, *M. guttula*, *M. errans*, and *Rhizomastix libera* (Ptáčková et al. 2013); *Mastigella erinacea* and *Mastigella rubiformis* (Zadrobílková et al. 2015); flagellates and cysts in *Mastigella nitens* (Frolov 2011), *Rhizomastix bicoronata*, *R. tipulae*, and *R. elongata* (Zadrobílková et al. 2016); and flagellates, amoebae, and cysts in *R. vacuolata* (Zadrobílková et al. 2016).

Earlier studies of members of *Mastigamoeba* and *Mastigella* (e.g., Frenzel 1897; Goldschmidt 1907a; Schulze 1875b) employed microcosms rather than typical modern laboratory culture conditions, mimicking normal environmental conditions and allowing some observations of succession of polymorphism, from which life cycle details could be inferred. Flagellates reproducing by mitosis, aflagellate amoebae, and large, multinucleate division stages giving rise to uninucleate cells were documented in *Mastigella vitrea* and *Mastigina setosa* (Goldschmidt 1907a, b).

A series of studies of *Pelomyxa* species has also employed microcosms as a culture method, permitting extensive observation of the life cycle of natural populations (Whatley and Chapman-Andresen 1990; Frolov 2011). *Pelomyxa palustris* progresses in spring from cysts containing four nuclei, to small binucleate amoebae (100 μm long), then to larger multinucleate amoebae with or without endosymbionts, and then in summer to large elongate multinucleate amoebae (up to 5 mm long) with 30–60 nuclei, endosymbionts, flagella, and a posterior uroid. In autumn, they progress to large, spherical amoeboid cells with bacteria around the thousands of nuclei; these giant cells then divide by plasmotomy to form cysts or small amoebae over winter (Frolov 2011; Frolov et al. 2007; Schirch 1914; Whatley and Chapman-Andresen 1990). Other life-cycle descriptions exist for *P. corona* (Frolov et al. 2004), *P. gruberi* (Frolov et al. 2006), *P. binucleata* (Frolov et al. 2005a; Frolov 2011), *P. flava* (Frolov et al. 2011), and *P. paradoxa* (Chystjakova et al. 2014).

Cysts

The structure of the cyst has been best characterized in *Entamoeba invadens* (see Samuelson and Robbins 2011). The cyst wall is composed mainly from chitin and various glycoproteins. Cysts of particular *Entamoeba* species are rounded and differ in the number of nuclei present, e.g., the uninucleate *E. polecki*; *E. histolytica*, *E. hartmanni*, and *E. marina* with four nuclei; and *E. coli* and *E. muris* with up to eight nuclei (recently summarized in Shiratori and Ishida 2016). During the encystation of *Entamoeba* trophozoites, so-called chromatoid bodies are formed in the cytoplasm. These are elongated bars with rounded ends and are formed by ribosomes arranged in helices. The chromatoid bodies disappear from the older cysts (Rosenbaum and Wittner 1970; Schuster 1990).

Apart from *Entamoeba* spp., cysts with various numbers of nuclei have been documented in some other members of Archamoebae: uninucleate cysts in *Mastigamoeba balamuthi* (Chavez et al. 1986), *M. punctachora* (Bernard et al. 2000), *M. schizophrenia* (Simpson et al. 1997), and *Iodamoeba buetschlii*, binucleate cysts in *Rhizomastix* spp. (Čepička 2011; Zadrobílková et al. 2016), and four-nucleated cysts in *Endolimax* spp. and *Pelomyxa palustris* (Frolov 2011; Frolov et al. 2007; Griffin 1988; Ptáčková et al. 2013; Whatley and Chapman-Andresen 1990). The cysts of *Endamoeba* are multinucleate. *Tricholimax* varies between two and four nuclei according to the age of the cyst (Collin 1913). The composition of the cyst wall of non-*Entamoeba* Archamoebae is still unknown. In *Pelomyxa*, the cyst has a central vacuole containing endosymbionts, and the cyst wall has three layers. The laminated structure of cyst walls would be better revealed by cryofixation techniques, which have not yet been employed, than by chemical fixation, which has been used hitherto except on cysts of *Rhizomastix* (Zadrobílková et al. 2016). The cyst of *Iodamoeba buetschlii* contains a characteristic glycogen-containing inclusion in the cytoplasm (see Fig. 5).

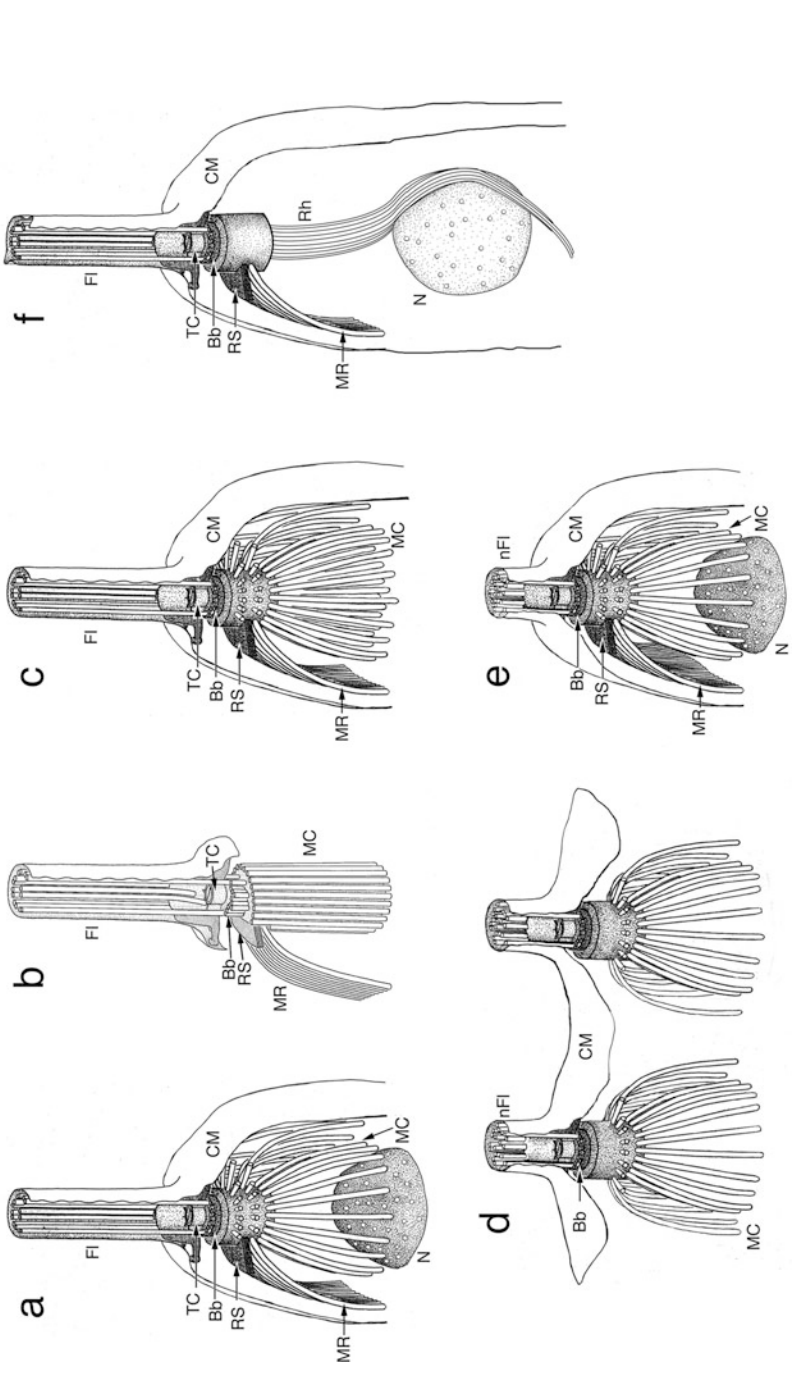

Fig. 2 Flagellar apparatus ultrastructure defines the identities of genera of flagellated Archamoebae. The features common to all flagellated Archamoebae include a single basal body (*Bb*), from which arises a flagellum (*Fl*) and a cone (*MC*) or rhizostyle (*Rh*) of microtubules, and (in most taxa) a

Ultrastructure

Flagellar Cytoskeleton

Flagella in Archamoebae appear to have degenerated in several groups independently, either to structures with dysfunctional axonemes or to the complete absence of a flagellar apparatus (discussed in Zadrobílková et al. 2015). Members of *Entamoeba*, *Endamoeba*, *Endolimax*, and *Iodamoeba* have no flagellar apparatus (El-Hashimi and Pitman 1970; Morris 1936; Rosenbaum and Wittner 1970; Zaman et al. 1998, 2000) and are not referred to further in the sections below.

Flagellated Archamoebae have a relatively simple microtubular cytoskeleton (see Fig. 2). Among the flagellated taxa that have been studied by TEM (see Table 1), the flagellar apparatus consists of one or more "monokinetids" – single, flagellated basal bodies – giving rise proximally to a cone or cylinder of microtubules, as well as (in most taxa) a lateral root of microtubules with a bilaminar "root sheet" at the origin of the root on its distal face. Members of *Mastigamoeba*, *Mastigella*, *Mastigina*, *Tricholimax*, and *Rhizomastix* typically have only one flagellum per cell, though the type species of *Mastigella*, *M. polymastix*, has up to four flagella per cell (Frenzel 1897) and *Tricholimax* has multiple nuclei, each with its own attached (internal) kinetid (Becker 1925; Brugerolle 1982, 1991; Collin 1913). The flagellar apparatus in *Mastigamoeba* varies between a wide distribution of microtubules, seen in Mastigamoebidae "A" (as defined in Ptáčková et al. 2013, Pánek et al. 2016; see also Table 1 and Figs. 2a and 3), and a very narrow single layer of microtubules, seen in members of Mastigamoebidae "B" (as defined in Ptáčková et al. 2013; Pánek et al. 2016; see also Table 1 and Figs. 2b and 3).

Fig. 2 (continued) transitional cylinder (*TC*). In most cells, the flagellar apparatus is usually directed perpendicularly to the cell membrane (*CM*), but the cone of microtubules can sometimes run parallel to it. (**a**) ***Mastigamoeba*** has a microtubular cone (*MC*) that connects to the nucleus; a microtubular root (*MR*) also arises from the basal body, immediately proximal to a bilaminate root sheet (*RS*); typically there is only one monokinetid flagellum per cell. This shows a representative flagellar apparatus from the group "Mastigamoebidae A" where the cone of microtubules (*MC*) arises laterally from both the sides and the base of the basal body; the flagellar transition zone is long. *Fl* flagellar axoneme, *TC* transition zone cylinder, *Bb* basal body. *RS* bilaminar root sheet, *MR* microtubular root. (**b**) ***Mastigamoeba*** showing a representative of group "B" where the cone of microtubules (*MC*) arises longitudinally from near the base of the basal body, and the flagellar transition zone (*TZ*) is short and contains no extra elements. (**c**) ***Mastigella*** has a microtubular cone that does not connect to the nucleus. There may be up to four long flagella per cell in some species. (**d**) ***Pelomyxa*** has numerous nonfunctional, short, monokinetid flagella (*nFl*) with "n + n" arrangement of microtubules. There is no obvious microtubular root or root sheet. (**e**) ***Tricholimax*** has a flagellar apparatus similar to that of *Mastigamoeba*, but it has nonfunctional "n + n" flagella (*nFl*), and it frequently has several nonflagellated monokinetids connected to nuclei in the cytoplasm. (**f**) ***Rhizomastix*** has a rhizostyle (*Rh*) – a tapering bundle of microtubules that extends from the base of the basal body, to wrap around the nucleus. Its flagellum has two vanes, which may contribute to its fast, jerky swimming movement. Scale bar = 250 nm (Figures (**a**) and (**c**) redrawn with modifications from Walker et al. 2001, and Figure (**b**) reproduced from Walker et al. 2001 with permission from Elsevier)

Table 1 Flagellar apparatus details for taxa described by TEM. Further details are provided in the taxonomic section. Where a value is given as "?," there is no data for that feature in a published account. Where a value is given as "(?)," the interpretation of data here differs from that given in the published account

(**x**–**aa**) *Mastigamoeba guttula*. In x–z, flagellates; in aa, aflagellate cell. Scale bars in **a–c**, **e–i**, **p–aa** =10 μm; in d = 20 μm, in j–m = 50 μm, in n, o = 200 nm (Figures a–c, e–m, and p–aa all reproduced from Ptáčková et al. 2013 with permission from Elsevier)

Flagella are usually positioned at the anterior end of the cell and used in movement, though particularly amoeboid cells in *Mastigella* may move predominantly by pseudopodia, with the poorly functional flagellum pointing in a different direction (Frenzel 1897; Frolov 2011; Goldschmidt 1907a; Walker et al. 2001, Zadrobílková et al. 2015). The flagellum of *Mastigella* is generally slower beating and less motile than that seen in *Mastigamoeba* and may be an intermediate stage that gave rise to the extreme flagellar reduction seen in *Pelomyxa* (discussed in Zadrobílková et al. 2015).

Giant amoeboid cells of *Pelomyxa* have numerous separate monokinetids, bearing (usually) short, nonfunctional flagella with a disorganized axoneme. Typically, a microtubular cone is formed, but this varies between a dense cone and a single layer of microtubules, with or without a lateral root (Fig. 2d; see Table 1 for further details). The number of monokinetids varies between ca. 50 and ca. 700 in *P. palustris* (Griffin 1988). Likewise, their density varies more than tenfold (Griffin 1988), and their abundance and distribution over the cell's sides or uroid also varies (e.g., compare *P. flava*, *P. paradoxa*, and *P. stagnalis*; Chystjakova and Frolov 2011; Chystjakova et al. 2014; Frolov et al. 2011). Whether basal bodies form flagella or merely "buds" can vary widely through the life cycle (e.g., *P. paradoxa* vs. *P. gruberi*; Chystjakova et al. 2014; Frolov et al. 2006). Flagella are typically not found on anterior pseudopodia in *Pelomyxa* (Frolov 2011) and have not been seen at all in *P. secunda* (Berdieva et al. 2015).

For further details of the flagellar cytoskeleton, see Fig. 2 and Table 1.

Nuclei and Cell Division

Numbers of nuclei are one of the main features that distinguish "pelomyxid" Archamoebae from "mastigamoebid" or "entamoebid" Archamoebae. In many pelomyxids, the usual state is cells with tens or hundreds of nuclei, whereas in other Archamoebae, the usual state is one or few nuclei, though stages with tens of nuclei may exist.

A uninucleate flagellate is the main trophic form in *Mastigamoeba*, some members of *Mastigella*, *Mastigina*, and *Rhizomastix*. Reproduction of uninucleate flagellates by mitosis has been documented only in *Mastigella* and *Mastigina* (Goldschmidt 1907a, b). The nuclei of *Mastigamoeba schizophrenia* appear in "pairs" of two adpressed nuclei, but the extent of differentiation within these pairs is unknown (Simpson et al. 1997). Some "flagellate" taxa may typically have more than one nucleus, such as *Tricholimax hylae*, which has 1–6 (Becker 1925; Brugerolle 1982, 1991; Collin 1913; Frenzel 1897), and members of *Mastigella* (Zadrobílková et al. 2015).

As discussed above, a few "flagellate" species also have distinct, large amoeba stages with more than one nucleus: *Mastigamoeba schizophrenia* has 2–10 (i.e., 1–5 pairs; Simpson et al. 1997); *M. punctachora* has 1–8 (Bernard et al. 2000); and *M. aspera* has two or more nuclei in its amoeba form, which would previously have

been described as a different species, *Dinamoeba mirabilis* (see Chystjakova et al. 2012). In at least one such species, *Mastigamoeba balamuthi*, the multinucleate amoebae (with on average 15 nuclei but up to 46), are the dominant trophic stage, reproducing while multinucleate by mitosis and subsequent plasmotomy (i.e., cytokinesis not preceded by mitosis), which results in large and asymmetric numbers of nuclei in daughter cells.

"Budding" plasmotomy, from multinucleate amoebae to uninucleate flagellates, only happens rarely and only under specific trophic conditions (Chavez et al. 1986). Production of small uninucleate flagellates, from a large, rounded amoeboid cell that is filled with smaller cells, has also been described from *Mastigina setosa* and *Mastigella vitrea* (Goldschmidt 1907a, b); whether this is a form of plasmotomy or more akin to sporogony is unclear. It resembles the processes described in *Pelomyxa palustris* (Frolov 2011; Whatley and Chapman-Andresen 1990).

In *Pelomyxa*, the main described trophic "adult" form is a large, multinucleate amoeba, which also has flagella (see above). This "flagellated" trophic form, typically a cylindrical amoeba, may in some cases later transform into an immotile, rounded amoeboid form with hundreds of nuclei (e.g., *P. corona*, *P. gruberi*; Frolov 2011; Frolov et al. 2004, 2006). It is unclear whether this rounded form is homologous to the large multinucleate amoebae seen in *Mastigamoeba schizophrenia* (Simpson et al. 1997) and *M. balamuthi* (Pánek et al. 2016) or to the large rounded forms that divide by plasmotomy in *Mastigella vitrea* and *Mastigina setosa* (Goldschmidt 1907a), as they are only rarely seen and have not been studied by electron microscopy. Species of *Pelomyxa* can be divided into taxa that have hundreds of nuclei in the adult motile form (e.g., *P. palustris*, *P. corona*, *P. prima*: Frolov 2011; Whatley and Chapman-Andresen 1990) and taxa with tens (e.g., *P. belevskii*, *P. stagnalis*; Frolov 2011; Ptáčková et al. 2013) or one or two nuclei in mature cells (e.g., *P. binucleata*, *P. flava*, *P. paradoxa*, *P. schiedti*; Chystjakova et al. 2014; Frolov 2011; Frolov et al. 2005a; Zadrobílková et al. 2015). Division from multinucleate adult cells to smaller juvenile cells is typically by unequal plasmotomy (Frolov 2011; Ptáčková et al. 2013; Schulze 1875a; Whatley and Chapman-Andresen 1990).

The trophozoites of *Entamoeba* spp. are uninucleate, and no multinucleate trophic forms are usually created. Mitosis of *Entamoeba histolytica* was studied, for example, by Solis and Barrios (1991) and by Chávez-Munguía et al. (2006).

Nuclear Chromatin

Patterns of nuclear chromatin appear to distinguish different species in Archamoebae, though there is not a clear taxonomic pattern above species level. Chromatin patterns can be a peripheral arrangement of small clumps of chromatin around the edge of the nucleus or a single large nucleolus or a few chromatin clumps joined together in the center of the nucleus (described further in Frolov 2011). Peripheral arrangements are common in *Entamoeba*, pelomyxids, and *Rhizomastix* (Čepička 2011; Chystjakova et al. 2014; Frolov 2011; Frolov et al. 2004, 2005a, b,

2006; Ptáčková et al. 2013; Zadrobílková et al. 2015, 2016) and are also present in "*Mastigina trichophora*," *Mastigella eilhardi*, and *Mastigella nitens* (Frolov 2011; Penard 1909; Zadrobílková et al. 2015).

Nuclear chromatin is used as a diagnostic feature in *Entamoeba* species, with *E. histolytica*, *E. dispar*, and *E. marina* showing a fine peripheral ring with a small central dot, *E. hartmanni* showing a large central nucleolus and thick peripheral clumps of chromatin, and *E. coli* showing peripheral clumps only (Shiratori and Ishida 2016). The majority of members of *Mastigamoeba* have large nucleoli, as do *Tricholimax hylae*, *Pelomyxa palustris*, *P. gruberi*, *P. stagnalis*, and *Rhizomastix* species. In both *Iodamoeba* and *Endamoeba*, the nucleolus is large and central, and there is no peripheral ring of chromatin (see section "Systematics and Taxonomy", below).

There are cajal-body-like stacked inclusions in the central nucleolus in *Pelomyxa stagnalis* (Chystjakova and Frolov 2011; Ptáčková et al. 2013), and *P. belevskii* has a loose stacked arrangement of "vermiform bodies" of chromatin around the edge of the nucleus, similar in size to the inclusion in *P. stagnalis* (Ptáčková et al. 2013).

Cell Coverings

As reviewed in Frolov (2011), most pelobionts are covered in a thin layer of amorphous or filamentous organic material. The extracellular layer may be irregularly, thinly distributed over the cell surface (e.g., Brugerolle 1982; Chavez et al. 1986; Simpson et al. 1997; Walker et al. 2001), often being thickest at the posterior end of the cell, particularly in pelomyxids (Frolov 2011). Finely filamentous cell coverings may be present, with filaments apparently perpendicular to the cell surface (e.g., *Pelomyxa palustris*, *P. gruberi*, *Mastigella nitens*: Frolov 2011) or parallel to the surface in the case of very thick coverings, which can reach up to 1 μm thickness (e.g., *P. flava*, *Mastigamoeba aspera*; Chystjakova et al. 2012; Frolov 2011; Frolov et al. 2011). These fine extracellular layers are rarely preserved well with chemical fixation for electron microscopy; cryofixation would be appropriate for further study.

Numerous species in pelobionts have been described with spines on the outside of the cell, with varying degrees of packing, from the dense, highly refringent layer of very tightly packed spines in *Mastigina chlamys* (Frenzel 1897; Seckt 1922), through regularly arranged but obviously discrete spines in *Mastigina setosa* (Goldschmidt 1907a; Skibbe and Zölffel 1991), to irregular and loosely packed spicules in *Mastigamoeba trichophora* (Lauterborn 1901), *Mastigamoeba pilosa* (Schoudeten 1907), and *Mastigina spicata* (Penard 1909). Frolov (2011) shows electron micrographs of "*Mastigina trichophora"* where hollow spicules are each placed in "boat-shaped" scales, which are packed in a tight layer over the extracellular glycocalyx. It is unclear whether these spines are made only of organic material (Frolov 2011) or are mineralized as well, as seen in the euglenid *Trachelomonas* (Conforti et al. 1994; Preisig 1994).

Mitochondrial Remnants

Like other anaerobic groups in the eukaryotes, Archamoebae are "secondarily amitochondriate." In almost all cases, such anaerobic eukaryotes retain reduced mitochondrion-related organelles (MROs) which have usually lost DNA, genome maintenance proteins, and a typical ATP-producing electron transport chain. They often still produce ATP by partial anaerobic oxidation of pyruvate (hydrogenosomes), but some have lost energy metabolic function entirely (mitosomes), preserving only a few other functions (such as aspects of mitochondrial type iron-sulfur cluster assembly machinery) and acquiring the ability to import ATP (Chan et al. 2005; Maguire and Richards 2014).

Both kinds of double-membrane-bound MROs have been described from Archamoebae (Barberà et al. 2007; Hampl and Simpson 2008). Mitochondrial cpn60 function has been demonstrated in *Entamoeba histolytica*, and localized, to the mitosomes in *E. histolytica* (Chan et al. 2005; Clark and Roger 1995; Leon-Avila and Tovar 2004; Tovar et al. 1999), and to hydrogenosome-like organelles in *Mastigamoeba balamuthi* (Gill et al. 2007; Hampl and Simpson 2008). Iron-sulfur cluster assembly proteins are closely related to those of epsilon proteobacteria both in *Mastigamoeba balamuthi* (Gill et al. 2007) and *Entamoeba histolytica* (Maralikova et al. 2010; van der Giezen et al. 2005), implying a single lateral transfer event where mitochondrial Fe:S assembly appears to have been lost entirely and replaced with an Fe:S assembly system that is not homologous to the standard mitochondrial system and is now cytosolic (Nývltová et al. 2013). The acquisition of alternatives to normal mitochondrial pyruvate dehydrogenase may have happened more than once, with *M balamuthi* and *E. histolytica* each possessing copies of pyruvate ferredoxin/oxidoreductase (Embley and Martin 2006; Gill et al. 2007); but *M. balamuthi* also possesses a pyruvate formate lyase that was laterally transferred from a firmicute (Stairs et al. 2011). Mitosomes are extremely abundant in *E. histolytica* implying that some functions are yet to be uncovered in detail (Aguilera et al. 2008) – an example being the synthesis of sulfur compounds required for encystation (Mi-ichi et al. 2015). The MROs of Archamoebae are discussed in the context of other MROs by Maguire and Richards (2014).

Ultrastructural reports also exist for double-membrane-bound organelles in *Mastigamoeba simplex*, *Mastigamoeba punctachora*, and *Mastigella commutans* (Walker et al. 2001), *Mastigella rubiformis*, *M. ineffigiata* (Zadrobílková et al. 2015), *Endolimax piscium* (Constenla et al. 2013), *Rhizomastix libera* (Ptáčková et al. 2013), *R. elongata* (Zadrobílková et al. 2016), and *Pelomyxa palustris* (Seravin and Goodkov 1987c). As previously discussed (Zadrobílková et al. 2015), there is a notable lack of reports of MROs in EM studies of *Pelomyxa*. This may be because of the difficulty of serially sectioning a large amoeba, a misidentification of MROs as symbionts, or, alternatively, the real absence of MROs in all examined species of *Pelomyxa* except *P. palustris*.

Golgi

Canonical Golgi dictyosomes have not been reported in the Archamoebae so far, though related elements of the endomembrane system have been shown to be functionally present in *Entamoeba histolytica* (Bredeston et al. 2005) and *Mastigamoeba balamuthi* (Dacks et al. 2004), with all "core" functions being present (Mowbrey and Dacks 2009). However, methods for detecting endomembrane system function and Golgi dictyosomes are diverse, and many eukaryotes do not possess canonical Golgi stacks that are easy to recognize by transmission electron microscopy. Tantalizing reports exist suggesting that *Entamoeba* may possess Golgi stacks that are only visible with the application of cryofixation techniques (Chavez-Munguia et al. 2000; Ghosh et al. 2000). A similar situation may hold in pelobionts: a few reports exist of Golgi-like stacks of membranes, but in each case, these may be poorly fixed endoplasmic reticulum, and further ultrastructural work, using different techniques, is required. The multi-membrane organelle seen in *Rhizomastix libera* (Ptáčková et al. 2013) is positioned close to the flagellar base, as per the Golgi dictyosomes of other superficially similar amoeboid taxa with flagella (e.g., Heiss et al. 2013; Walker et al. 2003), but the published preservation of *Rhizomastix* is not sufficiently good for any clear identification of the organelle, and it is not seen in *R. elongata* under better fixation conditions (Zadrobílková et al. 2016). Similar, though bigger and more organized stacked structures have been reported from *Pelomyxa palustris* (Seravin and Goodkov 1987b) and *P. corona* (Frolov et al. 2004) as well as reticulate multimembranous organelles from *P. flava* (Frolov et al. 2011). These have subsequently been interpreted as endoplasmic reticulum (Frolov 2011), as have reports of stacked structures in *Mastigamoeba schizophrenia* (Simpson et al. 1997), *M. punctachora* (Walker et al. 2001), and *Rhizomastix elongata* (Zadrobílková et al. 2016).

Peroxisomes

While Archamoebae have traditionally been considered to lack peroxisomes (Žárský and Tachezy 2015), an unpublished thesis reports peroxisomal proteins in both *Mastigamoeba balamuthi* and *Entamoeba histolytica* (Žárský 2012), which would be consistent with secondary loss of peroxisomal function in Archamoebae.

Symbionts

The best-known symbionts of Archamoebae are the three morphologies of prokaryotes that surround the nuclei of *Pelomyxa* species (Berdieva et al. 2015; Chystjakova et al. 2014; Frolov 2011; Frolov et al. 2006; Whatley 1976; Whatley and Chapman-Andresen 1990). There is one large bacterium with a distinctive axial cleft and up to two smaller methanogenic archaea, one of which is known as *Methanobacterium formicicum* DSM3637 (Frolov et al. 2004, 2005a, b, 2006, 2011; Griffin 1988; van Bruggen et al. 1988; Whatley 1976). *Methanobacterium*

formicicum DSM3637 was isolated from *P. palustris* (van Bruggen et al. 1983, 1988), and a draft of its genome has been published (Gutierrez 2012). Endobiotic prokaryotes also exist in *Mastigella* species (Frolov 2011; van Bruggen et al. 1985; Walker et al. 2001; Zadrobílková et al. 2015) and *Rhizomastix libera* (Ptáčková et al. 2013). The organic layer covering *Mastigamoeba aspera* also contains numerous small, rod-shaped prokaryotic ectobionts of uncertain identity (Chystjakova et al. 2012; Goldschmidt 1907a; Kudo 1950; Lemmermann 1914; Page 1970; Penard 1902, 1909, 1936; Schulze 1875b; Siemensma 1987).

The physiological role played by these endo- and ecto-symbionts has not been clearly demonstrated, but numerous cases exist of symbiosis between methanogenic archaea (which presumably derive hydrogen from within their hosts) and anaerobic eukaryotes with mitochondria that have been reduced to hydrogenosomes (Embley et al. 1995; Fenchel and Finlay 1995; Martin and Müller 1998; van Bruggen et al. 1983; van Hoek et al. 2000).

Endobiotic mastigamoebids have also been described as emerging from *Pelomyxa* (Greeff 1874; Hollande 1945; Whatley and Chapman-Andresen 1990); recent observations including sequence data confirm that this is not a life-cycle stage of *Pelomyxa* (Ptáčková et al. 2013).

Systematics and Taxonomy

Class Archamoebae Cavalier-Smith, 1983
Anaerobic/microaerophilic Amoebozoa with reduced mitochondria. May exist as amoebae, amoeboflagellates, or cysts. Ancestrally with a single apical flagellum, arising from a single basal body that gives rise proximally to a microtubular cone and laterally to a microtubular root arising immediately proximal to a double-layered "root sheet" sitting perpendicular to the axis of the basal body. Secondarily aflagellate or multiflagellate, with disordered flagellar axoneme, or with no flagellar apparatus. Amoeboid movement with eruptive lobopodia. Free-living or endobiotic.

Order Pelobiontida Page, 1976
For the current composition, see Pánek et al. (2016). The clade including mastigamoebids, pelomyxids, and rhizomastixids; using the branch-based definition introduced and discussed by Pánek et al. (2016), the clade consisting of *Mastigella eilhardii* Bürger 1905 and all organisms that share a more recent common ancestor with *M. eilhardii* than with *Entamoeba histolytica* Schaudinn 1903.

Suborder Mastigamoebina Frenzel, 1897
Rank changed from order to suborder by Pánek et al. (2016). The clade including Mastigamoebidae and Rhizomastixidae; using the node-based definition introduced and discussed by Pánek et al. (2016), the least-inclusive clade consisting of *Mastigamoeba balamuthi* (Chávez et al. 1986) Simpson et al. 1997, *Mastigamoeba abducta* Ptáčková et al. 2013, and *Rhizomastix libera* Ptáčková et al. 2013.

Family Mastigamoebidae Goldschmidt, 1907
Archamoebae with trophozoites which are uninucleate to multinucleate, with single motile anterior flagellum associated with microtubular cone, or aflagellate. Amoebae flattened, amoeboid movement slow, typically with multiple pseudopodia. Free-living or endobiotic. Current composition as per Ptáčková et al. (2013).

Mastigamoeba Schulze, 1875 (Fig. 3)
Mastigamoeba contains amoeboid cells where the flagellated basal body and the anterior nucleus are immediately adjacent to each other during movement. The basal body and nucleus are joined by a cone of microtubules.

Circumscription Archamoebae with a uniflagellated trophic stage, in which the nucleus and flagellum are connected by a cone of microtubules that arises from the base and sides of the single (flagellated) basal body; a cylinder is present in the transition zone of the flagellum. A single root of microtubules arises from the side of the basal body, and the root has a bilaminar "root sheet" on its anterior edge (Fig. 2a, b). Basal bodies usually have nine triplets of microtubules, but *M. schizophrenia* has nine doublets (Simpson et al. 1997). The flagellum has a conventional eukaryotic "9 + 2" arrangement of microtubules but lacks outer dynein arms, giving rise to a distinctively languid flagellar beat. The flagellates may, at least in some species, transform to amoebae with one, few, or many nuclei. Both flagellate and amoeboid forms may transform into cysts. Nuclei are usually single, but are paired in *M. schizophrenia*, and have vesicular nucleoli. In *M. punctachora*, the nucleus contains a small extranucleolar "dot" of chromatin (Bernard et al. 2000). The outside of the cell is usually naked, but in *M. aspera*, there are ectobiotic bacteria (Chystjakova et al. 2012) and spined species have been described. Cells have been found in soils and freshwater and marine habitats. Phylogenetic analyses divide this genus into two separate groups (as defined in Ptáčková et al. 2013; Pánek et al. 2016): "A" with a broad multilayered microtubular cone radiating laterally from the sides of the basal body, a long flagellar transition zone, and, in some taxa, a transitional column or spiral, microtubules arising from the base of the basal body or an MTOC immediately proximal to the basal body (Fig. 2a; Table 1) and "B" with a single-layered microtubular cone extending posteriorly from sides the basal body, and a short transition zone, and none of the extra features seen in some members of "A (Fig. 2b; Table 1)." There is little morphological variation at the light microscopical level in "B" (Fig. 3).

Type Species *Mastigamoeba aspera* Schulze, 1875
(See Chystjakova et al. 2012 for a recent description and discussion of synonymy with *Dinamoeba*; discussed further in Ptáčková et al. 2013)

Remarks Based on recent phylogenetic analyses (Stensvold et al. 2012; Ptáčková et al. 2013), the flagellum-lacking entamoebid genera *Endolimax* and *Iodamoeba* form an internal branch of *Mastigamoeba*, making the latter genus paraphyletic. Recent analyses also divide *Mastigamoeba* into "A" and "B" clades, as discussed

above. The full scope and character of *Mastigamoeba* is uncertain, as recent phylogenetic analyses do not include most of the previously described taxa in *Mastigamoeba*, and we lack electron microscopical data for many taxa, as well as molecular data on the phylogenetic position of *M. aspera*, the type species. The degree of overlap between *Mastigamoeba*, *Mastigina*, and *Tricholimax* has long been unclear, leading to confused and inconsistent taxonomy of some species (Frenzel 1897; Frolov 2011; Goldschmidt 1907a; Lemmermann 1914). Other genera that fall within the circumscription of *Mastigamoeba* include *Dinamoeba* Leidy, 1874 (*D. mirabilis* has long been regarded as a synonym of *M. aspera* – as most recently discussed in Chystjakova et al. 2012; Ptáčková et al. 2013) and *Phreatamoeba* Chávez et al. 1986 (transferred to *Mastigamoeba* by Simpson et al. 1997).

Endolimax Kuenen and Swellengrebel, 1917 (Fig. 4)
Endolimax contains aflagellate uninucleate amoebae reminiscent of *Entamoeba*. All are intestinal symbionts of various insects and vertebrates including humans.

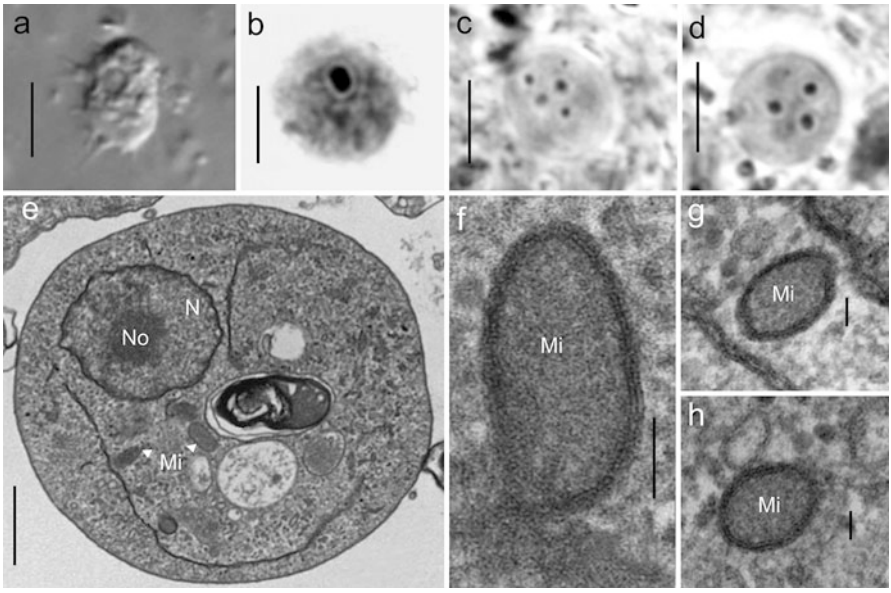

Fig. 4 ***Endolimax.*** (**a**) *Endolimax nana* live trophozoite (amoeba) showing characteristic finger-shaped pseudopodia and a single nucleus with a vesicular nucleolus. Differential interference contrast light microscopy. (**b**–**d**) *E. nana* prepared slides, stained with iron hematoxylin, bright field light microscopy: (**b**) trophozoite, showing a large spherical nucleolus in the nucleus. (**c**, **d**) Cysts with four nuclei. (**e**–**h**) Transmission electron micrographs of *Endolimax piscium* from Constenla et al. 2013: (**e**) Whole cell, showing nucleus (*N*) with central nucleolus (*No*), and mitochondrion-related organelles (*Mi*, *arrowheads*). (**f**–**h**) Mitochondrion-related organelles (*Mi*), with double membranes. Scale bars in a, c, d = 5 μm; in b = 10 μm, in e = 500 nm, in f, g, h = 50 nm (Micrographs in **e, f, g, h** reprinted from *Journal of Fish Diseases* 37, Constenla et al., *Endolimax piscium sp. nov. (Amoebozoa), causative agent of systemic granulomatous disease of cultured sole, Solea senegalensis Kaup,* pp. 229–240, Copyright (2013), with permission from John Wiley & Sons)

Circumscription Trophozoites are aflagellate amoebae measuring up to 20 μm. Actively moving cells form a single broad, hyaline, and eruptive lobopodium. Morphologically, *Endolimax* closely resembles *Entamoeba*, except that the nucleus of *Endolimax* does not contain peripheral heterochromatin (Figs. 4 and 9). There is a single large central nucleolus in the nucleus. Nucleoli in nuclei of cysts are often elongate. Cysts are rounded or elongate, with one to eight nuclei (usually four; rarely many). Approximately 20 *Endolimax* species have been described, all being commensals of the lower intestine of various animals (e.g., *E. nana* from humans, *E. caviae* from rodents, *E. gregariniformis* from birds, *E. clevelandi* from reptiles, *E. ranarum* from amphibians, *E. leptocoridis*, and *E. termitis* from insects). *Endolimax piscium* was reported from lesion in the muscle tissue of a fish (Costenla et al. 2013).

Type Species *Endolimax nana* (Wenyon and O'Connor 1917) Kuenen and Swellengrebel, 1917 (basionym *Entamoeba nana* Wenyon and O'Connor 1917).

Remarks Because it is aflagellate, *Endolimax* was traditionally considered a member of Entamoebidae. Based on SSU rRNA phylogeny, Cavalier-Smith et al. (2004) removed *Endolimax* from Entamoebidae and created the family Endolimacidae for it. Since *Endolimax* forms an internal branch of *Mastigamoeba*, Ptáčková et al. (2013) transferred it to Mastigamoebidae. The genus as a whole is relatively understudied (Poulsen and Stensvold 2016).

Iodamoeba Dobell, 1919 (Fig. 5)
Iodamoeba contains aflagellate uninucleate amoebae reminiscent of *Entamoeba* and *Endolimax* that are intestinal commensals of vertebrates.

Circumscription Trophozoites are aflagellate amoebae measuring up to 20 μm. The cells move slowly by hyaline lobopodia. The nucleus contains a single large nucleolus surrounded by globules, though these do not lie directly beneath the nuclear membrane as in *Entamoeba*. Cysts are often irregularly shaped and possess a single nucleus with an eccentric nucleolus. Typically, a large glycogen granule is present in the mature cyst. Four *Iodamoeba* species have been described from lower intestines of mammals (e.g., *I. buetschlii* from humans) and reptiles (*I. testudinis*).

Type Species *Iodamoeba buetschlii* (Prowazek 1912) Dobell, 1919 (basionym *Entamoeba buetschlii* Prowazek 1912).

Remarks Because it is aflagellate, *Iodamoeba* was traditionally considered a member of Entamoebidae. On the basis of recent molecular phylogenetic work (Stensvold et al. 2012; Ptáčková et al. 2013), it was recently removed from Entamoebidae and transferred to Mastigamoebidae together with *Endolimax* (Ptáčková et al. 2013).

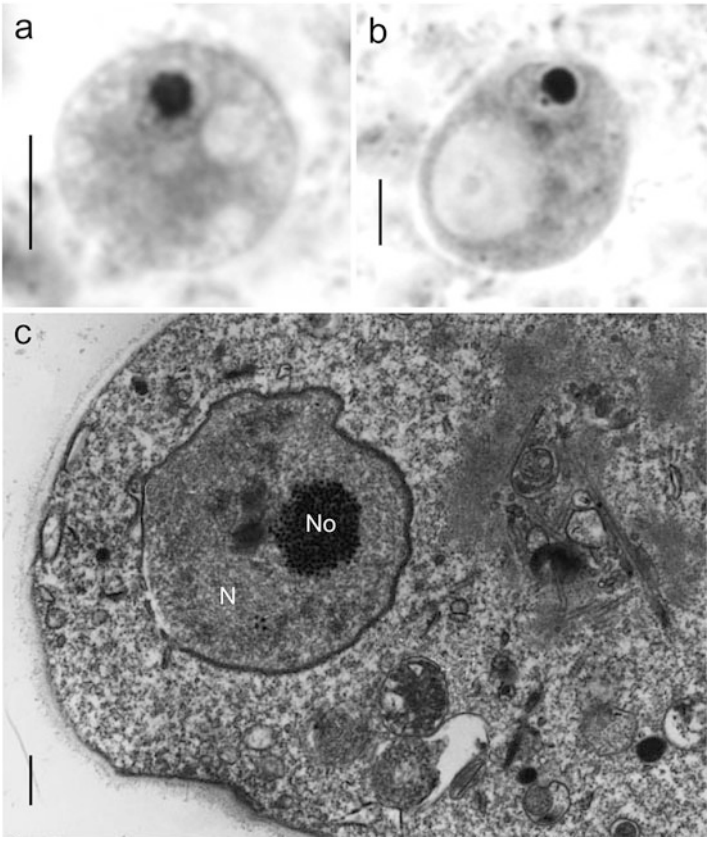

Fig. 5 ***Iodamoeba*** (**a**) Trophozoite of *Iodamoeba buetschlii* showing nucleus with central nucleolus and granules of chromatin; prepared slide, stained with iron-hematoxylin. (**b**) Cyst of *I. buetschlii* with a single vacuole; prepared slide, stained with iron-hematoxylin. (**c**) Transmission electron micrograph of cyst, showing the structure of nucleolar material (*No*) and chromatin in the nucleus (*N*). Scale bar in a = 5 μm, in b = 10 μm, in c = 1 μm (Micrograph in **c** reprinted from *Parasitology Research* 84, Zaman et al., *Ultrastructure of the Iodamoeba bütschlii cyst,* pp. 421–422, Copyright (1998), with permission from Springer)

Family Rhizomastixidae Ptáčková et al. 2013
Amoeboflagellate Archamoebae. Trophozoites with single anterior flagellum. Microtubular cone modified into the "rhizostyle." Amoeboid movement slow. See below and Ptáčková et al. (2013), for discussion of the *nomen nudum* Rhizomastigidae.

Rhizomastix Alexeieff, 1911 (Fig. 6)
Rhizomastix contains amoeboid uniflagellate or biflagellate species whose microtubular cone has been modified into a tube that extends through the cell. Most species are endobiotic, but two (and possibly a third) free-living species have been described as well.

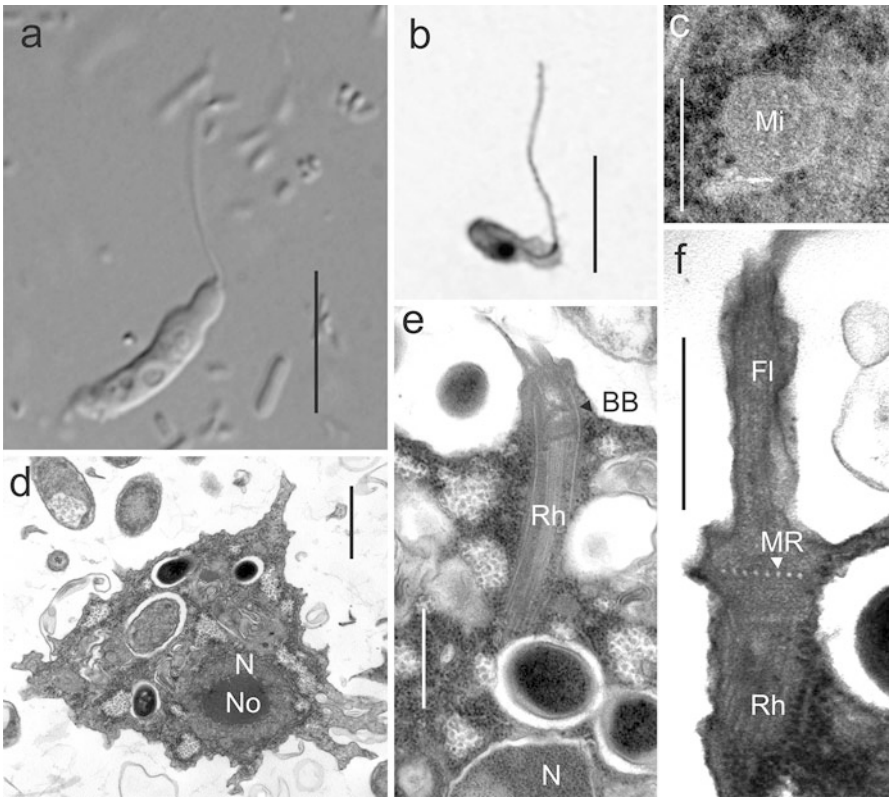

Fig. 6 ***Rhizomastix***. (**a**–**f**) *Rhizomastix libera*. (**a**) Light micrograph of flagellate showing central, rounded nucleus and nucleolus and posterior food vacuoles (DIC). (**b**) Protargol-stained cell showing the rhizostyle connecting the anterior flagellum to the central nucleus. (**c**–**f**) Transmission electron microscopy. (**c**) Mitochondrion-related organelle (*Mi*) with double membrane. (**d**) Whole cell, showing large nucleus (*N*) and nucleolus (*No*) and food vacuoles. (**e**, **f**) Details of the flagellar apparatus showing the flagellum (*Fl*), basal body (BB) with proximally extending microtubular rhizostyle (*Rh*), and laterally extending microtubular root (*MR*). *N* nucleus. Scale bar in a, b = 10 μm, in c, f = 200 nm, in d = 1 μm, and in e = 500 nm (Figures **c**, **d**, **e**, and **f** reprinted from *Protist* 164, E. Ptáčková et al., *Evolution of Archamoebae: Morphological and Molecular Evidence for Pelobionts Including Rhizomastix*, *Entamoeba*, *Iodamoeba*, *and Endolimax*, Pp. 380–410, Copyright (2013), with permission from Elsevier)

Circumscription Archamoebae with a uniflagellate (biflagellate in *R. biflagellata*) trophic stage. A single-layered cylindrical bundle of microtubules, the "rhizostyle," extends from the bottom edge of the basal body through the cell. A second microtubular element, arising from the base of the basal body and running parallel to the rhizostyle, may also be present. A single-layered root of microtubules arises from the side of the basal body (Fig. 2f). Fine structure of the basal body is unknown; a cylinder is present in the transition zone of the flagellum. The flagellum has a conventional eukaryotic "9 + 2" arrangement of microtubules, but it is unclear

whether it lacks outer dynein arms. Flagellar movement is relatively fast in comparison with *Mastigamoeba*. The nucleus is similar to that of *Entamoeba*, having a single central (large) nucleolus and peripheral heterochromatin granules at least in some species. The flagellates may transform to uninucleate amoebae. Binucleate cysts have been reported in some species. Sixteen *Rhizomastix* species have been described. Most of them are intestinal commensals of vertebrates and insects (e.g., *R. gracilis*, *R. biflagellata*, and *R. bicoronata*), three are described as free-living (*R. libera*, *R. borealis*, *R. varia*); and some are of uncertain status (*R. elongata*) (Ptáčková et al. 2013; Zadrobílková et al. 2016).

Type Species *Rhizomastix gracilis* Alexeieff, 1911.

Remarks The genus *Rhizomastix* was recently transferred into the Archamoebae and a new family Rhizomastixidae established to accommodate it (Ptáčková et al. 2013). *Rhizomastix* was classified with *Mastigamoeba* and *Mastigella* by Kudo (1939, 1977); Čepička (2011) suggested it might be related to pelobionts; its position was clarified on the basis of molecular and ultrastructural data (Ptáčková et al. 2013; Zadrobílková et al. 2016). The name Rhizomastigidae has historically been used for today's Mastigamoebidae (e.g., Bütschli 1880, 1884; Calkins 1901; Lepşi 1965; Reichenow 1952). The name was created by Bütschli (1884) as Rhizomastigina and later standardized to Rhizomastigidae by Calkins (1901); however, as it was not based on and often did not include *Rhizomastix*, Rhizomastigidae is regarded by some as a *nomen nudum* (Loeblich and Tappan 1961). The composition of Rhizomastigidae has typically been very confused (e.g., Cavalier-Smith and Scoble 2013), leading Ptáčková et al. (2013) to create Rhizomastixidae as the family containing *Rhizomastix*.

Suborder Pelomyxina Starobogatov, 1980
See Pánek et al. (2016) for current composition. The clade containing *Pelomyxa* and *Mastigella*; using the branch-based definition introduced and discussed in Pánek et al. (2016), the clade containing *Pelomyxa palustris* Greeff, 1874, and all organisms sharing a more recent common ancestor with *P. palustris* than with *Mastigamoeba balamuthi* (Chávez et al. 1986) Simpson et al. 1997.

Family Pelomyxidae Schulze, 1877
Anaerobic or microaerophilic flagellated amoebae with slow-beating monokinetid or immobile polykinetids. See Zadrobílková et al. 2015 for current composition.

Pelomyxa Greeff, 1874 (Fig. 7)
Pelomyxa was originally described as a large multinucleate amoeba, with a division of the cytoplasm into an inner layer containing organelles displaying fountain-flow movement and a clear hyaline outer layer from which pseudopodia can "roll" out and with a posterior uroid attaching the amoeba to the substrate. Later reports extended the description to refer to prokaryotes that coexist endosymbiotically in the cell (van Bruggen et al. 1988) and to non-motile flagella (Frolov 2011; Griffin 1979, 1988; Seravin and Goodkov 1987a).

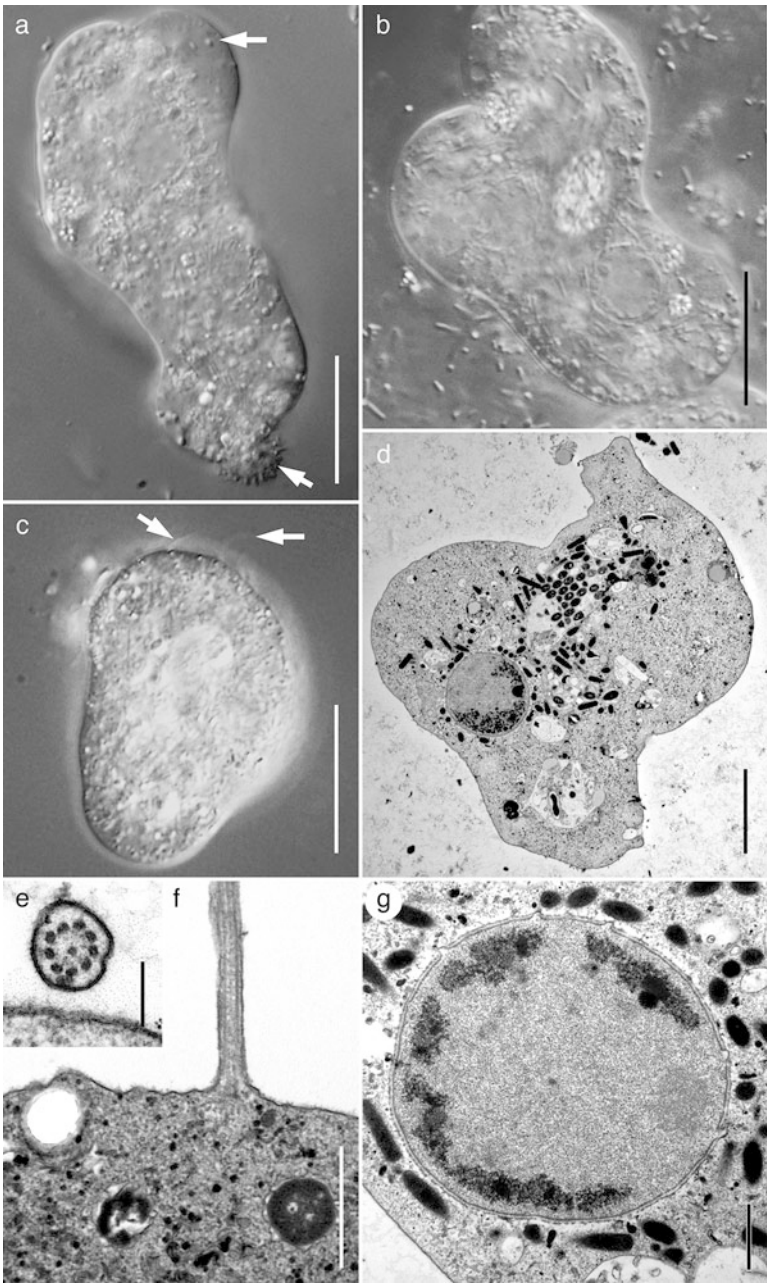

Fig. 7 ***Pelomyxa***. (**a**–**g**) *Pelomyxa schiedti*, strain SKADARSKE in (**a**, **b**), strain TIWI in (**c**), strain WACT07 in (**d**–**g**). (**a**–**c**) Differential interference contrast showing cells filled with granules and endosymbionts, distinctive nuclear structure (in **b**), leading pseudopodium (in **a**, *arrow upper right*), a bulbous, villous uroid-like area (in **a**, *arrow lower right*), and multiple immobile poorly

Circumscription *Pelomyxa* is distinguished by the form most usually encountered: a large multinucleate amoeba, with many inactive flagella. It includes polymorphic species, with a large multinucleate amoeboid feeding form up to 5000 μm long, with poorly motile or non-motile flagella that insert into a clear "hyaline" outer cytoplasmic layer, which encloses an inner layer filled with organelles, with endosymbiotic bacteria, and sometimes with refringent cytoplasmic granules (sand); movement is directed by fountain-flow cytoplasm and an anterior monopodium. The posterior uroid is active in food uptake. Cysts about 100 μm in diameter are known from at least one species. *Pelomyxa* species can be divided into two groups on the basis of the organization of the flagellar apparatus: the first group is characterized by a long basal body and very numerous radiating microtubules, while the second is characterized by a short basal body associated with a very reduced number of radiating microtubules. There is at least one intermediate state between these groups (Chystjakova et al. 2014). Cells have many flagella, each arising from a single basal body; each basal body gives rise proximally to a cone of microtubules, which has not been shown to extend to the nucleus (though several species do have microtubules surrounding the nucleus). The transition zone of each flagellum contains a transitional column. Flagella are with or (in most cases) without a 9 + 2 arrangement of microtubules in flagellar axoneme; the pattern of microtubules may be unstable in individuals in some species, particularly in the central pair or group of axonemal microtubules. The flagella insert into the hyaline outer cytoplasmic layer, which is devoid of organelles (ER, nuclei, vacuoles). Nuclei show distinctive, diagnostic patterns of chromatin condensation and may be surrounded by endosymbiotic bacteria. Morphological and molecular data suggest that *Pelomyxa* may have evolved from *Mastigella* by nuclear and flagellar multiplication (Zadrobílková et al. 2015).

Type Species *Pelomyxa palustris* Greeff, 1874.

Remarks *Pelomyxa* has been widely reported (e.g., Greeff 1874; Griffin 1988; Grüber 1885; Schirch 1914; Schulze 1875a; Whatley and Chapman-Andresen 1990; Frolov 2011). *Pelomyxa palustris* is currently relatively poorly known, and descriptions of it (e.g., Griffin 1988; Whatley and Chapman-Andresen 1990) probably encompass the variation of multiple species (Frolov et al. 2004; Goodkov et al. 2004). On the other hand, very few of the light microscopy-based species

Fig. 7 (continued) visible flagella (in **c**). (**d**–**g**) Transmission electron microscopy; (**d**) section through the cell showing the amoeboid body, single nucleus, and endosymbionts. (**e**) Transverse section of the flagellum with aberrant arrangement of microtubules. (**f**) Longitudinal section of the flagellar apparatus. (**g**) Detail of the nucleus, showing peripheral chromatin and small nucleolus. Scale bars in a–c = 20 μm; d = 5 μm; e = 200 nm; f and g = 1 μm (Figures **a**–**g** reprinted from *Protist* 164, E. Ptáčková et al., *Evolution of Archamoebae: Morphological and Molecular Evidence for Pelobionts Including Rhizomastix*, *Entamoeba*, *Iodamoeba*, *and Endolimax*, pp. 380–410, Copyright (2013), with permission from Elsevier)

descriptions currently available can be differentiated from the life cycle described by Whatley and Chapman-Andresen (1990). All the previous accounts of species probably describe real variation; however it is not currently possible to assign most of this variation to different species in any consistent or clear way, on the basis of the published descriptions. Species are currently distinguished mainly on characteristic patterns of nuclear chromatin, the thickness of the outer cytoplasmic layer, and the flagellar apparatus (Berdieva et al. 2015; Chystjakova and Frolov 2011; Chystjakova et al. 2014; Frolov 2011; Frolov et al. 2005a, b, 2006; Griffin 1979, 1988; Seravin and Goodkov 1987a; Ptáčková et al. 2013; Zadrobílková et al. 2015).

Mastigella Frenzel, 1897 (Fig. 8)
Mastigella contains amoeboid cells with a flagellated basal body with a cone of microtubules, but there is no connection between the cone and the nucleus. Endosymbiotic prokaryotes are present in several species.

Circumscription Archamoebae with a uniflagellated trophic stage, in which the nucleus is not connected to a cone of microtubules that arises from the base and sides of the single (flagellated) basal body; a cylinder is present in the transition zone of the flagellum. A single root of microtubules arises from the side of the basal body, and the root has a bilaminar sheet on its anterior edge. Basal bodies have nine triplets of microtubules. The flagellum has a conventional eukaryotic "9 + 2" arrangement of microtubules but lacks outer dynein arms. The flagellum may contribute to cell movement, but its beating is typically slower and less effective than that seen in *Mastigamoeba*. The flagellates may, at least in some species, transform to amoebae with one, few, or many nuclei. The nuclei may contain a distinctive distribution of chromatin; endosymbiotic bacteria may be present; the outside of the cell may be covered with irregular spines. Both flagellate and amoeboid forms may transform into cysts. Cells are from 3 to 150 μm long with one to four flagella up to 150 μm long. Reported from anoxic or low-oxygen freshwater or marine sediments (Walker et al. 2001; Zadrobílková et al. 2015).

Type Species *Mastigella polymastix* Frenzel, 1897.

Remarks *Mastigella* was introduced to describe an amoeboid flagellate with multiple long flagella extended from the cell body on small "necks" that wandered over the cell body and were not attached to the nucleus (Frenzel 1897). Subsequently, the concept of the genus changed to one of amoeboid flagellates without a connection between the flagellum and nucleus (Goldschmidt 1907a, b; Lemmermann 1914). Following from Goldschmidt's (1907a, b) informal group "Mastigamöben," *Mastigamoeba* and *Mastigella* were grouped as the Mastigamoebidae by Chatton (Chatton 1925; Kudo 1939, 1977) and have traditionally been thought of as sister taxa. This was initially supported by phylogenies that included the GenBank sequence AF421219: it had been ascribed to *Mastigella commutans* but belongs to *Mastigamoeba punctachora* (Ptáčková et al. 2013), meaning that these phylogenies

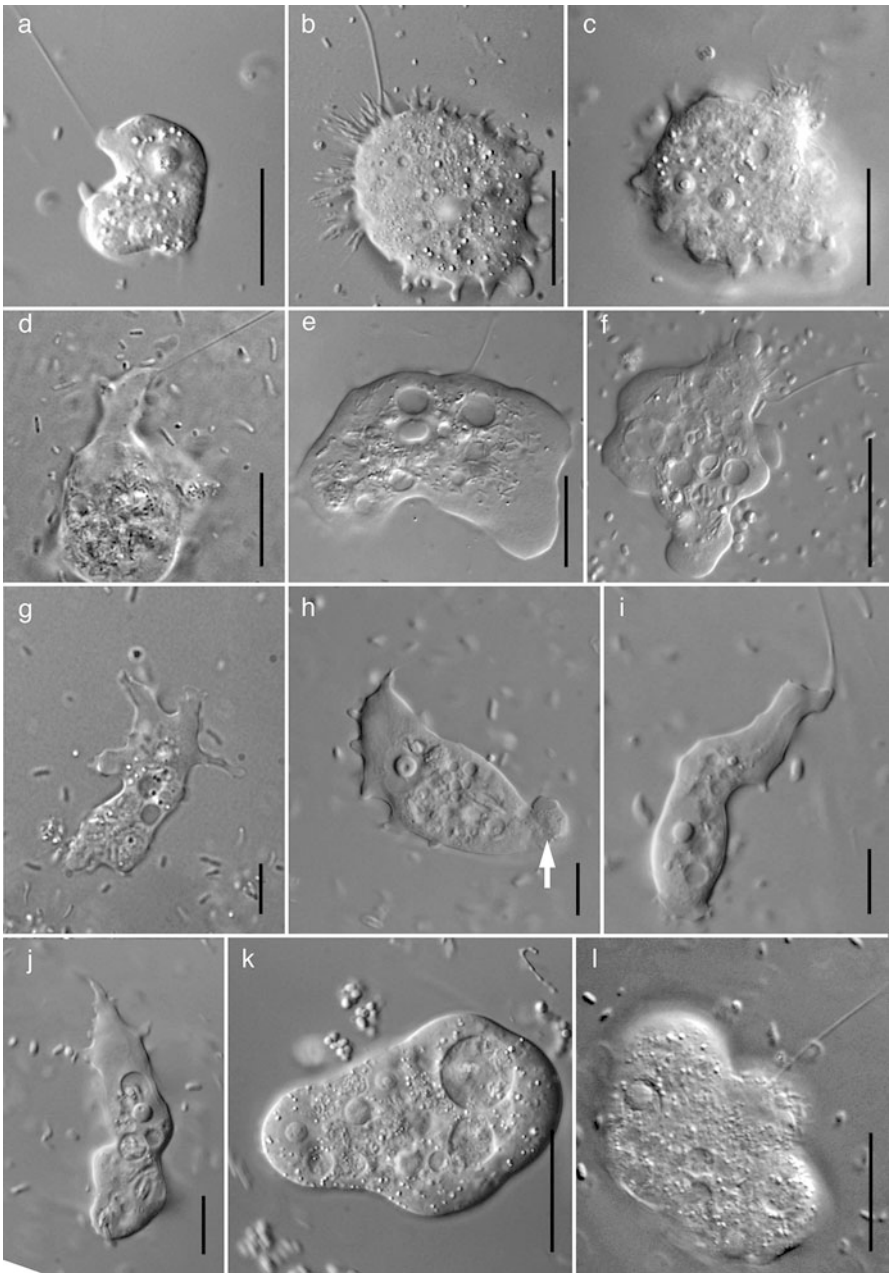

Fig. 8 ***Mastigella***. (**a**–**l**) Differential interference contrast. (**a**–**c**) *Mastigella erinacea* strain TOLEDO, showing binucleate cells with distinctive "fried-egg" nucleus and granular nucleolus, endosymbiotic bacteria, and highly variable villous, lobate or finger-shaped pseudopodia. (**d**, **e**) *Mastigella ineffigiata* strain OLB6AN, showing "shapeless" morphology and conspicuous

are silent on the placement of *Mastigella*. However, cell form and movement, nuclear structure, and the presence of endosymbiotic prokaryotes resembling methanogenic archaea (Frolov 2011; van Bruggen et al. 1985; Walker et al. 2001; Zadrobílková et al. 2015) all suggest a relationship of *Mastigella* with *Pelomyxa*. This hypothesis was supported by recent phylogenetic analyses where *Pelomyxa* forms an internal branch of *Mastigella*, while *Mastigamoeba* is phylogenetically more distant (Zadrobílková et al. 2015). Other nominal genera that fall within the circumscription of *Mastigella* include *Limulina* Frenzel, 1897; *Micromastix Frenzel*, 1897 (Frenzel 1897) and *Mastigamoebula Fantham*, 1919 (Fantham 1919).

Order Entamoebida Cavalier-Smith, 1993
Using the branch-based definition introduced by and discussed in Pánek et al. (2016), the clade consisting of *Entamoeba histolytica* Schaudinn, 1903 and all organisms that share a more recent common ancestor with *E. histolytica* than with *Mastigella eilhardi* Bürger, 1905.

Family Entamoebidae Chatton, 1925
Aflagellate Archamoebae. Flagellar apparatus completely reduced. Amoeboid movement typically monopodial and relatively fast. See Cavalier-Smith 1993 for current composition.

Entamoeba Casagrandi and Barbagallo, 1895 (Fig. 9)
Entamoeba contains most of the species of aflagellate Archamoebae. They are usually intestinal commensals of various animals, though at least three are likely to be free-living. A few species, including *E. histolytica* from humans, are pathogenic for their hosts.

Circumscription Trophozoites are aflagellate, uninucleate amoebae measuring up to 60 μm. The flagellar apparatus of *Entamoeba* is completely absent, and no cytoplasmic microtubules can be found in nondividing cells. Actively moving cells usually crawl using a single or several eruptive lobopodia; the hyaline lobopodia are clearly distinguishable from the granuloplasm. Uroidal filopodia have been rarely observed (Martínez-Palomo 1993). Nuclear structure is distinctive,

Fig. 8 (continued) endosymbionts. (**f**) *Mastigella rubiformis* strain HRAAN, showing cells with hyaline area, distinctive "*Pelomyxa*-like" nucleus, and prominent endosymbiotic bacteria. (**g**, **h**, **j**) *Mastigella eilhardi* strain ATCC 50342, showing pseudopodial variation; nucleus with "hollow," "donut-shaped" nucleolus; and endosymbiotic bacteria, with a posterior uroid (arrow). (**i**) *M. eilhardi* strain GO7 showing its characteristic swanlike long "neck" and posterior villous pseudopodia. (**k**) *Mastigella erinacea* strain KORISSION, showing binucleate or quadrinucleate cells with distinctive "fried-egg" nucleus with a granular nucleolus and villous pseudopodia from which the flagellum originates in some cells. Scale bars in a–f, i, k, l = 20 μm; g, h, j = 10 μm (Figures **a**–**l** reprinted from *Protist* 164, E. Ptáčková et al., *Evolution of Archamoebae: Morphological and Molecular Evidence for Pelobionts Including Rhizomastix*, *Entamoeba*, *Iodamoeba*, *and Endolimax*, pp. 380–410, Copyright (2013), with permission from Elsevier)

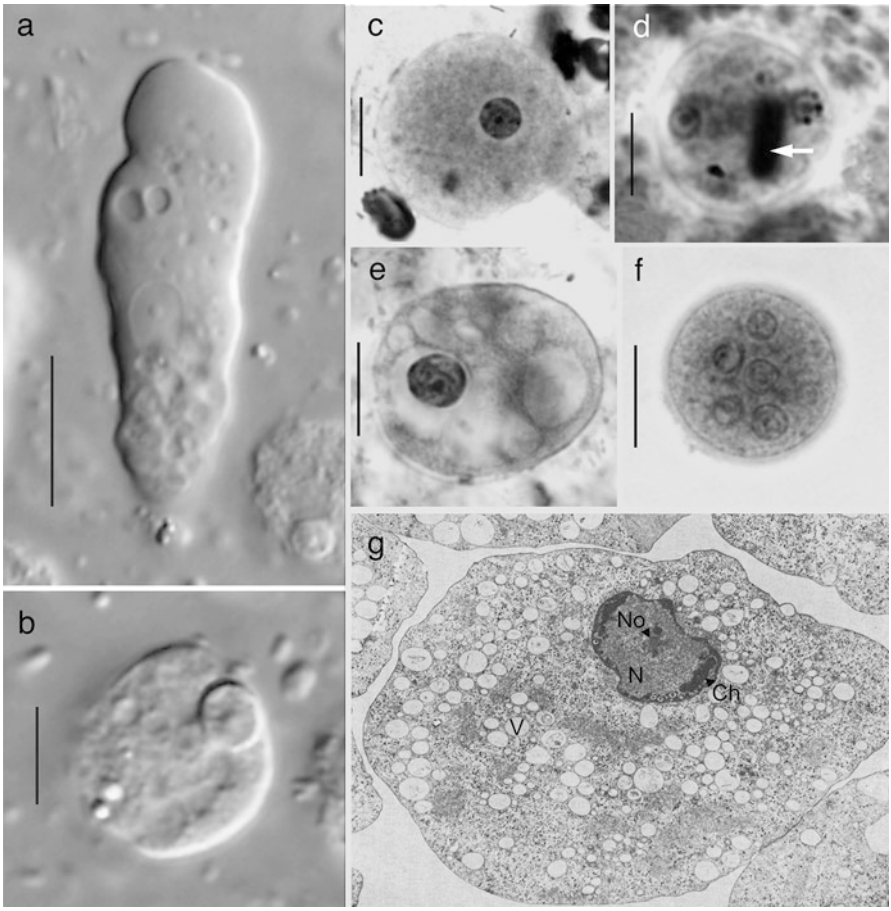

Fig. 9 ***Entamoeba***. (**a**) *Entamoeba moshkovskii* free-living trophozoite amoeba showing an anterior hyaline pseudopodium and central nucleus with the characteristic "dot" nucleolus (DIC). (**b**) *E. moshkovskii* resting cell, showing the nucleus with its characteristic "dot" nucleolus and peripheral chromatin (DIC). (**c**, **d**) Parasitic *Entamoeba histolytica* trophozoite (**c**) and immature cyst (**d**) with two visible nuclei and chromatoid body (*arrow*); prepared slide material, stained with iron-hematoxylin to show nuclei with a thick ring of peripheral chromatin and a small nucleolus. (**e**, **f**) Parasitic *Entamoeba coli* trophozoite (**e**) and cyst (**f**) with eight nuclei (five visible in the focal plane of the photograph); prepared slide material, stained with iron-hematoxylin to show nuclei with large chromatin granules. (**g**) Transmission electron micrograph of *E. histolytica*, showing numerous vacuoles (*V*) and the characteristic arrangement of nuclear chromatin (*Ch*) and nucleolus (*No*) in the nucleus (*N*). Scale bar in a, c, d, e, f = 10 μm; in b = 5 μm (Figure in **g** reprinted from *Parasitic Protozoa* Volume 3, 2nd Edition, J.P. Kreier & J.R. Baker, *Chapter 3: Parasitic amebas of the intestinal tract*., pp. 65–141, Copyright (1993), with permission from Elsevier)

with a single small, central nucleolus and conspicuous peripheral granules of heterochromatin (Fig. 9). The number and size of the granules differ between particular *Entamoeba* species. A cyst stage is documented for many species (see

above). The number of nuclei in the cyst is an evolutionarily important feature (Silberman et al. 1999). Cysts have been lost in *E. gingivalis*, which is found in the oral cavity of humans and transferred between hosts via saliva.

Many *Entamoeba* species have been described. The vast majority live as intestinal endobionts of various animals (e.g., *E. histolytica*, *E. dispar*, and *E. coli* from humans, *E. muris* and *E. cobayae* from rodents, *E. gallinarum* from birds, *E. invadens* from reptiles, *E. ranarum* from amphibians, *E. gadi* from fish, *E. aulastomi* from leeches, and *E. minchini* from insects). Some species are pathogenic, the best known being *E. histolytica*. Further information on endobiotic and parasitic species is given in the "Practical Importance" section.

Three *Entamoeba* species may be facultatively free-living. *Entamoeba moshkovskii* is relatively well known and has been repeatedly isolated from wastewaters, anoxic sediments, as well as from human stool (see Heredia et al. 2012; our observations). The second species, *E. ecuadoriensis*, has been isolated only once from sewage water (Clark and Diamond 1997). The third, *E. marina*, was isolated from marine tidal flats (Shiratori and Ishida 2016).

Type Species *Entamoeba coli* Grassi, 1879, Casagrandi and Barbagallo 1895 (basionym *Amoeba coli* Grassi 1879).

Remarks There was some uncertainty regarding the names of genera *Entamoeba* and *Endamoeba* during the first half of the twentieth century (see section "History of Genera in the Archamoebae"). *Entamoeba histolytica* can be, therefore, found under the name *Endamoeba histolytica* in the older literature. Since the 1950s, the concept of *Entamoeba* is stable, and *Endamoeba* is now considered a separate genus (e.g., Patterson et al. 2000). *Entamoeba* constitutes the family Entamoebidae. Historically, the other aflagellate Archamoebae, *Endolimax* and *Iodamoeba*, were classified within Entamoebidae as well but were recently removed from it (Cavalier-Smith et al. 2004; Ptáčková et al. 2013). *Endamoeba* is considered here as Archamoebae *incertae sedis*.

Archamoebae *Incertae Sedis*

Mastigina Frenzel, 1897 (Fig. 10)
Mastigina contains limax-shape amoeboid cells with a flagellum and no lateral pseudopodia and with a connection between the base of the flagellum and the rounded nucleus. Its microtubular ultrastructure has not been studied by electron microscopy.

Circumscription Archamoebae with a uniflagellated trophic stage, with limax amoeboid shape and no lateral pseudopodia, and in which the round nucleus is connected to the base of the flagellum, which has the distinctively languid flagellar beat typical of other pelobionts. One species, *Mastigina setosa*, has fountain-flow cytoplasmic movement (Goldschmidt 1907a). The outside of the cell is covered with

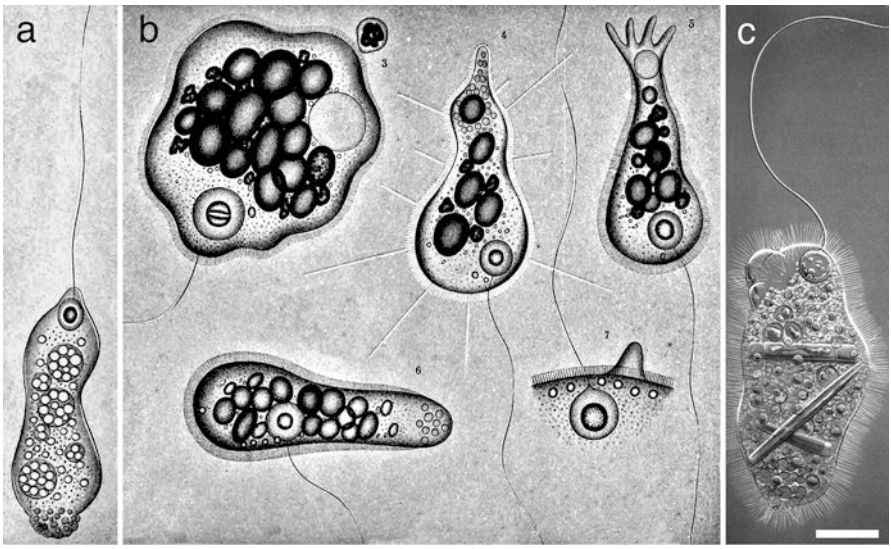

Fig. 10 ***Mastigina***. (**a**) Drawing of one of the two original species of *Mastigina*, *M. paramylon*, showing numerous starch granules inside the cell, connection between the long flagellum and the nucleus (with central vesicular nucleolus), and the lack of any lateral pseudopodia. (**b**) The type species of *Mastigina*, *M. chlamys*, showing a dense layer of short, refringent spines and in one case longer spines interspersed with the short ones, a connection between the long flagellum and the nucleus (with central nucleolus), and pseudopodia arising only at the anterior and posterior of the cell, not laterally. (**c**) *Mastigina setosa*, showing similar characteristics to *M. chlamys* but longer, less dense spines. Scale bar in a = 5 μm; in b, c = 20 μm (Drawings in **a** and **b** reprinted from *Untersuchungen über die mikroskopische Fauna Argentiniens*. *Erster Teil: Die Protozoen*. *I und II*, *Abteilung: die Rhizopoden und Helioamoeben*, J. Frenzel, (1897), Erwin Nägele, Stuttgart; with no known copyright restrictions. Drawing in **c** reprinted from *Archiv für Protistenkunde* Supplement 1, R. Goldschmidt, *Lebensgeschichte der Mastigamöben Mastigella vitrea* n.sp. *u*. *Mastigina setosa* n.sp., pp. 83–165, Copyright (1907), with permission from Elsevier)

closely packed spines in two species, *Mastigina chlamys* and *M. setosa* (Frenzel 1897; Goldschmidt 1907a; Skibbe and Zölffel 1991). Reported from anoxic or low-oxygen freshwater sediments.

Type Species *Mastigina chlamys* Frenzel, 1897.

Remarks *Mastigina* was not clearly distinguished from other pelobiont genera when it was introduced, in the original descriptions of *M. chlamys* and *M. paramylon* (Frenzel 1897). Goldschmidt (1907a) defined the genus on the basis of limax body shape with no lateral pseudopodia, round apical nucleus connected closely to the base of the flagellum (as opposed to elongated or drop-shaped, sometimes appearing removed from the base of the flagellum, in *Mastigamoeba*), characters that are adopted here. Goldschmidt (1907a) also regarded *Tricholimax hylae* as belonging to *Mastigina*, leading to later confusion about the characters

displayed by *Mastigina* species: he used fountain-flow cytoplasmic movement as a defining feature of *Mastigina*, despite it being present only in *M. setosa* and *T. hylae* and despite the two species in the original description of *Mastigina* not displaying it. Ultrastructural studies of *Tricholimax hylae* have been carried out under the name *Mastigina hylae* (Brugerolle 1982, 1991), and summaries of the genus have subsequently relied largely on descriptions of *T. hylae* (Griffin 1988; Brugerolle and Patterson 2000).

Perhaps on the basis that fountain-flow cytoplasm is also present in *Mastigamoeba aspera* (Chystjakova et al. 2012; Schulze 1875b), Lemmermann (1914) in turn regarded *Mastigina* as a junior synonym of *Mastigamoeba*, leading to further confusion about the distribution of fountain-flow cytoplasm and spines in pelobionts. Frolov (2011) redefined *Mastigina* as containing only taxa with spines on the surface, disregarding the criteria used by Frenzel (1897) and Goldschmidt (1907a). Although 50% of the species currently assigned to *Mastigina* do have spines, 50% do not, and there are also members of *Mastigamoeba* and *Mastigella* with spines.

In the absence of clear ultrastructural and phylogenetic data on any of these species, we see no reason to reject Goldschmidt's circumscription of the genus.

Family Tricholimacidae Cavalier-Smith, 2013

Monotypic family with the characteristics of the sole species. Using the diagnosis of Cavalier-Smith (2013), uniciliate (i.e., uniflagellate) endosymbiotic anaerobes with inactive cilium (i.e., flagellum) with numerous irregularly arranged doublets; no obvious transition zone cylinder; dense microtubule nucleating center attached to the proximal side of the single centriole (with doublets not triplets) nucleates (a) multilayered cone of microtubules that surround nucleus and (b) lateral rhizostyle, a broad band of microtubules with numerous underlying singlet and bundled microtubules.

Tricholimax Frenzel, 1897 (Fig. 11)

This monotypic genus has been described from the guts of amphibians. Cells have a limax shape with fountain-flow cytoplasmic movement and without lateral pseudopodia, and the anterior nucleus is connected to the short non-motile flagellum, which lacks normal 9 + 2 organization of the microtubular axoneme.

Circumscription The one species, *Tricholimax hylae*, exists mostly as flagellates measuring 50–135 μm. Flagellated amoeboid and cyst stages (up to 30 μm in diameter with up to four nuclei) may form. Flagellated cells have one to six nuclei, one of which is connected to the emergent flagellum. In the flagellar apparatus, there is a cone of microtubules arising from base and sides of the single basal body; these enclose the nucleus and connect to the nuclear envelope by microfibrils. A single root of 32 microtubules arises from the side of basal body, and there is a bilaminar sheet associated with the anterior edge. There is an "n + n" arrangement of microtubules in the flagellar axoneme, though no dynein arms are visible. There may be

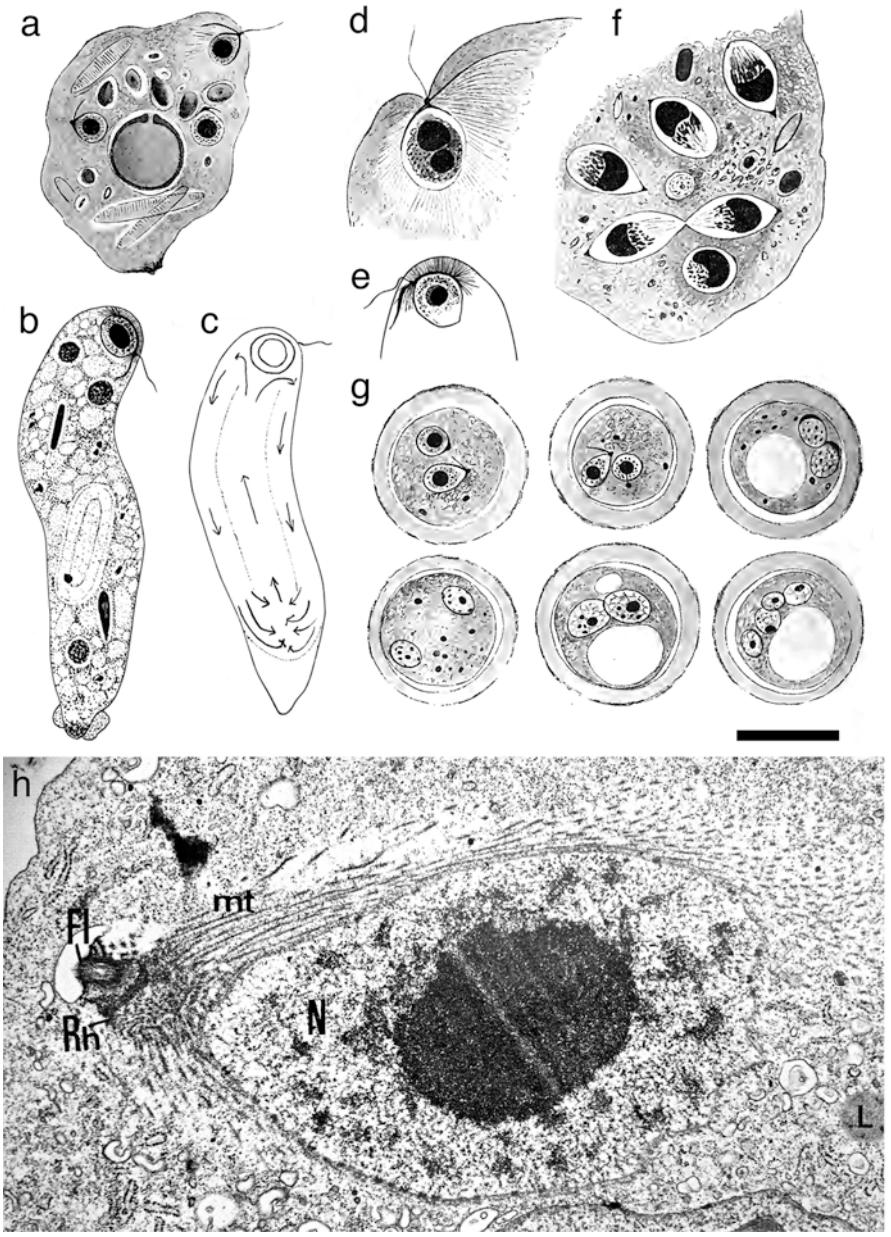

Fig. 11 ***Tricholimax hylae***. (**a**–**b**) Drawings of whole cells showing the microtubular connection between the short, nonfunctional flagellum and the large apical nucleus with its central nucleolus. Accessory nuclei, with attached kinetids, are visible in the cytoplasm in **a**, along with numerous food vacuoles. (**c**) Diagram showing the direction of fountain-flow cytoplasmic streaming, where the posterior uroid is not included. (**d**, **e**) The microtubular cone and lateral root (which are clearly visible under the light microscope, even without DIC optics). There is some variation in the

reduced internal basal bodies with cones of microtubules attached to extra internal nuclei (Brugerolle 1982, 1991).

Type Species *Tricholimax hylae* Frenzel, 1897.

Remarks This genus can be distinguished from *Mastigina* because of the atypical organization of the single non-motile flagellum. It has been widely described (Frenzel 1897; Goldschmidt 1907b; Collin 1913; Lemmermann 1914; Becker 1928; Sassuchin 1928; Ivanic 1936; Chatton 1953; Brugerolle 1982, 1991; Griffin 1988). The occurrence of the "n + n" flagellar organization and fountain-flow cytoplasm both here and in *Pelomyxa* has resulted in the placement of both genera in the Pelomyxidae, though this circumscription is now widened to also include *Mastigella*. No molecular phylogenetic information exists for *Tricholimax*, so its formal placement in the Pelomyxidae remains premature.

Endamoeba Leidy, 1879 (Fig. 12)
Poorly known genus containing aflagellate Archamoebae found in insects.

Circumscription Trophozoites measure up to 120 μm. They are aflagellate and move slowly by one or several lobopodia. Unlike in *Entamoeba*, there is no marked distinction between hyaloplasm and granuloplasm (Wenyon 1926). The nucleus of *Endamoeba* has a typical structure dissimilar from that of *Entamoeba* and other aflagellate Archamoebae (Wenyon 1926; compare Fig. 12 with Figs. 4, 5, and 9). Several species have been described from the hindgut of insects, such as *Endamoeba blattae* from cockroaches and *E. disparata* from termites.

Type Species *Endamoeba blattae* Bütschli, 1878 Leidy 1879 (basionym *Amoeba blattae* Bütschli, 1878).

Remarks Probable member of Entamoebidae. This classification is, however, tentative, since no sequence data from *Endamoeba* are currently available.

Fig. 11 (continued) presence of a single or a double nucleolus. (**f**) Nuclei dividing, showing a connection between the posterior poles of the nuclei, with anterior kinetids present. (**g**) Six cyst stages, showing variation in the number of nuclei from two to four, and gradual development of a central vacuole. (**h**) Transmission electron micrograph showing the flagellum (*Fl*), single basal body with microtubular root (*Rh*), and dense cone of microtubules (*mt*) connecting to the nucleus (*N*). Scale bar: in a, b, c = 30 μm, in d, e, f = 10 μm, in g = 20 μm, in h = 3 μm (Drawings in **a**, **d**, **f**, and **g** reprinted from *Archives de Zoologie expérimentale et générale* 51, B. Collin, Sur un ensemble de protistes parasites des batraciens (Note préliminaire). Pp. 59–76 (1913) with no known copyright restrictions. Maintenance and Cultivation

Various free-living Archamoebae from the genera *Mastigamoeba*, *Mastigella*, and *Rhizomastix* can be isolated and maintained in xenic cultures with bacteria. Sonneborn's *Paramecium* medium (cereal grass infusion medium, ATCC medium 802; see www.atcc.org) is suitable for freshwater strains (Ptáčková et al. 2013). Seawater 802 medium (ATCC medium 1525; see www.atcc.org) can be used for the cultivation of marine pelobionts (Zadrobílková et al. 2015). The strains grow well at room temperature in sealed 15 ml tubes with 10 ml of medium and transfers every 1–3 weeks or in sealed tissue flasks filled with medium and transfers every 1–2 months. Although the Archamoebae are anaerobic and die when exposed to oxygen for a longer period, no special precautions are necessary, since bacteria present in the culture quickly consume the oxygen. Most strains grow well also under anoxic conditions.

Members of the genera *Entamoeba* (including the free-living *Entamoeba moshkovskii*) and *Endolimax* can be isolated and maintained in xenic cultures as well. Various media developed for cultivation of intestinal flagellates and amoebae, both biphasic (e.g., LE medium, Robinson's biphasic medium) and monophasic (TYSGM-9 medium, Robinson's monophasic medium) can be used (see Clark and Diamond 2002). Culture conditions depend on the origin of the organisms – strains from invertebrates and poikilotherm vertebrates are cultivated at room temperature with transfers once a week to once a month; strains from homoiotherms should be cultivated at 37 °C with transfers approximately twice a week.

Only a few species of *Entamoeba* and *Mastigamoeba balamuthi* have been successfully axenized. The process of isolation and axenization of *Entamoeba histolytica* is described in Clark and Diamond (2002). For maintenance, several complex media, such as TYI-S-33, YI-S, and LYI-S-2 (ATCC medium 2154), can be used (for preparation, see Clark and Diamond 2002 and www.atcc.org). Apart from *Entamoeba* spp., only a single strain of *Mastigamoeba balamuthi* has been axenized (Chávez et al. 1986). Chávez et al. (1986) described the process of the axenization in a detail. *Mastigamoeba balamuthi* can be maintained in PYGC (Chávez et al. 1986) or LYI-S-2 (see above) media.

So far, only one successful long-term cultivation attempt of *Pelomyxa* spp. has been published (Zadrobílková et al. 2015). Cells of *Pelomyxa* spp. can be maintained alive for several months in hermetically closed flasks filled with fresh water and sediments, or with Lozina-Lozinskii medium supplemented with boiled detritus (see Chystjakova and Frolov 2011; Frolov et al. 2011).

Cultures of Archamoebae can be cryopreserved in the presence of 5% dimethyl sulfoxide using a standard procedure and stored in liquid nitrogen. Detailed protocols for cryopreservation of *Entamoeba* cultures are described in Diamond (1995) and Samarawickrema et al. (2001).

Evolutionary History

Phylogeny and Evolution

Separately and together, members of the Archamoebae have been considered to be some of the most deep-branching eukaryotes, on the basis of lacking mitochondria and Golgi dictyosomes, and having a "simple" or nonexistent flagellar apparatus. Using the argument that some or all of these traits are primitive, it was suggested that the pelobionts represent a very early stage in the evolution of eukaryotes (Brugerolle 1993; Cavalier-Smith 1983; Griffin 1979, 1988; Margulis 1970; Patterson 1994; Patterson and Sogin 1992; Whatley 1976; Whatley and Chapman-Andresen 1990). This evolutionary significance was in the context of an evolutionary paradigm known as the Archezoa hypothesis (Cavalier-Smith 1983), where "amitochondriate" protists represented basal eukaryotic lineages that had diverged before the acquisition of the mitochondrial endosymbiont and other key eukaryotic innovations (e.g., introns, Golgi dictyosomes, peroxisomes).

The Archezoa hypothesis was supported by molecular phylogenetic trees of eukaryotes consisting of a "crown" (animals, plants, fungi, and many algae) and a ladderlike sequential divergence of amitochondriate parasites from the base (Sogin 1991; Sogin and Silberman 1998).

In the late 1990s, developments in phylogenetic methods and the identification of mitochondriate remnant organelles led to the rejection of the Archezoa hypothesis and the crown/base view of eukaryotic relationships (Roger 1999). The development of evolutionary models incorporating heterogeneity among taxa (of evolutionary rate or of base composition) led to the realization that systematic phylogenetic error, such as "long branch attraction," had had a major effect on the positioning of "archezoan" organisms in the tree (Dacks et al. 2002; Holder and Lewis 2003; Philippe and Germot 2000). The finding of gene sequences of

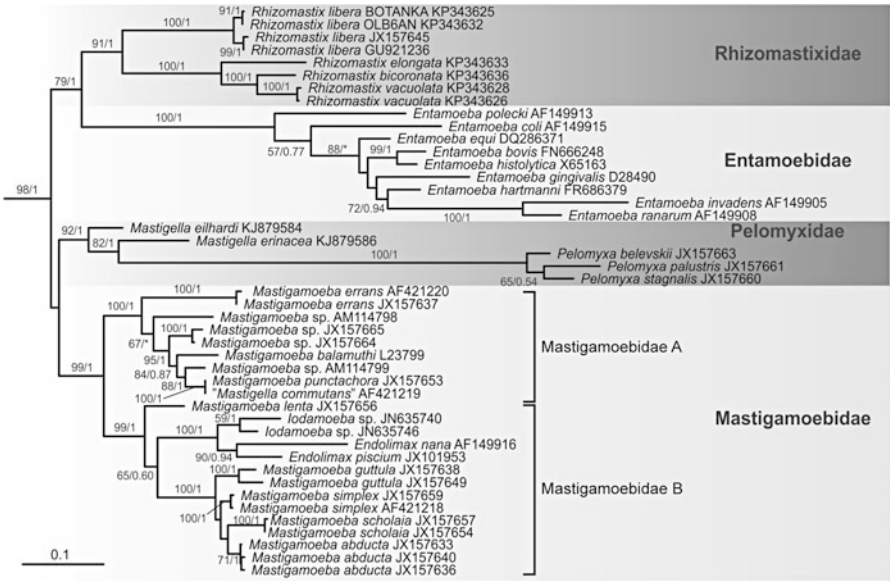

Fig. 13 Phylogenetic tree of Archamoebae based on SSU rRNA genes, showing generic relationships within families. *Mastigamoeba* is divided into two main clades, corresponding to "Mastigamoebidae A," with 100% ML bootstrap support and Bayesian posterior probability of 1, and "Mastigamoebidae B," with 99% ML bootstrap support and Bayesian posterior probability of 1. Note that the sequence labelled "*Mastigella commutans*" is thought to be from *Mastigamoeba punctachora* rather than *M. commutans* (see Zadrobílková et al. 2015). Support for relationships between families is not recovered from SSU rRNA data alone, requiring a multigene approach (Pánek et al. 2016). Sequences were aligned using the G-INS-I algorithm with default settings, on the MAFFT7 server (http://mafft.cbrc.jp/alignment/server/). The resulting alignment was manually edited to remove ambiguously aligned sites; the final dataset contained 1263 nucleotide positions. A maximum-likelihood phylogenetic tree was constructed in RAxML 7.2.3 (Stamatakis 2006) using the GTRGAMMAI model; the values at the branches represent statistical support in maximum likelihood (RAxML, 1000 pseudoreplicates)/Bayesian posterior probability (MrBayes, GTR + Γ + I + covarion model). Support values below 50/0.90 are not shown or are represented by an asterisk (*)

mitochondrial origin (*cpn60*, *HSP70*, *IscU*) and the localization of these gene products (by immuno-microscopy) to double-membrane-bounded organelles (Bui et al. 1996; Clark and Roger 1995; Roger et al. 1996, 1998; Tovar et al. 2003) have led to the identification of mitochondrion-derived organelles (i.e., hydrogenosomes and mitosomes) in almost all of the proposed "amitochondriate" organisms (van der Giezen 2009).

The identification of mitochondrial-remnant organelles (discussed above) and comparisons of ribosomal DNA sequences (Cavalier-Smith 1997; Hinkle et al. 1994; Milyutina et al. 2001; Morin and Mignot 1995; Silberman et al. 1999; Stiller and Hall 1999) and other genes (Arisue et al. 2002; Bapteste et al. 2002; Hannaert et al. 2000) now suggest that the Archamoebae are derived within the mitochondriate taxon Amoebozoa and are not deep-branching eukaryotes (Cavalier-Smith 1997, 1998; Edgcomb et al. 2002; Simpson and Roger 2004).

As discussed above, systematics within the Archamoebae is currently undergoing considerable flux, while many gene and protein sequences are obtained for many more representatives of the group. So far this has clarified that endobiotic taxa are distributed among the free-living taxa, showing that parasitism has clearly evolved multiple times in the Archamoebae (Pánek et al. 2016; Ptáčková et al. 2013; Stensvold et al. 2012; Zadrobílková et al. 2015, 2016). Obtaining multiple sequences from a single taxon can improve the robustness of placement of particular taxa, both at species level and at higher levels – for example the placement of *Pelomyxa* has long been unstable because the original sequence obtained was highly divergent (Milyutina et al. 2001; Ptáčková et al. 2013). Further sequences from *Mastigella*, *Tricholimax*, and *Mastigina* will be key to resolving relationships among the genera of the Archamoebae; and sequences from *Mastigamoeba aspera* would permit certainty in the proposed split of *Mastigamoeba* discussed above (Pánek et al. 2016) (Fig. 13).

Acknowledgments We gratefully acknowledge the input from Professor David J. Patterson on knowledge of free-living taxa and the input on knowledge of parasitic taxa from Professor RNDr. Jaroslav Kulda, who also provided the prepared slide material in the plates. This work was supported by a grant from the Czech Science Foundation (project GA14-14105S).

Myxomycetes

38

Steven L. Stephenson and Martin Schnittler

Abstract

The myxomycetes (class Myxogastria), also commonly known as plasmodial slime molds or acellular slime molds, are the most species-rich group within the Amoebozoa, with approximately 1,000 morphologically recognizable species having been described. These organisms are free-living predators of bacteria and other eukaryotic protists. Myxomycetes have been recorded from every terrestrial habitat investigated to date. The two trophic stages (amoeboflagellates and plasmodia) in the life cycle are usually cryptic, but the fruiting bodies are often large enough to be observed directly in nature. Fruiting bodies release airborne spores that are dispersed by air or, more rarely, animal vectors. Myxomycetes are associated with a wide variety of different microhabitats, the most important of which are coarse woody debris, ground litter, aerial litter, and the bark surface of living trees. Specimens can be obtained as fruiting bodies that have developed in the field under natural conditions or cultured in the laboratory. A substantial body of data on the worldwide biodiversity and distribution of myxomycetes has been assembled over the past 200 years, but there is a relative lack of molecular data, since myxomycetes are neither pathogenic nor of

economic importance. However, recent studies have produced the first, albeit still incomplete, molecular phylogenies of the group. Moreover, there appears to be a much higher level of diversity on the molecular level than reflected in the number of morphospecies, with the latter often consisting of reproductively isolated populations which can be considered as biospecies.

Introduction

General Characteristics

One of the major branches of the eukaryotic tree of life consists of an assemblage of amoeboid protists referred to as the supergroup Amoebozoa, which are close relatives to the Opisthokonta (Holozoa and Holomycota) as indicated by Baldauf (2008) and Bapteste et al. (2002). Dictyostelid (cellular) and true (acellular) slime molds are part of the Amoebozoa (Pawlowski and Burki 2009) the myxomycetes (class Myxogastria) are one of the most diverse groups in the Amoebozoa. Myxomycetes (also known as plasmodial slime molds or myxogastrids) are a group of free-living terrestrial heterotrophs with complex life cycles. The unicellular forms are amoebae and flagellates (collectively, the "amoeboflagellate" stage). These develop, usually via sexual fusion, into a multinucleate "plasmodium" stage, which is also trophic. The plasmodium stage can produce fruiting bodies, which release airborne spores that are dispersed by air or, more rarely, animal vectors. The amoeboflagellates and plasmodia are usually cryptic, but the fruiting bodies are often large enough to be observed directly in nature. Myxomycetes have been recorded from every terrestrial habitat investigated to date. They are associated with a wide variety of different microhabitats, the most important of which are coarse woody debris, ground litter, aerial litter, and the bark surface of living trees. Specimens can be obtained as fruiting bodies that have developed in the field under natural conditions or cultured in the laboratory. A substantial body of data on the worldwide biodiversity and distribution of myxomycetes has been assembled over the past 200 years, but there is a relative lack of molecular data, since myxomycetes are neither pathogenic nor of economic importance.

Since their discovery, the myxomycetes have been variously classified as plants, animals, or fungi. Because they produce aerial spore-bearing structures that resemble those of certain fungi and typically occur in some of the same ecological situations as fungi, myxomycetes have traditionally been studied by mycologists (Martin and Alexopoulos 1969). Indeed, the name most closely associated with the group, first used by Link (1833) more than 175 years ago, is derived from the Greek words *myxa* (which means slime) and *mycetes* (referring to fungi). However, abundant molecular evidence now confirms that they are amoebozoans and not fungi (Yoon et al. 2008). Interestingly, the fact that myxomycetes are protists was first pointed out by de Bary (1864) more than a century and a half ago, and he proposed the name Mycetozoa (literally meaning "fungus animal") for the group. However, myxomycetes continued to be considered as fungi by most mycologists until the latter half of the twentieth century and are still governed by the Botanical Code of Nomenclature.

Other Similar Microorganisms

The myxomycetes are the most prominent representatives of a guild of sometimes unrelated nonpathogenic microorganisms that share a number of ecological features

(Schnittler et al. 2006). For this reason, some of these non-related forms can be confused with myxomycetes (see below). All of these organisms have a free-living, predatory lifestyle and a life cycle that begins with solitary amoeboid cells. The latter increase their biomass by aggregation of cells or by undergoing nuclear divisions without cell division (e.g., the plasmodia of myxomycetes) and convert this biomass into typically stalked fruiting bodies that can develop within hours or days. These fruiting bodies are produced not as a true growth process but by rearrangement of the available biomass, ultimately to release propagules for (potentially, at least) long-distance dispersal. The production of airborne propagules is the key innovation that enables these microorganisms to colonize terrestrial habitat islands with a locally higher density of microbes serving as prey (Schnittler and Tesmer 2008).

Myxomycetes are neither pathogenic nor of economic importance. Only a few model species, especially *Physarum polycephalum* and *Didymium iridis*, have been used to investigate cell division and developmental biology in myxomycetes (Hüttermann 1973) or the importance of mating type genes (Collins 1979) and the distribution of group I introns in these organisms (Wikmark et al. 2007; Feng and Schnittler 2015).

Other non-related members of this guild include the prokaryotic myxobacteria (a group consisting of perhaps 40–60 species), which produce fruiting bodies that in some species can reach a height of as much as 1 mm (Reichenbach 1993). Their spores are distinctly smaller than the smallest myxomycete spores, which usually fall within the range of (4–)7–12(–22) μm. Eukaryotic microorganisms with a similar lifestyle are the sorocarpic amoebae formerly known as the acrasid cellular slime molds or Acrasea (Olive 1975; Stephenson 2014). This is a group of approximately 20 species now known to be polyphyletic, containing aggregating, fruiting body-forming amoebae of different supergroups, with most not belonging to the Amoebozoa (Brown et al. 2009, 2010, 2012). Examples include the genera *Acrasis*, *Copromyxa*, *Guttulinopsis*, and *Fonticula* (Dykstra and Keller 2000; Brown et al. 2012). All these genera form fructifications by the aggregation of amoebae; *Acrasis* possesses a cellular stalk, whereas the others form sessile fruiting bodies. The ciliate genus *Sorogena* (Colpodea) produces stalked fruiting bodies strikingly similar to those found in myxomycetes, but the spores contain both a micro- and a macro-nucleolus (Bardele et al. 1991; Sugimoto and Endoh 2008).

Other Eumycetozoan Slime Molds

The eumycetozoans as defined by Olive (1975) include the Myxogastria (true or acellular slime molds, myxomycetes), the paraphyletic protosteloid amoebae (protostelids; see ▶ Protosteloid Amoebae (Protosteliida, Protosporangiida, Cavosteliida, Schizoplasmodiida, Fractoviteliida, and Sporocarpic Members of Vannellida, Centramoebida, and Pellitida)), and the Dictyostelia (dictyostelid cellular slime molds or dictyostelids; see ▶ Dictyostelia). There are approximately 160 species known for the Dictyostelia (Romeralo et al. 2011) and about 35–40 species for the protosteloid amoebae (Spiegel et al. 2004), whereas at least 1,000 morphologically recognizable species of myxomycetes have been described (Lado 2005–2016).

Fig. 1 Fruiting bodies of *Ceratiomyxa fruticulosa*, the most commonly encountered species *Ceratiomyxa*. What is recognized as *C. fruticulosa* is most likely a species complex, with one of the morphotypes producing exclusively cylindrical fruiting bodies as it can be observed in this image. These consist, in contrast to all other myxomycetes, of a slimy matrix and solitary spores which develop on tiny stalks, giving the surface of the fruiting body a fur-like appearance (Photograph by M. Schnittler)

As recognized by Olive (1975), both the Myxogastria and protosteloid amoebae are sporocarpic, with fruiting bodies ultimately derived from a single amoeboid cell. In contrast, the fruiting bodies in the Dictyostelia are derived from an aggregation of amoebae. Both the Myxogastria and Dictyostelia appear to represent monophyletic groups (Fiore-Donno et al. 2010a; Schaap et al. 2006), whereas the protosteloid amoebae are found in several lineages throughout the Amoebozoa, although apparently restricted to the Conosa (Shadwick et al. 2009; Adl et al. 2012).

In all but the most recent treatments of the myxomycetes, the four described species of the genus *Ceratiomyxa* were considered as part of the Myxogastria as the sole members of its own order, Ceratiomyxales (Fig. 1). However, these organisms differ by exogenous spore development (solitary spores are formed individually on stalks emerging from a joint matrix) from all other myxomycetes (in which spores develop inside a fruiting body surrounded, at least in the early stages, by a peridium). It has been suggested that they should be regarded as a sister group to the Myxogastria (Fiore-Donno et al. 2008, 2010a), and there are as well treatments which consider them with the protostelids (Olive 1970, 1975; Olive and Stoianovitch 1979; Adl et al. 2012), a group better referred to as the protosteloid amoebae (Shadwick et al. 2009). Chapter 36, ▶ Protosteloid Amoebae (Protosteliida, Protosporangiida, Cavosteliida, Schizoplasmodiida, Fractoviteliida, and Sporocarpic Members of Vannellida, Centramoebida, and Pellitida) assigns *Ceratiomyxa* to the taxon Protosporangiida (and does not employ the taxon Ceratiomyxales). Nevertheless, they are mentioned in this chapter because of their long history of study as myxomycetes. Other than *Ceratiomyxa*, all of the organisms assigned to the myxomycetes constitute a well-defined monophyletic group traditionally placed into five different taxonomic orders (Echinosteliales, Liceales, Trichiales, Stemonitales, and Physarales; Martin and Alexopoulos 1969).

Occurrence and Distribution

Myxomycetes can be detected directly in the field by fruiting bodies (about 60% of all known species). Over the past 200 years, a substantial body of data on their worldwide diversity and distribution has been assembled (Stephenson et al. 2008). More recent studies have incorporated the use of moist chamber cultures (Stephenson and Stempen 1994), and about 40% of all species of myxomycetes are known primarily or even exclusively from specimens appearing in moist chamber (or sometimes, agar) cultures (Schnittler et al. 2015). Checklists are available for a number of regions of the world, such as arctic and boreal zones (Stephenson et al. 2000), Africa (Ndiritu et al. 2009), and the Neotropics (Lado and Wrigley de Basanta 2008). This is quite unlike the situation that exists for most other protists, for which distributional data are often very limited. Based on recordable occurrence of fruiting bodies, methods of community ecology can be applied to study these organisms (e.g., Stephenson 1988; Stephenson et al. 1993; Schnittler 2001b; Rojas and Stephenson 2011) and have shown surprisingly narrow ecological niches for some species.

It seems certain that the trophic stages of myxomycetes, especially the amoebae, have a much wider distribution in nature than reflected by the occurrence of fruiting bodies. In fact, some species may have lost the ability to fruit altogether. For example, molecular phylogeny shows the free-living amoebae formerly treated as *Hyperamoeba* are instead several different lineages of myxomycetes (Fiore-Donno et al. 2010b). These have been recovered from artificial as well as natural aquatic environments, including the coelomic cavity of sea urchins (Karpov and Mylnikov 1997; Zaman et al. 1999). An RNA-based study (Urich et al. 2008) identified the amoebae of eumycetozoans as a key group of soil microbes. Studies that have used environmental PCR to investigate the presence of myxomycetes in alpine soils (Kamono et al. 2012; Clissmann et al. 2015; Fiore-Donno et al. 2016) recovered numerous sequences hitherto not known from fruiting bodies.

Due to their dormant stages (spores can survive for decades, microcysts and sclerotia for months to years), myxomycetes are capable of surviving under rather severe environmental conditions, even the extremely xeric conditions found in the Atacama Desert (Lado et al. 2007; Wrigley de Basanta et al. 2012), parts of the Arabian Peninsula (Schnittler et al. 2015), and Mongolia (Novozhilov and Schnittler 2008). In theory, long-distance dispersal by means of spores (Kamono et al. 2009) would seem to provide myxomycetes with the potential to occur anywhere on the earth, but the actual distribution of most species is usually determined by the availability of suitable microhabitats for their establishment, growth, and development (Schnittler et al. 2000). However, global patterns of distribution do appear to exist as well, since some species are predominantly subtropical to tropical, whereas others are restricted to temperate regions of the world (Stephenson et al. 2008). Temperature certainly limits the formation of fruiting bodies in tropical species, which sometimes appear in Europe in greenhouses. However, habitat preferences are currently known only from fruiting bodies. Future studies that make use of environmental PCR (as noted above) may provide a very different picture of myxomycete distribution.

History of Knowledge

Since Linnaeus provided the first descriptions of a few organisms now known to be myxomycetes (e.g., *Lycoperdon epidendrum*, the original name for the common species *Lycogala epidendrum*), the nomenclatural starting point for the taxonomy of the group is the publication of *Species Plantarum* in 1753. The first noteworthy taxonomic treatment of the myxomycetes was published by de Bary (1859), who was the first to conclude that these organisms are protists and not fungi. Rostafinski, a student of de Bary, is credited with producing the first relatively comprehensive monograph (Rostafinski 1873, 1874–1876), albeit in Polish. However, much of the information in the monograph was made available in English publications by Cooke (1877) and Massee (1892).

The single most significant pre-twentieth century publication on the myxomycetes was the first edition of Arthur Lister's *A Monograph of the Mycetozoa* (Lister 1894). This monograph, revised and expanded versions were published by his daughter Gulielma Lister (1911, 1925), became the standard reference to the myxomycetes during the early part of the twentieth century. Thomas Macbride published the first edition of his book *The North American Slime-Moulds* in 1899 and followed this with a greatly expanded second edition in 1922. These two works (Macbride 1899, 1922) are of particular importance because they were the basis of yet another work, *The Myxomycetes*, which Macbride coauthored with George Martin (Macbride and Martin 1934). Several decades later, Martin collaborated with Constantine Alexopoulos to produce their comprehensive world monograph, *The Myxomycetes* (1969). The Martin and Alexopoulos monograph, published by the University of Iowa Press, still remains the single most definitive treatment for the myxomycetes.

Until recently, identification of myxomycetes was based almost exclusively upon morphological characters of the fruiting body (Martin and Alexopoulos 1969), and keys and descriptions to the various morphospecies have been provided in a number of monographs over a period of almost a century and a half (e.g., Rostafinsky 1874–1876; Lister 1894, 1911, 1925; Martin and Alexopoulos 1969; Nannenga-Bremekamp 1991; Neubert et al. 1993, 1995, 2000; Ing 1999; Stephenson 2003; Poulain et al. 2011). However, recent molecular phylogenies (Fiore-Donno et al. 2012, 2013) show that the classical system of classification used for myxomycetes is in need of revision (see Table 1).

Practical Importance

Myxomycetes are neither pathogenic nor of economic importance. Only a few model species, especially *Physarum polycephalum* and *Didymium iridis*, have been used to investigate cell division and developmental biology in myxomycetes (Hüttermann 1973) or the importance of mating type genes (Collins 1979) and the distribution of group I introns in these organisms (Wikmark et al. 2007; Feng and Schnittler 2015).

Table 1 Comparison between the traditional classification of myxomycetes followed in most monographs and groupings emerging from molecular phylogenetics. Only important genera (e.g., isolated position or species-rich) are listed

Groups supported by molecular phylogenies	Traditional classification
Myxogastria[a]	Class Myxogastria (myxomycetes)
Dark-spored basal clade/Collumellidia[b]	
Echinosteliid superclade (*Echinostelium*)	Order Echinosteliales
Fuscisporoid superclade	
Meridermid clade (*Meriderma*)	Order Stemonitales *pro parte (p.p.)*[d]
Stemonitid clade (*Stemonitis*, *Comatricha*)	Order Stemonitales *p.p.*[e]
Lamprodermid clade (*Badhamia*, *Physarum*, *Didymium*, *Lamproderma*)	Orders Physarales, Stemonitales *p.p.*[f]
Bright-spored basal clade/Lucisporidia[c]	
Cribrarioid superclade (*Cribraria*)	Order Liceales *p.p.*[g]
Trichioid superclade	
Reticularioid clade (*Lycogala*, *Reticularia*, *Tubifera*)	Order Liceales *p.p.*[h]
Liceoid clade (*Licea*)	Order Liceales *p.p.*[i]
Trichoid clade (*Arcyria*, *Hemitrichia*, *Trichia*)	Order Trichiales[j]

[a]The genus *Ceratiomyxa*, highly distinct from all other members of the group, is probably best excluded from the Myxogastria, which is supported by current molecular investigations (Kretzschmar et al. 2016). This would make endogenic spore formation a uniting character for all Myxogastria. *Ceratiomyxa* shows affinities to some of the protostelids, which are not a monophyletic group (Shadwick et al. 2009, ▶ Protosteloid Amoebae (Protosteliida, Protosporangiida, Cavosteliida, Schizoplasmodiida, Fractoviteliida, and Sporocarpic Members of Vannellida, Centramoebida, and Pellitida))

[b]Dark-spored myxomycetes sensu Cavalier-Smith (2013): spores with melanin (except for *Echinostelium*), therefore usually violaceous brown in color

[c]Bright-spored myxomycetes sensu Cavalier-Smith (2013): spores with various other pigments (yellowish or reddish colors)

[d]*Meriderma* was split off from *Lamproderma* and forms a distinct clade within the dark-spored myxomycetes; the peridium, which fragments into tiny pieces, distinguishes the genus from *Lamproderma*

[e]The classical Stemonitales include all dark-spored myxomycetes with non-calcareous fruiting bodies. However, molecular phylogenies (Fiore-Donno et al. 2012) show the classical Physarales nested within the Stemonitales

[f]*Lamproderma* shows closer affinities to the classical Physarales, defined by calcareous fruiting bodies, even if calcareous structures are absent or reduced to little splinters on the peridium

[g]The order Liceales, with only the absence of a capillitium as the unifying character, were long thought not to be monophyletic (Eliasson 1977, 2015), but *Cribraria* forms a highly distinct clade in molecular phylogenies (Fiore-Donno et al. 2013)

[h]The genera *Lycogala*, *Reticularia*, and *Tubifera* form a monophyletic clade, but the latter does not include *Dictydiaethalium*, which shows a closer relationship to the traditional Trichiales (Leontyev et al. 2014)

[i]*Licea*, as the largest genus of the traditional Liceales, is not monophyletic, since at least some species show closer affinities to the traditional Trichiales

[j]This order, defined by free elaters as capillitial structures, is best maintained in the light of molecular investigations, although the traditional boundaries between genera do not seem to reflect natural relationships

Habitats and Ecology

Myxomycetes have been recorded from every major type of terrestrial ecosystem examined to date (Stephenson et al. 2008), and at least a few species have been recovered from aquatic habitats (Lindley et al. 2007). Temperature and moisture are thought to be the main factors limiting the occurrence of myxomycetes in nature (Alexopoulos 1963), and species richness tends to increase with increasing diversity and biomass of the associated vegetation giving rise to the plant detritus that supports the bacteria and other microorganisms upon which both trophic stages feed (Madelin 1984; Stephenson 1989). Some species of myxomycetes (e.g., *Badhamia utricularis* and *Fuligo septica*) are known to excrete exoenzymes, thus enabling them to literally consume the fruiting bodies of fungi. The pH of the substrates potentially available to myxomycetes in a particular habitat also represents an important factor influencing their distribution (Harkönen 1977; Stephenson 1989; Wrigley de Basanta 2000; Mosquera et al. 2000; Rojas et al. 2010). Although many myxomycetes appear to have a relatively wide pH tolerance, this is not the case for all species. For example, some species of *Paradiacheopsis* are found almost exclusively on bark that is quite acidic (Schnittler et al. 2016), whereas numerous species in the Physarales are restricted largely to substrates with a pH >5.0 (Schnittler and Stephenson 2002).

Microhabitats

Virtually all knowledge we have about myxomycete ecology and distribution is based only upon the occurrence of fruiting bodies. A few studies employing environmental PCR to detect myxomycete sequences in various types of substrates (Clissmann et al. 2015: bright-spored myxomycetes in wood; Fiore-Donno et al. 2016: dark-spored myxomycetes in soil) indicated that amoebal populations seem to be more widely distributed than data on fruiting body occurrence would suggest. In temperate regions of the world, where the fruiting bodies of myxomycetes appear to be most abundant, these organisms are associated with a number of different microhabitats. These include coarse woody debris, the bark surface of living trees, ground litter, and aerial portions of dead but still standing herbaceous plants. Each of these microhabitats tends to be characterized by a distinct assemblage of species (Stephenson 1988, 1989; Stephenson and Stempen 1994). The myxomycetes associated with coarse woody debris are the best known, since the lignicolous (wood-inhabiting) species typically occurring in this microhabitat tend to be among those characteristically producing fruiting bodies of sufficient size to be detected with the naked eye in the field (Martin and Alexopoulos 1969). Many of the more common and widely known myxomycete taxa, including various species of *Arcyria*, *Lycogala*, *Stemonitis*, and *Trichia*, are predominantly lignicolous. The assemblage of myxomycetes present on coarse woody debris changes with the stage of decomposition (Takahashi and Hada 2009). For example, some taxa (e.g., *Badhamia*) are restricted largely to the early stages when bark is still present. Several hundred species of myxomycetes are predominantly or completely lignicolous,

including most of the species with large compound fruiting bodies. As such, it is one of the most diverse microhabitats for myxomycetes.

Moist Chamber Cultures

The myxomycetes associated with the bark surface of living trees and with ground litter tend to be much less conspicuous and more sporadic in their occurrence and are thus difficult to detect in the field. However, the moist chamber culture technique as it applies to myxomycetes (Gilbert and Martin 1933) provides a convenient method of supplementing field collections (see, e.g., Novozhilov et al. 2017) when studying such microhabitats as bark and litter. It essentially involves blind collection of substrates with populations of amoebae, microcysts, and/or spores present and incubating these with at first abundant and then decreasing moisture conditions. The technique has been used with considerable success by many researchers (e.g., Keller and Brooks 1976; Blackwell and Gilbertson 1980; Harkönen 1981; Stephenson 1989) and works best in arid habitats (Schnittler et al. 2015). More than 200 species of "corticolous" (bark-associated) myxomycetes have been reported from bark in the field and/or in moist chamber culture (Mitchell 1980; Snell and Keller 2003). Many of these species are also known to occur in other microhabitats, but at least some species appear to be restricted to the bark of living trees. Prominent examples include various species of *Echinostelium*, *Licea*, and *Macbrideola* (Alexopoulos 1964; Mitchell 1980) with small fruiting bodies.

Ground litter supports an exceedingly diverse assemblage of myxomycetes, with approximately 400 species having been reported from this microhabitat, including many members of the Physarales that can be cultured. It seems likely that many myxomycetes fruiting on the upper litter layers actually inhabit the soil-litter interface as amoebae (Stephenson et al. 2011). A number of special microhabitats support rare assemblages of myxomycetes with seemingly specialized species present. In tropical regions, myxomycetes have been reported from epiphyllous liverworts growing on living leaves (Schnittler 2001a) and on decaying portions of the inflorescences of large tropical herbaceous plants, especially members of the order Zingiberales, which provide a highly basic pH (Schnittler and Stephenson 2002). An additional microhabitat in temperate regions supports about two dozen species of bryophilous (bryophyte-inhabiting) myxomycetes, which are found associated with mosses covering the surface of rocks, usually sandstone, in moist cool gorges (Schnittler et al. 2010). Likewise, about 25 species, some with specially adapted thick-walled spores, are known from dung (coprophilous myxomycetes, Eliasson and Keller 1999). In deserts, decaying portions of succulent plants represent another special microhabitat, from which about 50 species of "succulenticulous" myxomycetes have been reported (Lado et al. 1999). The amoebae of these myxomycetes probably prey on yeasts, and their spores are likely to be dispersed by fruit flies (*Drosophila* spp., Stephenson 2010).

The amoebae of myxomycetes are exceedingly abundant in most arable soils (Madelin 1984). Environmental PCR approaches that target the 18S rRNA (gene)

are problematic because so-called universal primers are poorly suited to detecting myxomycetes (Stephenson et al. 2011; Schnittler et al. 2017). However, in a large molecular data set for the soil microbial community obtained using a metatranscriptomic approach, Urich et al. (2008) found that myxomycetes indeed represent a major component of total protozoan soil biodiversity. The occurrence of myxomycetes in soil was discussed in detail by Stephenson et al. (2011) and Stephenson and Feest (2012).

Characterization and Recognition

General Life Cycle

The myxomycete life cycle (Fig. 2) includes two very different trophic stages, one consisting of uninucleate haploid amoebae, with or without flagella (the term "amoeboflagellate" encompasses both types of cells), and a distinctive multinucleate

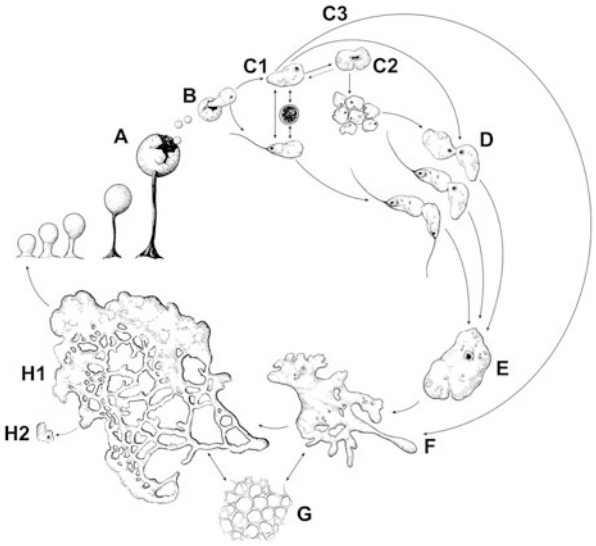

Fig. 2 Life cycle of a myxomycete. A fruiting body (*A*) releases spores (*B*) that germinate to produce uninucleate amoebae (*C1*), which can convert into resistant microcysts (middle structure) or flagellated forms (lower structure). The uninucleate cells divide (*C2*) to build up often large populations. The sexual cycle involves syngamy of two compatible uninucleate cells (*D*) to produce a zygote (*E*). [An additional hypothetical life cycle involves a uninucleate cell developing directly into a plasmodium.] The zygote gives rise to a plasmodium (*F*). The latter increases in size by phagocytosis and subsequent nuclear divisions to develop into a larger structure (*H1*). It has been reported that small portions of the plasmodia can separate as amoebae (*H2*). Under adverse conditions a plasmodium can transform into a resistant sclerotium (*G*). The segregation of a plasmodium into fruiting bodies (left side of the figure) completes the life cycle (Drawing by A. Mele)

Fig. 3 Phaneroplasmodium of a myxomycete. This is one of three different types of plasmodia produced by these organisms. The phaneroplasmodia of some species of myxomycetes can reach more than a meter in total extent (Photograph by R. Darrah)

Fig. 4 Group of solitary fruiting bodies of *Didymium bahiense* var. *microsporum* (Physarales). Such fruiting bodies usually develop by segregation of a larger plasmodium into smaller portions (Photograph by M. Poulain)

structure, the plasmodium (Martin et al. 1983). Plasmodia (Fig. 3) are motile and in some species can reach a size of more than a meter across. Large plasmodia contain many thousands of synchronously dividing diploid nuclei. Under suitable conditions, the plasmodium gives rise to one or (in most species) many fruiting bodies (also referred to as sporocarps for the Myxogastria or sporophores in *Ceratiomyxa*) containing haploid spores (Figs. 4 and 5). The spores represent the most durable of the three dormant stages in the life cycle, with the others being microcysts (derived from amoebae) and sclerotia (derived from plasmodia).

The fruiting bodies produced by myxomycetes are somewhat suggestive of those produced by certain dicaryan fungi (Eumycota), but they are considerably smaller (usually no more than 1–3 mm tall) and totally different in structure, since all visible components, except for the spores, are composed of extracellular material and thus do not show a cellular structure. Presumably, the spores are wind dispersed and

Fig. 5 Fruiting bodies of *Leocarpus fragilis* (Physarales). This is one of the most distinctive of all myxomycetes (Photograph by M. Schnittler)

complete their life cycle by germinating to produce uninucleate amoebae or flagellate cells (both forms are convertible; Stephenson et al. 2008). These feed and divide by binary fission to build up large clonal populations in the various microhabitats in which these organisms occur. Ultimately, this stage in the life cycle gives rise to the plasmodium, usually following gametic fusion between mating-type compatible amoeboid cells. Presumed apomictic strains occur in culture (Collins 1980, 1981; Clark and Haskins 2013); to what extent these occur in nature is unknown (Feng et al. 2016). Bacteria apparently represent the main food resource for both trophic stages, but plasmodia are also known to feed upon yeasts, eukaryotic microalgae, and fungal spores and hyphae (Stephenson and Stempen 1994; Smith and Stephenson 2007).

Plasmodium

Plasmodia are characterized by often colorful pigments (including white, yellow, or orange to red tints), but possess only a few characters useful in distinguishing among species of myxomycetes. It is possible to recognize three fundamentally different types (Alexopoulos 1960). These are protoplasmodia, aphaneroplasmodia, and phaneroplasmodia. Protoplasmodia are microscopic structures with only a few nuclei present, whereas aphaneroplasmodia and phaneroplasmodia are larger, multinucleate structures that are essentially giant cells. Aphanoplasmodia, characteristic of those myxomycetes assigned to the Stemonitales, are thin, transparent, and difficult to observe in nature; they generally become evident only when emerging from a particular substrate (e.g., a decaying log) just prior to the formation of fruiting bodies. Phaneroplasmodia are more robust and often highly pigmented and represent the type of plasmodium usually observed in nature. Plasmodia are extremely flexible structures and are capable of penetrating even very solid wood, most likely through the pits present in the dead cells making up the wood (Feest et al. 2015). Both aphanoplasmodia and phaneroplasmodia go through a stage that resembles a

protoplasmodium in the earliest stages of development. As a result of active cytoplasmic streaming, portions of a plasmodium are able to reach relatively distant food sources (Nakagaki et al. 2007).

Fruiting Body

Myxomycete fruiting bodies are morphologically very diverse (see Stephenson and Stempen 1994 or Schnittler et al. 2012 for a summary of morphological terms and characters; Neubert et al. 1993–2000, Poulain et al. 2011, www.slimemold.uark.edu for images showing their diversity). In *Ceratiomyxa*, fruiting bodies produce external spores on separate stalks, which is one of the characters that distinguishes the four members of this genus from all of the "true" myxomycetes. In spite of the fact that "slime mold" is the most widely used common name applied to the myxomycetes, *Ceratiomyxa* is the only genus in which the fruiting body actually has a slimy appearance at maturity. All of the true myxomycetes possess stalked or sessile fruiting bodies with internally formed spores (Fig. 6). Large aphaneroplasmodia and phaneroplasmodia primarily segregate into subportions by plasmotomy, with each subportion developing into a fruiting body (usually referred to as a sporocarp), often with a hypothallus at the base. Although possession of a stalk seems to be an

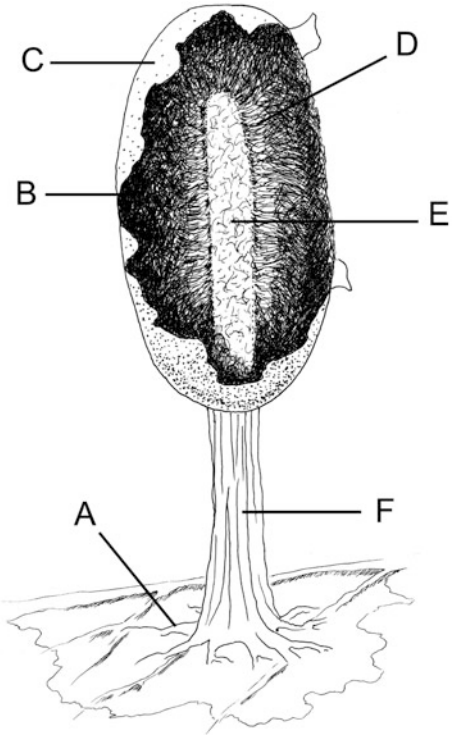

Fig. 6 Morphological features of the fruiting body of a myxomycete. (**a**) Hypothallus, (**b**) spores, (**c**) peridium, (**d**) capillitium, (**e**) columella, and (**f**) stalk (Adapted from Stephenson (2003))

Fig. 7 Compound fruiting body of *Tubifera montana* (Liceales), with evidence of the individual fruiting bodies still apparent. This type of compound fruiting body evolved, most likely independently, in several different groups of myxomycetes (Photograph by M. Schnittler)

ancient character (Fiore-Donno et al. 2012), in the majority of genera, sessile species exist beside stalked ones. In some species several fruiting bodies may share a common stalk, which seems to be the first step in the evolution of compound fruiting bodies. Large compound fruiting bodies, which are most often sessile, have evolved independently within several different lineages (Fig. 7). In some of these, single fruiting bodies are still recognizable (pseudoaethalia), but in other instances (aethalia) they are not.

The stalk, if present, is always acellular (although it can be filled with spore-like cells in some members of the Trichiales) and is secreted externally (Spiegel and Feldman 1989). In the dark-spored orders Echinosteliales and Stemonitales, the stalk forms as an invagination into the developing fruiting body, and the fruiting body rises upwards on it. Stalks formed in such a fashion usually extend into the spore mass as a central continuation, called a columella, which often diverges into many fine branches. In the other myxomycetes, the visible stalk emerges by constriction of the external surface of the plasmodial mass from which the fruiting body is derived. All structures holding the spore mass and allowing it to dry out slowly are referred to as a capillitium (Figs. 8 and 9). In the case of internal stalks, these are the branches of the columella, which is connected with the peridium in some taxa (Echinosteliales, genus *Meriderma*) but is not in others (most other Stemonitales). Capillitial structures are thus either extensions of the stalk (Echinosteliales and Stemonitales), tubular threads that are often stuffed with lime (Physarales), or free, threadlike structures called "elaters" that are often ornamented with spiral bands (Trichiales). In compound fruiting bodies, peridial remnants from the individual fruiting bodies may form a pseudocapillitium (found in some members of the Liceales).

Fruiting bodies are usually surrounded by an extracellular layer (peridium), although it may often be evanescent. In the latter situation, the peridium is simple and membranous, but it can as well be multilayered and covered with organic material or lime which shows different degrees of crystallization (Physarales). Spores are usually dispersed by air in nearly all species with solitary, stalked sporocarps, but dispersal may also occur by means of insects, especially in taxa

Fig. 8 Capillitial structures in *Lamproderma echinosporum* (Stemonitales), showing the stalk extending into the spore mass as a columella, where the capillitium branches off. Scale bar = 100 µm (Photograph by Y. K. Novozhilov)

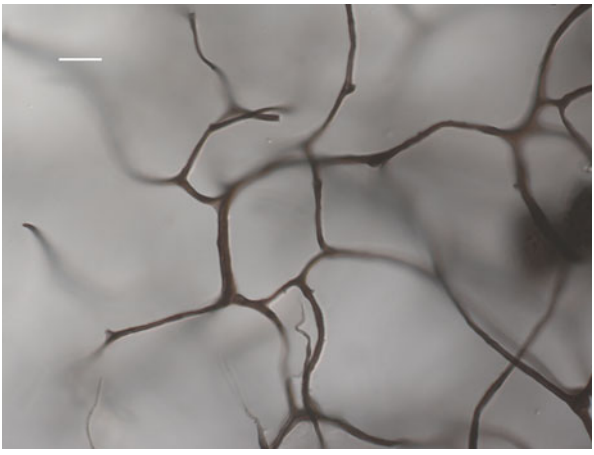

Fig. 9 Expanded view of the outer capillitial structures in *Lamproderma echinosporum*. Scale bar = 10 µm (Photograph by Y. K Novozhilov)

with compound fructifications (e.g., *Fuligo*, *Tubifera*, or *Reticularia*), or from the impact of falling raindrops (*Lycogala* or *Reticularia*). The latter are an example of convergent evolution with some of the gasteromycetes (e.g., puffballs) in Basidiomycetes (Estrada-Torres et al. 2005). Similar to many gasteromycetes, these

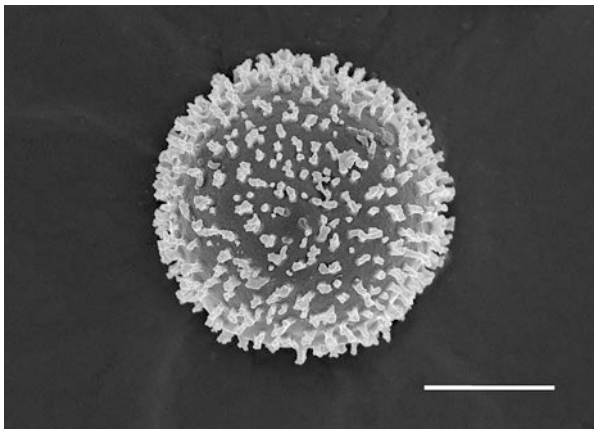

Fig. 10 A single spore of *Meriderma spinulisporum* (Stemonitales) as observed by scanning electron microscopy. Typically, myxomycete spores are nearly completely spherical, lack a hilum, and are ornamented with warts, spines, or ridges which sometimes form a more or less complete reticulum. Scale bar = 5 μm (SEM micrograph by A. Ronikier)

myxomycete species possess spores with an extremely hydrophobic ornamentation composed of a reticulum of ridges (Hoppe and Schwippert 2014).

Spore number per fruiting body ranges from just two in *Echinostelium bisporum* to 10^4–10^6 (but up to 10^{11}) in large compound fruiting bodies (Schnittler and Tesmer 2008). The spores of the vast majority of myxomycetes are spherical and range from 4 to 22 μm in diameter, with most species producing spores 10 ± 2 μm in diameter. Except for *Ceratiomyxa*, these spores lack a microscopic indentation (hilum) due to their internal development and are rarely smooth but more often ornamented with hydrophobic warts, spines, or elevated ridges (Fig. 10). Spores with yellow, reddish, or brown pigments (Trichiales: naphthoquinones; Iwata et al. 2003) occur in the bright-spored myxomycetes (Blackwell and Busard 1978; Rebhahn et al. 1999), whereas the dark-spored Stemonitales and Physarales have more uniform brown to nearly black spores pigmented by melanin (Loganathan et al. 1989; Dembitsky et al. 2005). Except for peridia with thick outer layers of organic material or lime, spore color determines the color of the fruiting body as a whole. In addition, false silvery to blue colors may also occur, as is the case for *Diachea leucopodia* or many species of *Lamproderma*. These false colors derive from interference of light reflected on the outer and inner surface of extremely thin peridia.

Sexual and Asexual Reproduction

Myxomycetes should be expected to be primarily sexual (Lahr et al. 2011; Spiegel 2011), as sex is a general attribute of eukaryotic life (Speijer et al. 2015). However, experiments on monosporic cultures suggest that they include a mixture of heterothallic (sexual) strains, where fusion of amoebae leads to the formation of a diploid plasmodium, and non-heterothallic presumably asexual strains, where single amoeboflagellates can mature into haploid plasmodia (Clark and Haskins 2010). Heterothallic isolates reproduce sexually, and fusion of compatible amoebae is controlled by mating type genes. As such, monosporic cultures, grown from a single

spore, usually do not form plasmodia. In contrast, non-heterothallic isolates can form plasmodia in monosporic cultures; most likely the life cycle can be completed by means of automixis (a degenerated meiosis or coalescence of meiotic products leading to diploid spores). In this case, the life cycle should be completed in the diploid stage (Clark and Haskins 2013). In addition, in the model organism *Physarum polycephalum*, the (temperature-dependent) diploidization of a haploid plasmodium has been identified as a possible initial event (Schaap et al. 2016). Conversion from heterothallic (sexual) to non-heterothallic (presumably automictic) forms within a species was reported by Collins (1980). Figure 1 in Feng et al. (2016) presents and discusses possible reproductive options.

Apart from cultivated stains, which are mostly limited to members of the Physarales, our knowledge about the occurrence of these reproductive modes in natural populations is very limited. A molecular investigation of bryophilous (bryophyte-associated) species of *Lamproderma* did not exclude the possibility of asexual reproduction (Fiore-Donno et al. 2011). Feng and Schnittler (2015) found that the distribution of introns in the 18S rRNA gene of the morphospecies *Trichia varia* was consistent with the existence of three sexual but reproductively isolated cryptic species. A third case study in *Meriderma* spp. (Feng et al. 2016) suggested predominant sexual reproduction. As such, we must assume that natural populations of myxomycetes consist mostly of clonal strains of amoebae, but the development of fruiting bodies is predominantly coupled with a sexual event.

The chromosomes of myxomycetes are small and difficult to count (Hoppe and Kutschera 2013). Ribosomal RNA genes that are most important for barcoding in this group of organisms are located in a few to several hundred copies on extrachromosomal plasmids (Torres-Machorro et al. 2010) and do not show Mendelian inheritance (Ferris et al. 1983). The only relatively complete myxogastrid genome sequence to date is that of an axenic culture of *Physarum polycephalum*, which shows extremely long stretches of single-sequence repeats together with large homopolymeric tracts, hampering assembly (Schaap et al. 2016).

Systematics

Recent molecular phylogenies have found a monophyletic clade (referred to as the "macromycetozoa"; Fiore-Donno et al. (2010a)) composed of the Dictyostelia, Myxogastria, and *Ceratiomyxa* (Pawlowski and Burki 2009). The Myxogastria is monophyletic but deeply divided into two groups (Fiore-Donno et al. 2010b), the bright-spored myxomycetes and the dark-spored myxomycetes; this division corresponds largely to the occurrence of melanin in spore walls. Cavalier-Smith (2013) recently proposed the formal names Lucidisporidia and Columellidia, respectively. Detailed phylogenetic relationships within the two groups have yet to be resolved; therefore, current knowledge does not allow the arrangement of all myxomycete genera into a natural system. Most of the traditional orders seem not to be

monophyletic, as shown by the contrasting traditional and informal classifications provided in Table 1.

Particularly problematic is the circumscription and sometimes the systematic position of a number of genera in several of the orders (Erastova et al. 2013). This suggests that morphological characters that are easy to observe tend to be overweighed (Schnittler and Mitchell 2000). These include traits like spore arrangement (single versus clustered). There are several rare cluster-spored species which essentially differ only in this character from more common single-spored species. The same is true for solitary versus compound fruiting bodies and the presence or absence of fruiting bodies with stalks (i.e., stalked versus sessile). In contrast, molecular data suggest that characters such as the structure of the peridium and the type of connection it has with the capillitium are evolutionarily conservative and appear to be seriously underweighted.

Maintenance and Cultivation

Only a small percentage (about 70 species, Clark and Haskins 2010, 2011) of the approximately 1,000 morphologically described species of myxomycetes can currently be induced to complete their life cycle in cultures with an appropriate bacterium present as a food source. Even fewer have been cultured under axenic conditions. The vast majority of these are litter-inhabiting members of the order Physarales. Media typically used to culture myxomycetes include weak nutrient agar to which various substrate decoctions have been added (Haskins and Wrigley de Basanta 2008). Fruiting can often be induced by adding sterile oatmeal flakes to a particular culture. Groups with specialized growth requirements, such as the nivicolous myxomycetes, are often difficult or impossible to culture (Shchepin et al. 2014). From these experiments, an independent biological species concept was developed (Clark 2000), which is not necessarily consistent with the prevailing morphological species concept (see discussion in Feng et al. 2016; Walker and Stephenson 2016).

For diversity studies, the moist chamber culture technique (Stephenson and Stempen 1994) is often used. For this simple technique, which is very convenient as well for demonstrations and school experiments (Keller and Braun 1999), samples of various types of dead plant material are placed on filter or toilet paper in sterile Petri dishes and allowed to soak with water. During the slow desiccation of the cultures, myxomycetes (particularly corticolous species) are regularly induced to fruit.

Spiegel et al. (2004) provided a synopsis of the eumycetozoans, with special regard to the methods used for carrying out inventories, various culturing techniques, and the preservation of specimens. A relatively nontechnical description of all of the techniques involved in collecting and studying myxomycetes is given in Stephenson and Stempen (1994).

Evolutionary History

A complete molecular phylogeny of the myxomycetes is gradually being developed (Fiore-Donno et al. 2008, 2010a, b, 2012, 2013). Many genes (Schaap et al. 2016) and especially rRNA sequences are rich in introns and extremely divergent, which makes it difficult if not impossible to develop universal primers. As is the case for other groups of protists (Adl et al. 2014), the most promising sequence for barcoding seems to be the first part of the 18S rRNA gene (SSU, Feng and Schnittler 2017; Schnittler et al. 2017). In contrast to the fungi, the ITS region is extremely variable even among closely related species of myxomycetes. The 18S region contains several insertion sites for group I introns (ten are currently known), which makes the myxomycetes an interesting model system for studying these structures (Johansen et al. 1993, 1997; Haugen et al. 2003). Introns may be independently acquired even within closely related biospecies (Feng and Schnittler 2015) and can contain homing endonuclease genes, seemingly following the Goddard-Burt cycle of intron acquisition and loss (Goddard and Burt 1999).

Due to the fragile nature of the fruiting body, fossil records of myxomycetes are exceedingly rare. Domke (1952) described a species of *Stemonitis* and Dörfelt et al. (2003) a species of *Arcyria* from Baltic amber dating from the Eocene. The maximum age that could be assigned to either of these fossils is about 50 million years, which is older than that of the few records of fossil spores that appear to be those of myxomycetes, which date only from the Oligocene and Pleistocene (Graham 1971). Molecular dating analyses that have considered eumycetozoans seem to indicate that the sorocarpic ancestors of myxomycetes may have existed even before the colonization of land by plants (Fiz-Palacios et al. 2013), but the highly divergent 18S rRNA gene sequences point as well to recent speciation events (Aguilar et al. 2013; Feng and Schnittler 2017).

Acknowledgments The first author gratefully acknowledges the support provided by a number of grants from the National Science Foundation and the information gained from numerous colleagues over his career. Angela Mele provided the drawing used as the basis for Fig. 2 and Randy Darrah helped modify this and several of the other figures. The second author would like to thank a number of colleagues, especially Y. K. Novozhilov, D. Wrigley de Basanta, C. Lado, D. Leontyev and several former Ph.D. students, especially Y. Feng, N. Dagamac and J. Tesmer, for fruitful discussions and collaborations.

Dictyostelia

39

Sandra L. Baldauf and Joan E. Strassmann

Abstract

Dictyostelia are common amoebae, mostly known from forest soil and litter. They respond individually to adverse conditions by forming simple amoeboid cysts (microcysts) or en masse by aggregation. Aggregates can include >100,000 amoebae and culminate in either thick-walled highly resilient macrocysts (zygocysts), the sexual cycle of Dictyostelia, or multicellular fruiting bodies (sorocarps). In contrast to Myxomycetes, Dictyostelia form pseudoplasmodia, and sorocarp formation in most species includes cellular differentiation and cell death (~20% of the aggregate). Traditional classification recognized three genera based on sorocarp morphology. However, these morphologies are now known to have evolved multiple times and thus correspond to morphotypes rather than phylogenetic taxa. Acytostelid morphotypes (traditional *Acytostelium* spp.) have tiny delicate sorocarps with acellular stalks (no cell death). Polysphondylid morphotypes (traditional *Polysphondylium* spp.) have cellular stalks bearing regularly spaced whorls of side branches. Dictyostelid morphotypes (traditional *Dictyostelium* spp.) also have cellular stalks but with diverse morphologies ranging from solitary sorocarps with a single sporehead to sorocarps with multiple sporeheads on irregularly spaced side branches and/or various arrangements of clustered sorocarps. There are ~150 described species, which molecular

phylogeny places into eight distinct divisions, and the taxonomy of group is now being formally revised accordingly. The best-known species is *Dictyostelium discoideum*, an important model organism widely used to study, e.g., cell signaling, cellular differentiation, and social behavior. Other taxa are also under development as models, including full genome data from all major divisions. Given its age (~600 myr), molecular depth, and small number of described species, it is expected that substantial dictyostelid diversity remains to be discovered.

Introduction

General Characteristics

Dictyostelia is a monophyletic group of sorocarpic terrestrial amoebae also known informally as cellular slime molds or social amoebae. Their closest well-known relatives are Myxomycetes (Fiore-Donno et al. 2010; ▶ Myxomycetes), from which they most notably differ in forming pseudoplasmodia (instead of true plasmodia) and fruiting bodies (sorocarps) with differentiated cell types. Dictyostelid amoebae feed primarily on bacteria (Potts 1902; Cavender 1973; Vadell 1993) and are distributed worldwide (Raper 1984; Cavender 1990), although they have been isolated primarily from forest soils and soil litter. Amoebae probably exhibit some preference in their bacterial prey (Singh 1947b; Depraitere and Darmon 1978; Nasser et al. 2013), including carrying them along with spores to new locations ("farming"; Brock et al. 2011). Thus, dictyostelids are important components of soil communities, potentially affecting the size and composition of the soil microbiota (Stout 1973; Landolt et al. 1992).

Dictyostelids were the first discovered (and are still the best-studied) organisms with aggregative multicellularity, whereby a single-celled trophic stage alternates with a multicellular (developmental) dispersal stage (Fig. 1). This is especially well studied in the model organism *Dictyostelium discoideum*, and much of what is known is based on studies of this species. The trophic stage (vegetative cycle; Fig. 1) is strictly unicellular, consisting of independent amoebae (often referred to as myxamoebae) feeding on bacteria (Raper and Smith 1939; Depraitere and Darmon 1978; Vadell 2000; Kessin 2001). Amoebae multiply by binary fission, which occurs roughly every 8–10 h under optimal growth conditions in the lab (Escalante and Vicente 2000). The population grows until food becomes scarce, at which point cells can switch to one of the three alternative pathways resulting in the formation of microcysts, macrocysts, or fruiting bodies (sorocarps; Fig. 1). Sorocarps consist of a stalk, which may be cellular or acellular, supporting a bolus of spores (sorus). However, not all responses are found in all species – for example, microcysts are unknown in *D. discoideum* and its immediate relatives (the redefined genus *Dictyostelium*; see below). Of the three responses, sorocarp formation is the best studied because of its multicellular nature and central importance for species identification.

The long-standing traditional taxonomy of Dictyostelia recognized three genera, which correspond to three general sorocarp morphologies (Fig. 2) – dictyostelid (traditional *Dictyostelium* spp.), polysphondylid (traditional *Polysphondylium* spp.), and acytostelid (traditional *Acytostelium* spp.) (Olive 1975; Raper 1984; Hagiwara 1989). More recently, morphological (Swanson et al. 2002) and molecular analyses (Schaap et al. 2006) reject this traditional classification, and molecular phylogeny in particular identifies instead up to eight major divisions, none of which correspond to the three genera (Fig. 3). Thus, the traditional genus-level designations are now understood to refer to morphotypes rather than phylogenetic taxa. The taxonomy of

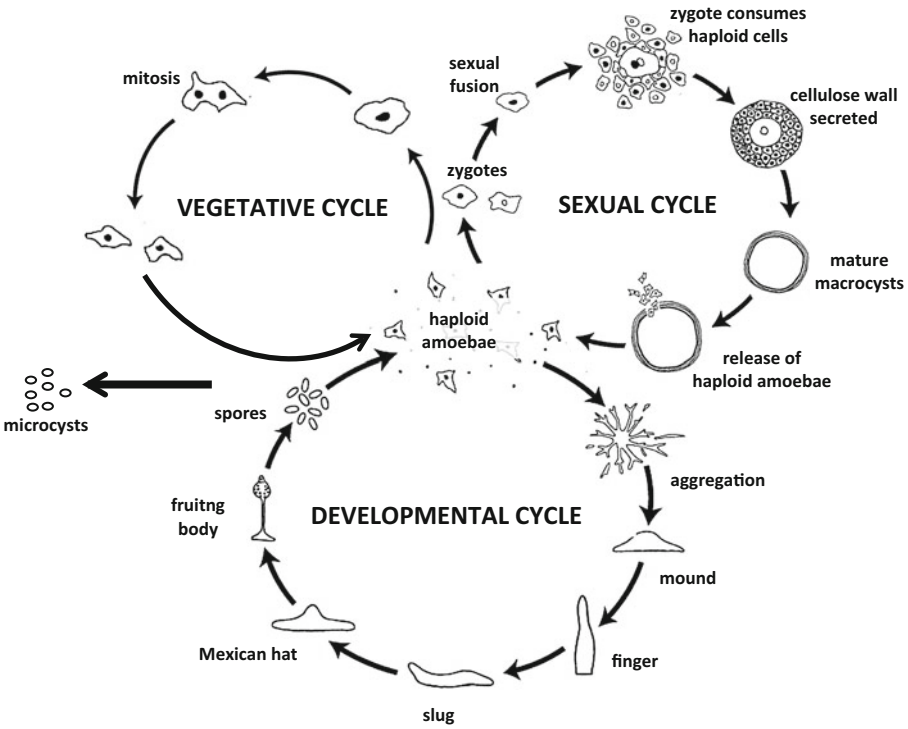

Fig. 1 Life cycle of Dictyostelia, based on *Dictyostelium discoideum*. The trophic stage (vegetative cycle) consists of haploid amoebae, which actively pursue their bacterial prey and which reproduce asexually. Various stimuli, particularly scarcity of food, lead to either the sexual or the social (developmental) cycle. In the developmental cycle, amoebae aggregate by the 10s–100s of thousands and then cooperate to form a multicellular fruiting body (sorocarp). The fruiting body consists of a ball of live spores supported by an inert stalk, which in all but acytostelids is cellular, consisting of the dead remains of ~20% of the aggregate cells. In the sexual cycle, amoebae aggregate, two cells of opposite mating type fuse, and the resulting zygote consumes the remaining aggregate. The result is a giant, hardy macrocyst with a thick multilayered cell wall. The macrocyst eventually undergoes recombination and meiosis and then hatches hundreds of recombinant, haploid progeny (Courtesy of S. Sheikh, D. Brown, and J. Strassmann)

the group is being formally revised, and the new proposed taxonomy is shown in Fig. 3. The new taxonomy is used here but is relatively easily mapped back to the traditional taxonomy by noting that nearly all new genera correspond to traditional *Dictyostelium* spp. with the exception of most *Heterostelium* spp. and *Rostrostelium ellipticum* (Fig. 3, Table 1)

Occurrence

The first dictyostelid to be formally described was *Dictyostelium mucoroides* (Fig. 4a), reported in 1869 by the German mycologist Oscar Brefeld, who was

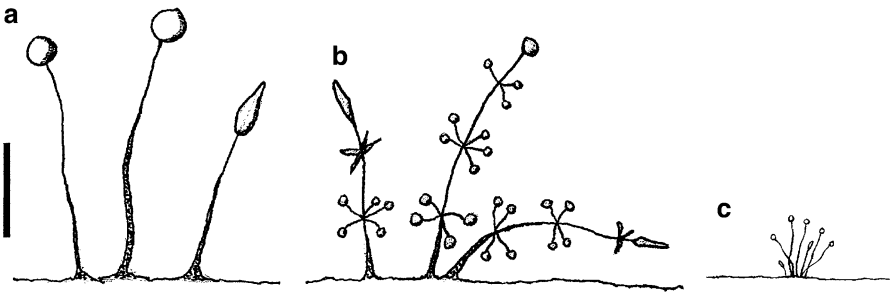

Fig. 2 Three Dictyostelia morphotypes. Representative schematics are shown for the three general sorocarp morphologies (morphotypes) occurring in Dictyostelia: (**a**) dictyostelid, (**b**) polysphondylid, and (**c**) acytostelid. Scale bar = 1.0 mm (Reproduced with permission from Swanson et al. (2002))

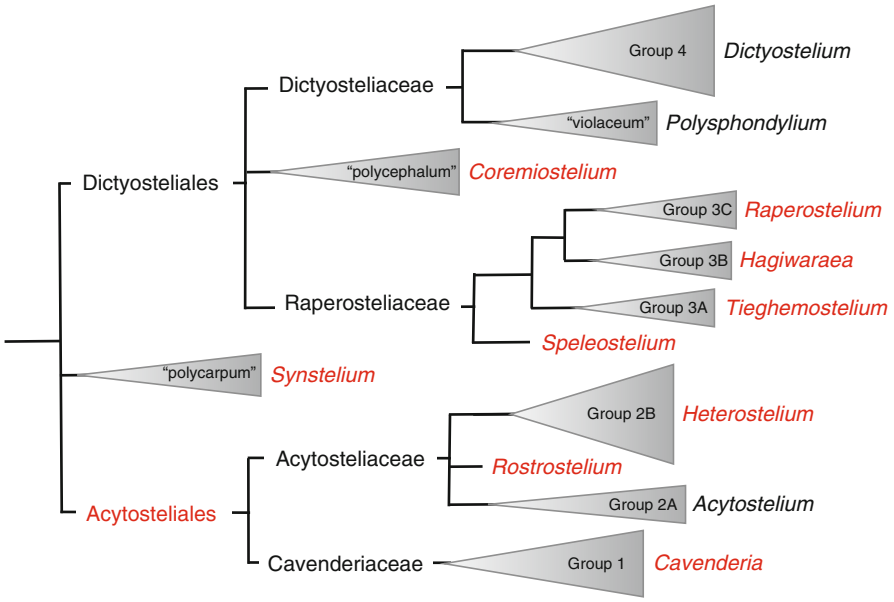

Fig. 3 Schematic phylogeny of Dictyostelia showing the major molecular groups and proposed new taxonomy. Informal names based on the molecular phylogeny are shown enclosed in shaded triangles (Schaap et al. 2006; Romeralo et al. 2011; Singh et al. 2016). Recently proposed names are shown in *red* (Sheikh et al. in press)

studying substrates such as animal dung and decomposing plant material looking for new microorganisms. Brefeld originally found *D. mucoroides* sorocarps on horse dung, leading to the idea that dictyostelids are coprophilous. Although later studies showed that their primary habitat is forest soils (Cavender and Raper 1965a; Raper 1984; Hagiwara 1989), they have also been found in agricultural soils (Agnihothrudu 1956), prairies (Smith and Keeling 1968; Rollins et al. 2010) and

deserts (Benson and Mahoney 1977). Further species have been found on dung (Raper 1984) as well as under-decomposed grasses, on mushrooms and wood (Hagiwara 1992), and on epiphytes in tropical forests (Stephenson and Landolt 1998). Recent surveys extending to high latitudes and altitudes, poorer soils, and even forests bordering on subarctic sand dunes (Romeralo et al. 2010) have resulted in the isolation of many new species, indicating that the habitat tolerance of dictyostelids is wider than previously suspected.

Lyophilized collections of type cultures are available at the American Type Culture Collection (ATCC – Rockville, Maryland, USA). The Dicty Stock Center (dictybase.org/StockCenter/StockCenter.html) also maintains frozen spores of almost all natural isolates. All species isolates from the first molecular survey of Dictyostelia (Schaap et al. 2006) are also available from the University of Dundee (p.schaap@dundee.ac.uk), while most of the species isolated from 2006 to 2016 are

available from Uppsala University (sandra.baldauf@ebc.uu.se). Kenneth Raper's original collection of dictyostelids is maintained at the University of Wisconsin (Madison) by M. Filutowicz (msfiluto@wisc.edu).

Literature

E. W. Olive (1902): "*Monograph of the Acrasieae*" is the first work that includes the dictyostelids as a group.

Bonner (1967): "*The Cellular Slime Molds*" includes an introduction to the group and detailed treatments of some of the best-known species. The book also includes information on other groups thought at the time to possibly be related to dictyostelids, such as labyrinthulids, plasmodiophorids, and acrasids (now placed within Stramenopila, Rhizaria, and Heterolobosea, respectively).

L. S. Olive (1975): "*The Mycetozoans*" is an excellent condensed introduction to mycetozoan morphology, ecology, and life history, including detailed descriptions of dictyostelids as well as myxogastrids and some protostelids (see ▶ Protosteloid Amoebae (Protosteliida, Protosporangiida, Cavosteliida, Schizoplasmodiida, Fractoviteliida, and Sporocarpic Members of Vannellida, Centramoebida, and Pellitida)). In addition to labyrinthulids and plasmodiophorids, the book also includes descriptions of acrasids (▶ Heterolobosea) and other sorocarpic taxa now recognized as non-amoebozoan such as *Fonticula alba* and *Guttulinopsis vulgaris* (Brown et al. 2012).

K. B. Raper (1984): "*The Dictyostelids*" is an in-depth overview and currently the most comprehensive single resource available on the group. It deals almost exclusively with the dictyostelids, including detailed descriptions of 50 species. There is also information on dictyostelid ecology, distribution and culture conditions, as well as dichotomous keys for the three "traditional genera." It also includes some discussion of the acrasid cellular slime molds, sensu L. S. Olive (1975).

H. Hagiwara (1989): "*The Taxonomic Study of Japanese Dictyostelid Cellular Slime Molds*" covers all Japanese species known at the time, many of which are missing from Raper's book. New morphological characters for identification are included, such as base and tip morphology, aggregation shape, and growth pattern.

R. H. Kessin (2001): "*Dictyostelium*: *Evolution*, *Cell Biology*, *and the Development of Multicellularity*" is a comprehensive book with a focus on cell and molecular biology of *D. discoideum*.

W. F. Loomis (2012): "*Dictyostelium*: *a developmental system*" is a collection of chapters by different authorities on the different development stages and their evolution, plus molecular techniques and genomics.

M. Romeralo et al. (2015):"*The Dictyostelids*" is the most recent collection of essays by leaders in the field.

History of Knowledge

The first persons to describe dictyostelids were a mycologist (Brefeld 1869) and a botanist (van Tieghem 1880). Although the unusual dictyostelid life cycle soon captured the interest of developmental biologists, it was not until the isolation of axenic strains of *D. discoideum* (Fig. 4b) that their potential as an experimental model began to be realized (Sussman and Sussman 1967). Brefeld described the first dictyostelid (*D. mucoroides*, Fig. 4a; Brefeld 1869) as well as the first polysphondylid (*Polysphondylium violaceum*, Fig. 4c; Brefeld 1884). It was also Brefeld who suggested the generic name *Dictyostelium*, which combines *Dictio-* (from gr. δίκτυον, net), used in botany to refer to something forming netlike structures, and *stelium* (tower), referring to the presence of a stalk formed by a network of cells. Brefeld thought that the aggregated amoebae fused to form a true plasmodium; however van Tieghem soon realized that the amoebae remain independent throughout the life cycle and denoted the aggregate as a pseudoplasmodium (van Tieghem 1880). His published accounts of acrasids and dictyostelids, which together he called Acrasiées, provided the criteria for their eventual taxonomic removal from the Myxomycetes because of the lack of a true plasmodium, although the acrasids are now removed from Amoebozoa altogether and placed in Heterolobosea (see below; Adl et al. 2012). van Tieghem's experiments with dictyostelids also led him to anticipate the role they would play in the field of developmental biology.

The phylogenetic position of Dictyostelia has been controversial for most of its scientific history, due to various similarities with fungi, plants, acrasids, and even animals (e.g., Loomis and Smith 1990). Traditionally, the group Dictyostelia was most often placed with fungi based on superficial similarities between their sorocarps and fungal fruiting bodies (e.g., Cappuccinelli and Ashworth 1977). However, E.W. Olive noted as early as 1902 that dictyostelids lack hyphae, and he placed them instead with acrasids (family Acrasidae; Olive 1902; ▶ Heterolobosea) using a name first proposed by van Tieghem (1880). L. S. Olive (1975) and Raper (1984) later suggested that acrasids were probably not closely related to Dictyostelia based on morphological and behavioral differences between their amoebae. Dictyostelids also differ from acrasids in their developmental cycle, including aligned streaming of amoebae and highly developed sorocarps with cellulosic stalks. Page and Blanton (1985) were the first to suggest splitting *Acrasis* and also *Pocheinia* from Dictyostelia and placing them instead in Heterolobosea. This was eventually confirmed by molecular phylogeny (Roger et al. 1996; Baldauf et al. 2000), and *Acrasis* (+ *Pocheinia*) and Dictyostelia are now recognized to be extremely distantly related, being members of Discoba and Amoebozoa, respectively (Adl et al. 2012).

Modern experimental study of Dictyostelia arguably began with the discovery of *D. discoideum* strain NC4 in forest soils of North Carolina (Raper 1935). It was Raper's subsequent slug-grafting experiments with this strain which demonstrated that the stalk and spores develop from the front and rear of the migrating

pseudoplasmodium, respectively, in this and related species, experiments that are considered classics in the field (Raper 1940). In another classic series of experiments, Bonner demonstrated the existence of a chemotactic agent responsible for cell aggregation, which he termed an "acrasin" (Bonner 1947). Subsequent identification of the *D. discoideum* acrasin as cyclic AMP (cAMP), also in Bonner's lab (Konijn et al. 1967), was the first demonstration of extracellular signaling by cAMP, an important intracellular signaling molecule across eukaryotes (e.g., Ravnskjaer et al. 2016). The role of cAMP as an acrasin was later found to be restricted to *D. discoideum* and its parent taxon (the redefined *Dictyostelium s.s.*; Fig. 3), while a variety of small molecules serve as acrasins in other Dictyostelia (e.g., glorin, folate, and pterin). Subsequent work showed that extracellular cAMP signaling also plays a central role in post-aggregative developmental signaling, a role that is probably universal among and ancestrally present in Dictyostelia (reviewed in Schaap 2016).

The sexual stage of *D. discoideum* was discovered in the early 1970s (Fig. 5; Clark et al. 1973; Erdos et al. 1973), before which it was thought that Dictyostelia were exclusively asexual and haploid. Although the existence of the macrocyst had been known for some time, its relationship to sexuality was not firmly established until later (Clark et al. 1973; Erdos et al. 1973). This began with the discovery that macrocyst formation in certain species depends upon mixing amoebae of opposite mating type. This lead eventually to the discovery that the macrocyst is a diploid resting phase (Fig. 5). However, work with macrocysts was still hampered by problems with germination and recovery of the zygote (Katz 1978; Newell

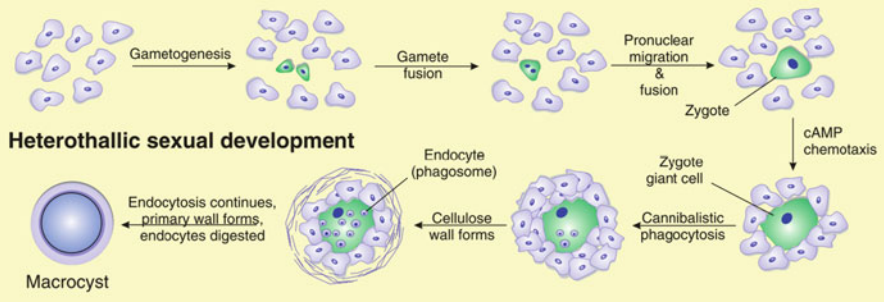

Fig. 5 Sexual development of heterothallic *D. discoideum* in mixed mating type (type I/type II) cultures. Small, motile gametes fuse to produce a binucleate cell that increases in size to become a binucleate giant cell. As growth continues, the pronuclei swell, migrate together, and fuse producing a true zygote giant cell (ZGC). Amoebae are chemically attracted to the ZGC, which begins to ingest and convert them to endocytes. Meanwhile, aggregate cells begin to build a multilayered, loose precyst sheath. Sexual phagocytosis continues until all of the amoebae are ingested as endocytes. The endocytes are gradually digested by the zygote as the macrocyst matures and the macrocyst wall is formed (O'Day and Keszei 2012) (Reproduced with permission of authors and journal)

1978b), until the development of temperature-sensitive mutants and the application of parasexual genetics (Kessin et al. 1974). Macrocysts occur throughout Dictyostelia (Fig. 3), indicating that a sexual phase formed by aggregating cells also evolved very early (Schaap et al. 2006; O'Day and Keszei 2012; Du et al. 2015).

Genetic studies in *D. discoideum* began with the selection of morphogenetic mutants by Sussman (1956). This research then accelerated with the creation by mutagenesis of the first axenically growing strain, AX2, making it possible to grow *D. discoideum* in the lab on simple defined growth media (Sussman and Sussman 1967). This facilitated the isolation of additional mutants to be used as genetic markers (Franke and Kessin 1977). *Dictyostelium discoideum* can now be transformed with foreign DNA (Escalante and Vicente 2000) and manipulated with a suite of sophisticated molecular tools and techniques (reviewed in Schaap 2011). Full genome sequences are also now available from representatives of all major phylogenetic groups (Fig. 3; Glöckner et al. 2016; Singh et al. 2016) as well as 20 separate clones of *D. discoideum* (Ostrowski et al. 2015) facilitating both macro- and microevolutionary studies.

Practical Importance

Dictyostelium discoideum is an important, widely used, and well-developed experimental model for the study of processes at the cellular level such as cell motility, chemotaxis, cytokinesis, and phagocytosis (Schaap 2011; Romeralo et al. 2013). At the multicellular level, it is also used to study, e.g., cell-cell communication (Newell 1978a), cellular differentiation, development, and competition (Maeda et al. 1997; Kessin 2001; Escalante and Vicente 2000; Strassmann et al. 2000; Loomis 2014; Romeralo et al. 2015). Dictyostelids have a number of important features that have contributed to their popularity for experimental study – they are easy to isolate and grow, are nonpathogenic, have a small genome, and readily complete their life cycle under laboratory conditions. This has been augmented by the development of molecular tools such as whole genome sequences, transcriptome profiles, genetic transformation, and targeted mutagenesis (Loomis 2013; Faix et al. 2013). With the development of a comprehensive phylogeny of Dictyostelia (Schaap et al. 2006; Romeralo et al. 2011; Sheikh et al. 2015), it is now also possible to study these phenomena within a robust evolutionary framework (Fig. 3)

Dictyostelium discoideum has a long history of use in medical research (reviewed in Romeralo et al. 2012). Comparative genomics of *Dictyostelium* and pathogenic Amoebozoa such as certain species of *Entamoeba* and *Acanthamoeba* allow the identification of amoebozoan-specific genes with potential applications in controlling amoebic diseases (Du et al. 2015). *Dictyostelium* is also used as a model for studying aspects of the mammalian immune response, as it displays basic similarities in traits such as lymphocyte motility and macrophage phagocytosis (Jin et al. 2009; Tatischeff 2013; Cosson and Lima 2014). It has also been used to study other disease processes, and *D. discoideum* is used as a model for a number of human disease-related proteins.

Habitats and Ecology

The primary habitat of dictyostelids appears to be the surface layers of forest soils and the soil litter. These substrates have yielded most of the ~150 known species, including such diverse types as *Coremiostelium polycephalum* (Fig. 4d), *Cavenderia bifurcatum* (Fig. 4e), *Heterostelium colligatum* (Fig. 4f), *Heterostelium arachnoides* (Fig. 4h), *Acytostelium magnuphorum* (Fig. 4i), *Acytostelium subglobosum* (Fig. 4j), and *Dictyostelium sphaerocephalum* (Fig. 4l). Although the common species *D. mucoroides* (Fig. 4a), *P. violaceum* (Fig. 4c), *Heterostelium pallidum* (Fig. 4g), and *Dictyostelium purpureum* (Fig. 4k) were first isolated from animal dung, these are now known to be widespread members of the soil microbial community (Romeralo et al. 2013). Other species isolated from dung include the much more rare *Dictyostelium aureum* (Olive 1902) as well as "*Dictyostelium roseum*" (van Tieghem 1880), one of a number of species that have only been isolated once and are only known by their description (Raper 1984). Otherwise, no dictyostelids are known to be strictly coprophilic. Perhaps the closest to this is *Speleostelium caveatum* (Raper 1984), which lives in the dung of cave-dwelling bats and preys on other dictyostelid amoebae (Waddell and Vogel 1985). This fascinating and highly molecularly distinct species (Schaap et al. 2006; Romeralo et al. 2011), which can disrupt the developmental cycle of other dictyostelids (Waddell and Vogel 1985; Nizak et al. 2007), has also never been re-isolated. Some dictyostelids have also been isolated from decaying plants and fungi, such as *Tieghemostelium lacteum*, first isolated from a decaying mushroom (van Tieghem 1880), and L. S. Olive frequently isolated species from rotting wood (Olive 1975). Recent explorations of new habitats have also yielded new species such as *Dictyostelium ammophilum* isolated near the Great Kobuk Sand Dunes at the Kobuk Valley National Park, Alaska, USA (Romeralo et al. 2010).

Geographically, dictyostelids are distributed worldwide, from Alaska (Romeralo et al. 2010) and northern Sweden (Perrigo et al. 2013) to the tropics (Cavender 1973; Vadell 1993; Cavender et al. 2016). In general, diversity appears to increase toward the equator and lower altitudes (Cavender 1973; Hagiwara 1984; Swanson et al. 1999) and, as in many groups of plants and animals, appears to be highest in the tropics (Cavender 1978; Kawabe 1980). However, there are species that appear to be endemic to temperate (Cavender 1978; Hagiwara 1982) as well as subalpine zones (Traub et al. 1981). The neotropical region in particular seems to be a center of diversification (Vadell and Cavender 2007). The most widely encountered species are *D. sphaerocephalum* (Fig. 4l) and *D. mucoroides* (Cavender 1983) (Fig. 4a) followed by *P. violaceum* (Fig. 4c) and *He. pallidum* (Fig. 4g), although the latter is now known to be a species complex (Fig. 9; Romeralo et al. 2011). Species such as *D. discoideum*, *D. purpureum*, and *Raperostelium minutum* are more restricted in distribution, while the crampon or basally digitate species (*Hagiwaraea* spp.) are some of the most restricted.

The first studies on the ecology of dictyostelids were conducted by Raper (1939), who grew *D. discoideum* with different bacteria as food. Later, Singh (1947a, b) studied the influence of humidity on dictyostelid growth. Dictyostelids inhabit soils

over a wide spectrum of moisture regimes, although amoebal density is greatest at intermediate moisture levels (Cavender and Raper 1965b) and decreases with decreasing moisture (Rollins et al. 2010). Overall the abundance of dictyostelid amoebae can be quite high, ranging from hundreds to thousands per gram of soil (Cavender and Raper 1965b).

Forest soils, preferably slightly acidic ones, are the best habitat for dictyostelids, in terms of numbers of amoebae recovered and species diversity (Cavender and Raper 1965b; Landolt et al. 2006). However, some species are also tolerant of alkaline or neutral conditions, and a few, such as *D. mucoroides* (Fig. 4a), are tolerant of a wide range of pH. The numbers of dictyostelid spores and amoebae also decrease progressively with soil depth. Early studies indicated optimal growth temperatures of 20–25 °C, with considerable overlap among species (Raper 1984). However, species isolated from higher latitudes prefer lower temperatures (Romeralo et al. 2010). In temperate zones, there are also seasonal fluctuations with spring and fall peaks in spore and amoebal numbers (Cavender and Raper 1965b; Frischnecht-Tobler et al. 1979). A relationship has been demonstrated between vascular plants and dictyostelid species, such that different dictyostelids seem to preferably associate with certain plant species (Cavender and Raper 1965b, 1968; Cavender and Kawabe 1989). Most dictyostelids also appear to be phototactic during the slug and rising sorogen stage of the life cycle (Fig. 1; Raper 1984; Bonner 2006), possibly to aid the aggregate in finding an exposed microsite to erect the sorocarp and thus increase its dispersal opportunities.

Escherichia coli and *Klebsiella pneumoniae* (or *K. aerogenes*) are the preferred laboratory food sources for all examined species. Experiments conducted in the field (Kuserk 1980) suggest that food plays a prominent role in shaping the local diversity of dictyostelids. There is also some evidence of bacterial prey preference in the wild (Singh 1947a; Depraitere and Darmon 1978; Nasser et al. 2013), and it has been shown recently that *D. discoideum* spores can cotransport selected bacterial prey (Brock et al. 2011). Response of the larger species to light and differential temperatures (Raper 1940; Bonner et al. 1950; Kessin 2001), humidity (Bonner and Shaw 1957), gases (Bonner and Dodd 1962; Bonner and Lamont 2005), and solutes (Slifkin and Bonner 1952) is quite dramatic during migration and development, indicating great environmental sensitivity. Smaller species may be even more sensitive to some of these factors since they are more difficult to culture, for example, *Rostrostelium ellipticum*, *Tieghemostelium menorah*, *Cavenderia stellatum* (Fig. 10c), and *Heterostelium oculare* (Fig. 10g). The use of these organisms as monitors of the soil environment (e.g., Vadell 2004) could potentially rival their popularity as tools for developmental biology.

To summarize, species diversity and composition change with forest type (Cavender and Raper 1965c), soil moisture gradient (Sutherland and Raper 1978), vegetational diversity (Hagiwara 1976), altitude (Hagiwara 1976; Cavender 1983; Romeralo and Lado 2006), and latitude (Cavender 1973). Optimal conditions for dictyostelid development are moderate temperature, high soil oxygen, medium humidity, and sufficient bacteria (Cavender and Raper 1968; Raper 1984). However, there are reasons to suspect that the diversity of Dictyostelia is still largely unknown.

Sampling efforts have mostly used a narrow set of culture conditions that tend to favor larger, faster-growing species. Meanwhile more recent studies that focused on tiny and/or slower-growing species have identified many new ones (Fig. 10; Cavender and Vadell 2000; Cavender et al. 2013). Dictyostelia is also ancient (>600 mya; Fiz-Palacios et al. 2013) and of extreme molecular depth (Schaap et al. 2006) despite the small number of described species. Although dictyostelids are largely absent from culture-independent (metagenetic) surveys, this is probably due to the strong AT bias and generally divergent nature of their rRNAs (Romeralo et al. 2011). In fact, preliminary metagenetic sampling with Dictyostelia-specific rRNA primers suggests hidden diversity at all taxon levels (SLB, ms in prep).

Kin Recognition and Cheating

How Dictyostelia interact with each other and other organisms in the soil is only beginning to be understood, mostly based on studies in *D. discoideum*. Dictyostelids recognize kin using two membrane proteins with highly polymorphic extracellular domains, TgrB1 and TgrC1 (see below), which also help induce competence for post-aggregative cell differentiation (Hirose et al. 2011). The fact that dictyostelid spores are dispersed as a unit should increase the likelihood that nearby amoebae will be clonal and thus produce clonal fruiting bodies. However, genetically distinct clones of *D. discoideum* have been shown to co-occur in nature (Fortunato et al. 2003a) and to give rise to a small proportion of mixed-clonal fruiting bodies (Gilbert et al. 2007). Genetically distinct clones can also form fruiting bodies together in the lab. Moreover, in some of these cases, certain clones may be overrepresented in spore compared to stalk, a phenomenon known as cheating (Strassmann et al. 2000). Cheating appears to be due to a combination of preset clonal characters (fixed cheating) and inter-clonal interactions (facultative cheating) (Buttery et al. 2009), the contributions of which vary along a linear gradient (Fortunato et al. 2003b).

Cheating appears to have costs and benefits. Chimeric slugs move less distance toward light than clonal slugs (Foster et al. 2002). However larger slugs also move farther than smaller ones, and joining with others may sometimes be the only way to become large (Foster et al. 2002). This advantage of forming a larger slug may extend to joining with amoebae from a different species entirely, e.g., between the distantly related *D. purpureum* and *D. discoideum* (Fig. 9). Interestingly, in the latter case, the resulting fruiting bodies take on the form of one or the other species rather than being intermediate (Jack et al. 2008). Although each clone contributes some cells to each type, there are predictors as to which clone is likely to prevail in contributing more to spore than stalk. In general, stronger amoebae are more likely to become spores, whether they are stronger because they did not divide recently or because they were fed on a high-sugar diet (Castillo et al. 2011; Gomer and Firtel 1987; Thompson and Kay 2000). The cells that initiate the aggregation are also more likely to end up as spores (Huang et al. 1997; Kuzdzal-Fick et al. 2010). It also appears that not all cells participate in aggregation. These "loner" cells may represent

a form of "bet-hedging," able to take advantage of an improved environment in situ (Dubravcic et al. 2014; Tarnita et al. 2015; Wolf et al. 2015).

Some evidence that cheating, and protection from it, are important aspects of dictyostelid evolution comes from experimental evolution. A single clone passaged through 30 generations in the lab resulted in many lines of cheaters, some of which could not even form fruiting bodies on their own (obligate social parasites; Kuzdzal-Fick et al. 2011). Meanwhile, non-obligate social parasites from the same evolved population were less vulnerable to these cheaters than were naïve clones, indicating that they were evolving resistance to cheating (Levin et al. 2015). Mutation accumulation experiments, where each new generation is initiated with a randomly selected clone, show reduced cheating. This suggests that there is selective pressure to maintain competitive behavior (Hall et al. 2013).

Dictyostelids distinguish kin from non-kin using the tiger genes, *tgrB1* and *tgrC1* (Benabentos et al. 2009; Hirose et al. 2011; Ho et al. 2013). Clones with different *tgrB1*and/or *tgrC1* alleles show clear signs of sorting early in the developmental cycle (Ostrowski et al. 2015). However, sorting is not complete, possibly because mixed tiger genes are a useful marker of chimerism and promote competition within the slug. Kin selection appears to be stronger in *D. purpureum* than in *D. discoideum*, showing that it varies among species (Mehdiabadi et al. 2009; Mehdiabadi et al. 2006). Environmental structure and local growth patterns can also cause much sorting even before the recognition genes would come into play (Buttery et al. 2012; Gilbert et al. 2012; Smith et al. 2014). *Dictyostelium discoideum* also shows molecular evolutionary signatures of social selection. Single gene knockout experiments identify over a hundred genes that cause cheating when knocked out (Santorelli et al. 2008). Social genes also show molecular signatures of frequency-dependent selection, suggesting that rare types are prevailing over more common ones (Ostrowski et al. 2015).

Farming may also influence interactions among clones in Dictyostelia. Some *D. discoideum* clones have enduring symbioses with *Burkholderia* bacteria (Fig. 6), and dictyostelid spores may carry food bacteria, which they release after spore dispersal to generate new food populations (Brock et al. 2011; DiSalvo et al. 2015). Moreover, this appears to be a complex interaction apparently driven by a third non-prey bacterial partner, which is also a *Burkholderia* sp. (Fig. 6; DiSalvo et al. 2015). Thus, the non-prey carried bacteria may perform a protective function, being harmful to other dictyostelid clones without harming their host (Brock et al. 2013; Stallforth et al. 2013). There is also evidence of coevolution between the symbiont bacteria and *D. discoideum* (Brock et al. 2015).

Characterization and Recognition

Taxonomy

Dictyostelid amoebae are essentially indistinguishable among species, and therefore dictyostelid taxonomy is based on aggregation patterns and sorocarp morphology, now augmented with molecular phylogeny. One of the main distinguishing traits is

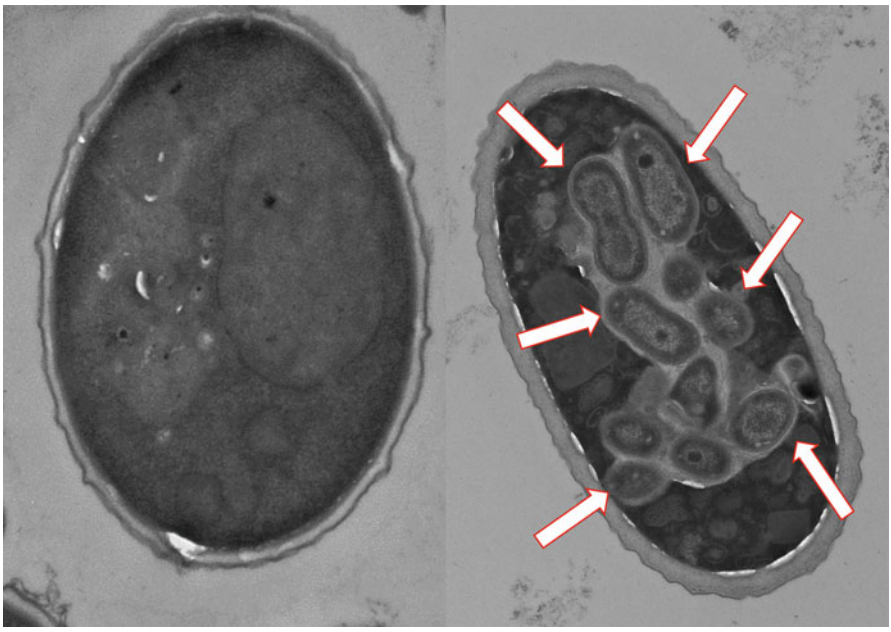

Fig. 6 Micrographs of spores from nonfarmer (*left*) and farmer (*right*) strains of *D. discoideum*. The farmer strain carries bacteria belonging to *Burkholderia* clade 2 (DiSalvo et al. 2015). *Arrows* indicate individual bacterial cells (Micrographs courtesy of Longfei Shu)

the presence (dictyostelids and polysphondylids; Fig. 7b, c) or absence (acytostelids; Fig. 7d) of a cellular stalk. Species with larger sorocarps may also have additional support structures such as a basal disc (e.g., *D. discoideum*; *Cavenderia mexicanum*; *Dictyostelium gargantuum*; Fig. 7e) or a crampon or holdfast base (e.g., *Hagiwaraea* spp.; Fig. 7f). Aggregation characters include acrasin identity, aggregation pattern (presence/absence/degree of streaming; Fig. 7g), the presence/absence of a migration stage (sorogen; Fig. 7h, i), the presence/absence of a stalk during migration (Fig. 7h, i), and patterns of early development (Fig.7j–l). Sorocarps vary in their general habits, such as the presence/absence/degree of clustering (Fig. 8a–d), and in specific sorocarp morphology, such as the presence/absence/degree and pattern of branching (Fig. 8e–i). At least eight acrasins have been identified so far (see above for examples), and acrasin identity remains unknown for most species (Bonner 1983; Schaap et al. 2006).

Spore characters used for identification include size, shape, and the presence/absence/organization of starch granules. Most species have elliptical spores (Fig. 8j, k), but all acytostelids except *Ro. ellipticum* have spherical spores (Fig. 8l, m), as do some dictyostelids (e.g., *Dictyostelium rosarium* and *T. lacteum*). Spore sizes can be as small as 1.5–2.0 × 3.5–5.0 μm but are most commonly in the range of 2.5–3.5 × 6.5–8.0 μm. However, spore size can change with cell ploidy – e.g. – *D. discoideum* spores are in the common size range when haploid but 3.0–4.0 × 10–13 μm

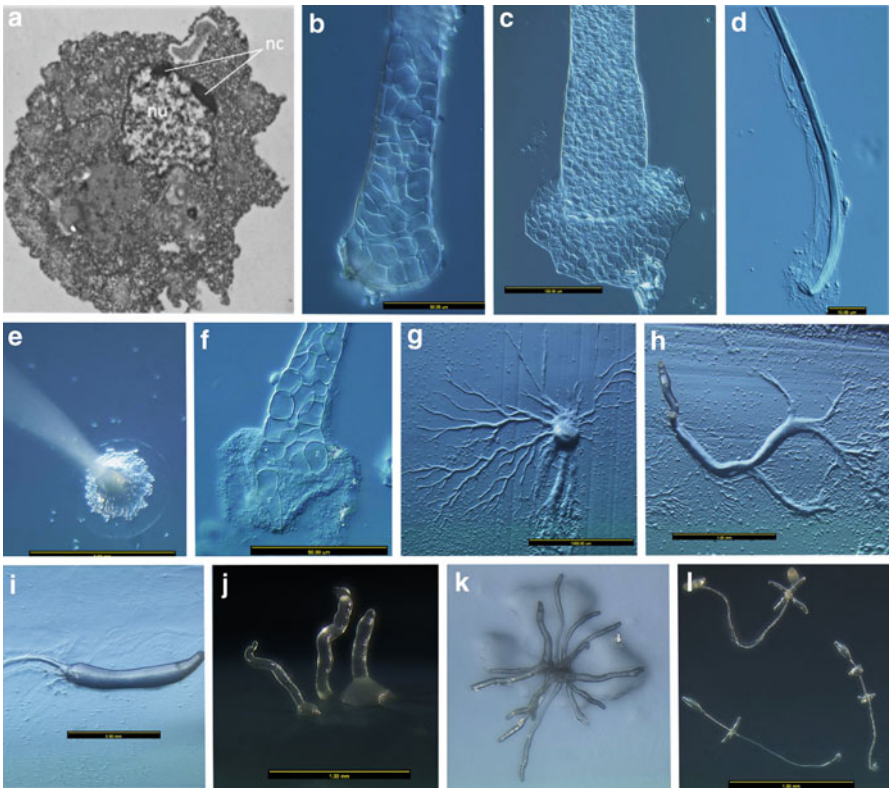

Fig. 7 Transmission electron microscopy (**a**) and light micrographic (**b**–**l**) images of (**a**) dictyostelid amoeba with prominent nucleus (nu) and lobed nucleolus (nc); sorocarp stalk types, (**b**–**c**) cellular (*D. purpureum*, *D. discoideum*), (**d**) acellular (*A. irregulosporum*); sorocarp support structures, (**e**) basal disc (*D. discoideum*), (**f**) crampon base (*Hagiwaraea vinaceofuscum*); aggregation patterns, (**g**) streaming (*D. discoideum*); cell migration behavior, (**h**) stalked (*Dictyostelium implicatum*), (**i**) stalkless (*D. discoideum*); and early sorocarp development, (**j**) Ca. *aureostipes*, (**k**) *Cavenderia multistipes*, (**l**) *He. pallidum* (Photographs courtesy of Longfei Shu (a) and Andrew Swanson and Frederick Speigel (b–l))

when diploid (Sussman and Sussman 1962). Spores can contain starch granules that may be concentrated in their polar regions. Polar spore granules can be either loosely distributed (unconsolidated; Fig. 8j) or compact (consolidated; Fig. 8k) (Traub and Hohl 1976; Hagiwara 1989).

Traditional classification of Dictyostelia recognized three morphologies, previously given the rank of genera (Fig. 2), although these are now recognized as non-monophyletic morphotypes (Fig. 3). Acytostelid types (*Acytostelium* spp. and *Ro. ellipticum*; Fig. 3, Fig. 4i, j, Table 1) produce an acellular stalk tube (Fig. 7d), and therefore all cells in the aggregate survive to form spores. In contrast, dictyostelid and polysphondylid morphotypes have differentiated stalk and spore cells, so that a substantial number of cells in the initial aggregate (~20% in *D. discoideum*; Raper

1984) are sacrificed to build the cellular stalk (Fig. 7b, c). Polysphondylid sorocarps (*Polysphondylium* spp. and many *Heterostelium* spp.; Fig. 3, Table 1.) are characterized by whorls of regularly spaced side branches (Figs. 4c, f–h, 7l, and 8h, i), while all other species with cellular stalks are considered to have dictyostelid-type morphologies (some or all members of all genera except *Acytostelium*; Table 1). Dictyostelid-type sorocarps may be unbranched (e.g., Figs. 4a, b, l, and 8e), irregularly branched (e.g., Fig. 8f, g), and/or consist of clusters of sori that may be gregarious (Fig. 8a, b), loosely clustered (Fig. 8c), or tightly clustered (coremiform; Figs. 4d and 8d).

Molecular phylogenetic analyses based on 18S rRNA and α-tubulin (Schaap et al. 2006) and 18S + ITS rRNA (Romeralo et al. 2011) were the first data to thoroughly reject the traditional classification system. These data divide Dictyostelia into eight distinct divisions, none of which correspond to the three traditional genera, and the taxonomy of the group is currently being revised to accommodate the new

phylogeny (Fig. 3, Table 1). Recent molecular analyses utilizing partial (Romeralo et al. 2013; Singh et al. 2016) and whole (Sheikh et al. 2015) genome data further divide Dictyostelia into two higher-order taxa. The new classification system elevates the two major divisions to the level of order, with the names Acytosteliales and Dictyosteliales, which correspond to, respectively, the molecular groups 1 + 2 and 3 + 4, the latter including also the violaceum and polycephalum complexes (Fig. 3). The major molecular groups are outlined below using the new taxonomy.

Cavenderiaceae (molecular Group 1) consists of a diverse set of dictyostelid morphotypes that are currently assigned to a single genus, *Cavenderia* (Figs. 9 and 10a–c). These species produce sorocarps that vary considerably in size and morphology, ranging from solitary to clustered, with or without side branches. However, the majority of Cavenderiaceae tend to have small sorocarps with irregularly spaced side branches (Romeralo et al. 2011). Although there are still a relatively small number of described species, they are widely distributed including species isolated from Antarctica, Mexico, and Thailand. These species were originally noted as having smaller spores than the other major taxa (Schaap et al. 2006), but two recent isolates, *Cavenderia boomeransporum* (Fig. 10a) and *Cavenderia myxobasis*, have some of the largest spores yet seen in Dictyostelia (Romeralo et al. 2011).

Acytosteliaceae (molecular Group 2) is the most morphologically diverse, including examples of all three morphotypes (Schaap et al. 2006). The family currently consists of three genera, *Acytostelium*, *Heterostelium*, and *Rostrostelium*. *Acytostelium* (molecular Group 2A; Figs. 9 and 10d–f) includes nearly all known acytostelid morphotypes. Thus, *Acytostelium* is the most homogeneous division of Dictyostelia, consisting entirely of small delicate species that do not differentiate stalk cells. In contrast, *Heterostelium* is extremely diverse and includes a mixture of dictyostelid and polysphondylid morphotypes (Figs. 9 and 10g–j). The deepest branches of the group are two molecularly very distinct dictyostelids, *He. oculare* (Fig. 10g) and *Heterostelium boreale*. These are then sister lineages to a dense cluster including all small, unpigmented polysphondylids (Figs. 4f–h, 8h, l, and 10h, i) and a further cluster of small, pale dictyostelids (Fig. 10j). The third genus of Acytosteliaceae is *Rostrostelium*, which consists of a single species, *Ro. ellipticum* (formerly *Acytostelium ellipticum*). Molecular sequences from this isolate place it either as the sister group to *Heterostelium* (Schaap et al. 2006) or the sister group to *Heterostelium* + *Acytostelium* (Singh et al. 2016), but never with the other acytostelid types (*Acytostelium* spp.). Thus, sorocarp morphology is especially plastic in Acytosteliaceae, including gain and loss of regular branching and probably also loss and gain of cellular differentiation.

Raperosteliaceae (molecular Group 3; Fig. 9) includes *Raperostelium*, *Hagiwaraea*, *Speleostelium*, and *Tieghemostelium*. This is morphologically a relatively conservative collection of species, as all assigned taxa have dictyostelid-type morphology. That is, all Raperosteliaceae have sorocarps with differentiated cell types and side branches that are either irregularly arranged or absent (Fig. 10k–m). Nonetheless, taxa vary greatly in size, ranging from species with very small sorocarps, such as *Ra. minutum*, to a distinct cluster of species with relatively

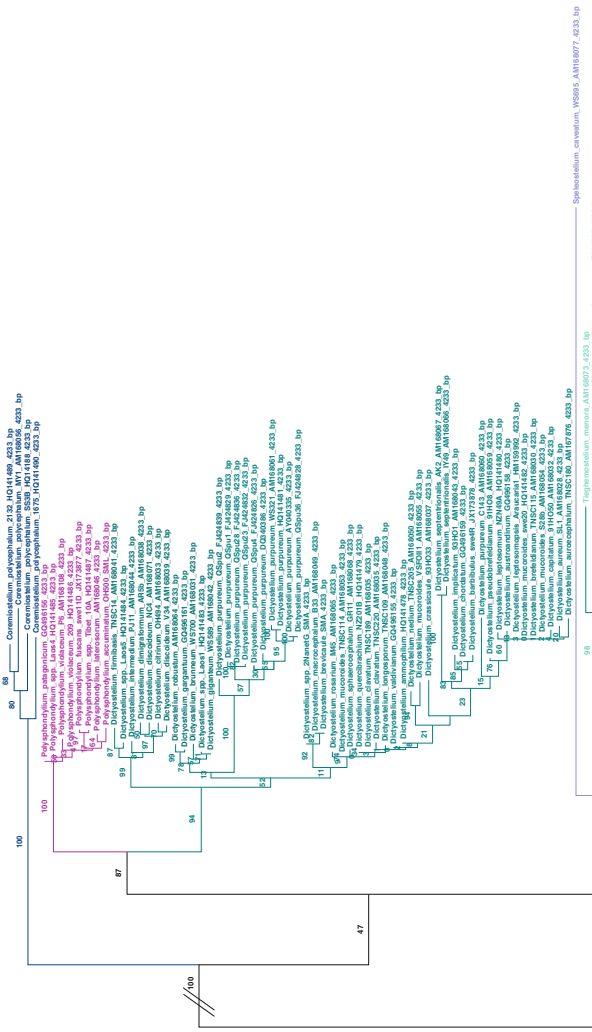

Fig. 9 (continued)

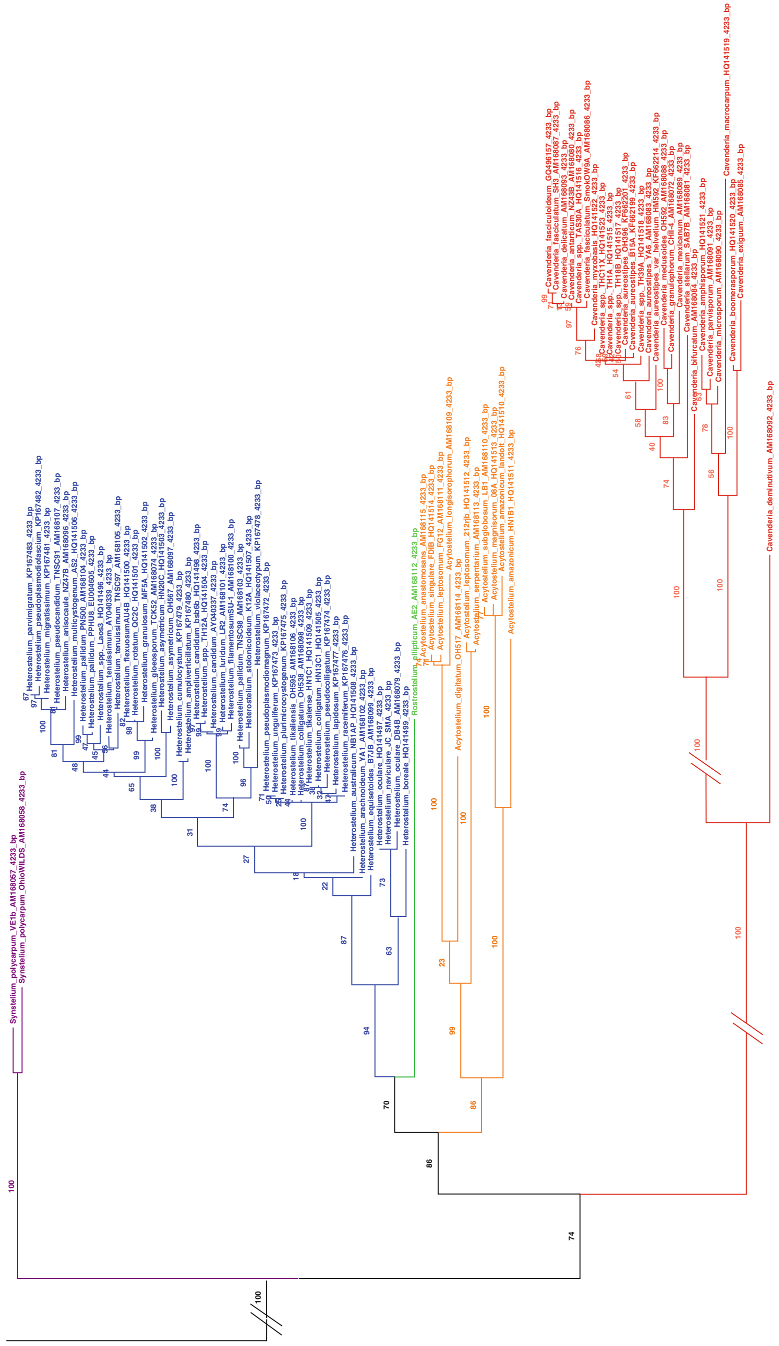

Fig. 9 (continued)

large sorocarps, the *Hagiwaraea* (molecular Group 3B). The latter are especially distinctive in having crampon-like bases to their sorocarps, which likely help to support these relatively large structures (Figs. 7f and 10m). One of the most intriguing members of Raperosteliaceae is *Sp. caveatum* (formerly *Dictyostelium caveatum*; Fig. 9). This is the only dictyostelid known to prey on the amoebae of other species (see above).

Dictyosteliaceae (*Dictyostelium*, *Polysphondylium*, and *Synstelium*) is again morphologically diverse, particularly the redefined *Polysphondylium* (Fig. 3), which includes both dictyostelid and polysphondylid morphotypes. However, unlike the polysphondylid types in *Heterostelium* (Acytosteliaceae; see above), which tend to be delicate and unpigmented, species in *Polysphondylium* tend to have large robust sorocarps with lavender-violet pigmented sori (Figs. 4c and 10q). In fact, the one described dictyostelid morphotype in this group (now, *Polysphondylium laterosorum*) also has lavender-pigmented sori. Meanwhile, *Dictyostelium* (molecular Group 4, Fig. 9) consists purely of dictyostelid morphotypes, including the type species of Dictyostelia, *D. mucoroides* (Fig. 4a), and the model organism *D. discoideum* (Fig. 4b). This is the most speciose genus of Dictyostelia and includes many of the more frequently encountered species (Fig. 10n–p). Isolates of *Dictyostelium* tend to have large aggregates, stalkless migration, and robust sorocarps, often with a single large sorus. However, more recent isolates include species with clustered or coremiform sorocarps, e.g., *Dictyostelium austroandinum* (Fig. 10n) and *Dictyostelium valdivianum* (Fig. 10p). A number of these new species also have polar granules in their spores, a feature previously thought to be universally absent from the group (Schaap et al. 2006). *Dictyostelium s.s.* also appear to be the only Dictyostelia that use cAMP as both a developmental signaling molecular and an acrasin.

Dictyostelia also includes two molecularly very distinct dictyostelid morphotypes whose phylogenetic affinities have been difficult to resolve. *Coremiostelium* (formerly the polycephalum complex; Fig. 3, Table 1) consists of four isolates that are morphologically almost indistinguishable but show as much molecular distance among them as almost any two species in the whole of *Dictyostelium* (Romeralo et al. 2011). Similarly, *Synstelium* (formerly the polycarpum complex; Fig. 3, Table 1) consists of two morphologically similar isolates, with a large molecular distance between them (Schaap et al. 2006; Romeralo et al. 2011). Recently multigene phylogenies place *Coremiostelium* as the first major branch of Dictyosteliales and *Synstelium* as sister to *Heterostelium* + *Rostrostelium* (Singh et al. 2016), although these results still rely on a small number of sequences and conflict with alpha-tubulin and 18S rRNA phylogeny (Schaap et al. 2006).

Fig. 9 A comprehensive phylogeny of Dictyostelia based on 18S rRNA. The tree shown was derived by maximum likelihood analysis of 4233 universally aligned 18S rRNA sequence positions using RAxML (version 7.2.8, GTRGAMMA substitution model) and 1000 bootstrap replicates. Only bootstrap values above 50% are shown. Taxon names are followed by their 18S rRNA GenBank accession number. Colours are used to indicate the different genera (Sheikh et al. in press)

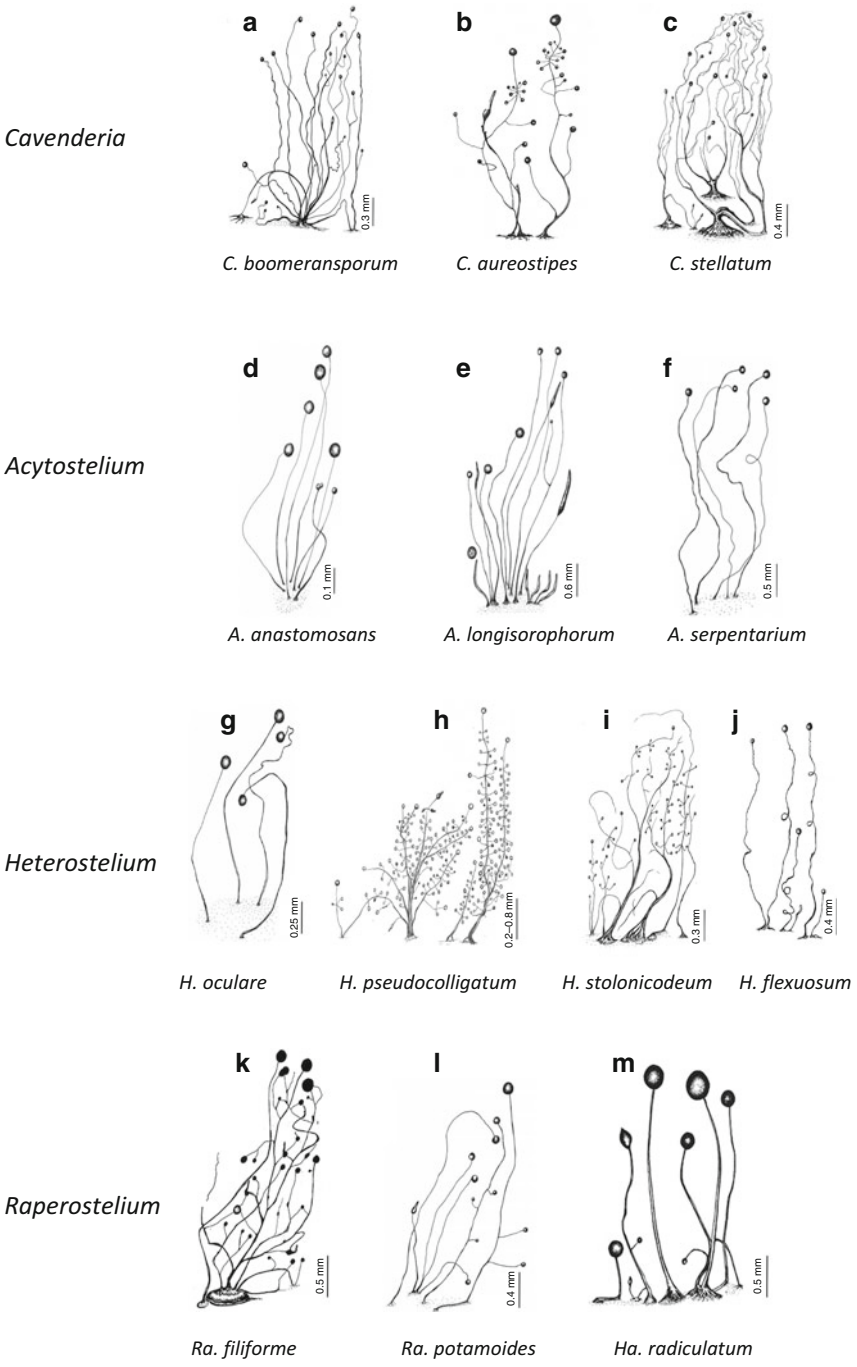

Fig. 10 (continued)

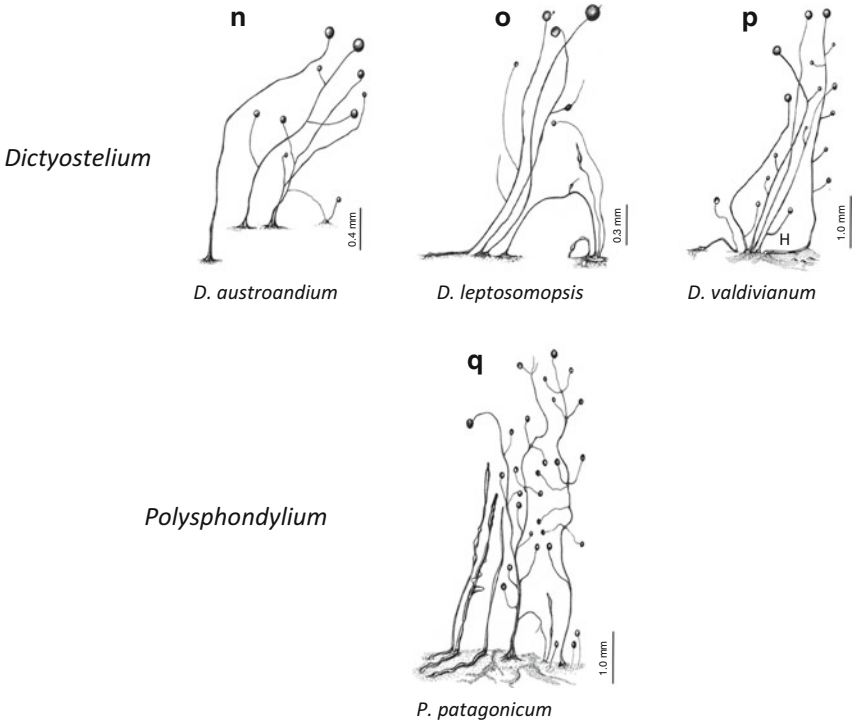

Fig. 10 Examples of recently described species from all major groups within Dictyostelia. Illustrations are reproduced with permission from Cavender et al. (2005) (**c**–**g**, **l**), Vadell et al. (2011) (**n**–**q**), Cavender et al. (2013) (**k**), Landolt et al. (2008) (**a**, **i**–**j**, **m**), Cavender et al. (2016) (**h**), and courtesy of E. Vadell (**b**) (Figure courtesy of S. Sheikh and D. Baldauf)

A reexamination of morphological data in light of molecular phylogeny shows that most of the characters that form the basis of traditional dictyostelid classification are phylogenetically unreliable (Schaap et al. 2006; Romeralo et al. 2011). Among the more broadly consistent characters are spore traits. *Cavenderia* and *Heterostelium* species tend to have oblong spores with tightly grouped (consolidated) polar granules (Fig. 8k), while the spore granules of Raperosteliaceae are loosely grouped (unconsolidated), and polar granules appear to be mostly absent in Dictyosteliaceae (Fig. 8j; Schaap 2007; but see Romeralo et al. 2011). Species in Acytosteliales and Raperosteliaceae often display a clustered or gregarious sorocarp habit, a character that is found dispersed throughout these groups. Meanwhile *Dictyostelium* species mainly form large solitary fruiting bodies, and branched forms are rare. However, sorocarp morphology also appears to be quite plastic, as the incidence of cryptic species seems to be very high (Mehdiabadi et al. 2009; Romeralo et al. 2011).

Recent attempts to isolate new species suggest that there are many Dictyostelia remaining to be discovered using standard isolation techniques alone. In fact, in the

last 10 years, the number of described species has almost doubled, all initially based on morphological characterization and confirmed by molecular phylogeny (Fig. 10). For example, 15 new species were recently isolated from samples collected at one of the most widely studied locations, the Smoky Mountains National Park in North Carolina, USA (Cavender et al. 2005). These include five new acytostelids (e.g., Fig. 10d–f) and ten new dictyostelids (e.g., Fig. 10c, 10g, 10l). Numerous species have been isolated from richly sampled locations such as Tikal National Park in Guatemala (35 new species; Vadell 1993). More recent expeditions to new locales have yielded many new species, such as the Iguazu region of Argentina (11 new dictyostelids, e.g., Fig. 10o, 10p; 3 new polysphondylids, e.g., Fig. 10q; Vadell and Cavender 2007; Vadell et al. 2011), the seasonal rain forests of Central America (ten new dictyostelids, e.g., Fig. 10k; Cavender et al. 2013), and three scattered locations in Australia (three new polysphondylids, six new dictyostelids, e.g., Fig. 10a, 10m; Romeralo et al. 2011). Much of this increased sampling has been supported by the Planetary Biodiversity Inventory (PBI) of Mycetozoa (National Science Foundation, USA; slimemold.uark.edu).

Life Cycle, Ultrastructure, and Genome

Life Cycle Detailed descriptions of the life cycle, development, and ultrastructure of *D. discoideum* are given in Olive (1975), Raper (1984), Kessin (2001), Schaap (2011), and Loomis (2012). Therefore, only minimal descriptions are given here (Fig. 1). The amoebae of *D. discoideum* and most other species emerge upon germination of the spores through a longitudinal split in the spore wall. The amoebae actively pursue their bacteria prey using short filose-like pseudopodia. Upon food depletion or under various other unfavorable environment conditions, amoebae respond by forming microcysts, macrocysts, or fruiting bodies (sorocarps; Fig. 1). Microcysts are a highly resilient resting stage, consisting of a dormant amoeba surrounded by a double-layered cell wall (Khan 2006). These structures differ considerably from dictyostelid spores, which have a three-layered cell wall and more condensed cytoplasm (Hohl et al. 1970; Kawabe et al. 2009), and macrocysts, which are highly resistant with a five-layered cell wall (Fig. 5; O'Day and Keszei 2012). Macrocyst formation represents the sexual cycle in Dictyostelia and leads to the formation of a diploid zygote that attracts and preys upon other haploid cells (O'Day and Keszei 2012). Sorocarp formation transforms free-living amoebae into what, in all but acytostelids, is arguably a true multicellular structure with distinct tissues, differentiated cell types, and a kind of programmed cell death (not homologous to apoptosis).

It is not fully understood how amoebae decide whether to form microcysts, macrocysts, or sorocarps. However, quorum sensing, the ability to detect the density and ratio of surrounding amoebae and prey (bacterial) cells, appears to be important (Du et al. 2015). Essentially, under conditions of low prey density, amoebae will aggregate if they sense the presence of sufficient numbers of fellow amoebae; otherwise they will encyst (Du et al. 2015). Factors affecting macrocyst formation

are more elusive (Raper 1984), and many species cannot be induced to form macrocysts in the lab. However, many species are also only available as a single isolate and may thus be clonal and lack complementary mating types (Schaap et al. 2006). However, in general, there seems to be a requirement for cool, moist conditions, and probably also food shortage and high amoebal density (O'Day and Keszei 2012).

Sorocarp Formation The sorocarpic cell cycle of *D. discoideum* in the lab takes about 72 h from spore to spore at an optimum growth temperature of 22–25 °C. Since there is no food ingestion once sorocarp development begins, the spore and stalk walls and slime sheath are composed largely of cellulose, thought to be derived by amino acid conversion (Freeze and Loomis 1977). However, EM data suggest that cells are full of glycogen early in fruiting, so the direct source of glucose for cellulose formation may in fact be glycogen (F Spiegel, pers. comm.). Lack of food induces amoebae to begin preparation for aggregation by synthesizing acrasins and the receptor proteins that enable them to respond to acrasin and other external chemical factors. The amoebae also synthesize species-specific cell adhesion proteins, particularly TgrB1 and TgrC1, whose polymorphic extracellular domains aid the amoebae in identifying close relatives (Strassmann and Queller 2011; Du et al. 2015). At the same time, ammonia and certain other environmental factors can halt or even reverse development and induce amoebae of some species to form microcysts instead (Lonski 1976). For this reason, some dictyostelids can be encouraged to fruit in the lab by placing small amounts of activated charcoal in the culture dish.

Aggregation is initiated in *D. discoideum* by a sharp increase in cyclic AMP (cAMP) production, called an acrasin pulse. The pulse, which is repetitive (every 6 min in laboratory conditions), produces directional pseudopodial responses in starving, receptive cells, whose receptor sites are concentrated at one end (polarised) (Swanson and Taylor 1982). Subsequent cell movement occurs along the acrasin gradient. Responding cells degrade the incoming acrasin and then release an acrasin pulse of their own. Thus, pulses occur periodically (Durston 1974), each followed by a refractory period during which background cAMP is cleared by phosphodiesterase (Gerisch and Hess 1974). This gives rise to waves of signal propagating outward from the aggregation center. As cells begin to contact each other, they adhere and form streams, creating aggregation patterns that vary among species. As the cells gather into a mound, the tip of the mound takes on the role of an organizing center, continuing to secrete pulses of acrasin and also cAMP (or additional cAMP if this is also the acrasin). This causes the cells within the mound to begin differentiating into prespore and prestalk cells (Schaap 2011).

As amoebae stream into the mound, the tip is forced upward until the whole pseudoplasmodial mass falls over and becomes a slug. The slug is a polarized multicellular unit with a specialized ("head") region capable of detecting signal and directing migration of the slug toward differences in temperature, relative humidity, solute concentration, and light. The slug moves as a unit by means of a coordinated helical motion of the individual cells inside a slime sheath (Clark and Steck 1979). It is organized from the tip (Rubin and Robertson 1975), which

continues to emit pulses of cAMP. Waves of cell contraction and elongation appear to proceed from tip to rear at regular intervals. The cells of the *D. discoideum* slug are partially differentiated (Bonner 1952), with the anterior approximately 20% (Bonner and Slifkin 1949) destined to become stalk cells and the remaining posterior cells to become spores, except for the rearguard cells, which form the disc (Raper 1940). It should be noted that many species lack a migratory phase, in which case the sorocarp arises directly from the mounded aggregate.

In some migrating species, the sorocarp stalk is secreted continuously during migration, while in others, such as *D. discoideum*, stalk formation only begins after migration stops. In the latter case, the prestalk cells begin by secreting a stalk tube that is brought to the agar surface by flattening of the slug ("Mexican hat" stage, Fig. 1; Raper and Fennell 1952). As the stalk tube forms, prestalk cells migrate down into the tube in an inverted fountain movement. Once inside the tube, these cells vacuolate, construct cellulose walls, and die. The rearguard cells of the slug, which form the basal disc, also vacuolate and die. The prespore cells then move up the growing stalk where they eventually differentiate into spores encompassed by slime (Fig. 1). Construction of the *D. discoideum* sorocarp takes about 8 h in the lab.

Dictyostelid sorocarps do not dry out and release individual spores for wind dispersal, as in ▶ Myxomycetes but rather stay together as a unit so that the spores are dispersed en masse. Thus, dictyostelid spores are probably not transported long distances by wind. Instead, sorocarps tend to be transported by water or animals such as insects, rodents, amphibians, bats, birds (Suthers 1985; Stephenson and Landolt 1992), and even large mammals (Perrigo et al. 2012). This is presumably aided by having small erect fruiting bodies (Loomis 2012; Huss 1989), and there may be a fitness trade-off between having large numbers of spores that can be distributed together (single large sporehead or "sorus") versus smaller numbers of spores potentially distributed to multiple locations (accessory sori, branched, or grouped sorocarps). It has also been postulated that clustered fruiting bodies may lessen the potential for desiccation in drier habitats (Romeralo et al. 2013).

The Macrocyst Formation of a zygotic cyst or "macrocyst" marks the sexual cycle in Dictyostelia (Fig. 5). Its function was not discovered until the 1970s (Erdos et al. 1973), based on ultrastructure studies showing the presence of a synaptonemal complex (Erdos et al. 1972). This was confirmed by genetic studies indicating the production of recombinant progeny (Erdos et al. 1975; Okada et al. 1986; Francis 1988) and further studies detailed in O'Day and Keszei (2012). Macrocyst formation requires fusion competence (Blaskovics and Raper 1957). Other important factors that have been identified include a combination of environmental factors, particularly darkness (Hirschy and Raper 1964), excess water (Weinkauff and Filosa 1965), ethylene (Amagai 1984), low phosphate, and the presence of calcium ions (O'Day and Keszei 2012). However, these undoubtedly vary between species so the list is far from complete, nor is it exclusive.

Macrocyst formation begins with the formation of fusion-competent cells (Blaskovics and Raper 1957; O'Day et al. 1987). In *D. discoideum*, a tripartite mating locus gives rise to three mating types, any one of which can mate with any

other (Bloomfield et al. 2010) resulting in heterothallic, homothallic, or bisexual fusions (Fig. 5; O'Day and Keszei 2012). However, *D. mucoroides*, *Ra. minutum*, and *P. violaceum* appear to be homothallic (O'Day and Keszei 2012), although the possibility of apomixis cannot be ruled out. Competent cells aggregate together, until two compatible cells meet, attach, and fuse to form a binucleate zygote. The two nuclei eventually fuse, producing a giant cell or zygote (McConachie and O'Day 1987). The zygote then attracts other cells to the aggregate by release of cAMP and additional chemical signals (pheromones) (O'Day 1979; Saga and Yanagisawa 1983; O'Day et al. 1987; Amagai 1984). This aggregation process shares similarities to pre-sorocarpic aggregation in *D. discoideum*, including cAMP pulses and cell streaming, but on a much smaller scale, as only ~200 cells contribute to the sexual aggregate (O'Day 1979).

Eventually, the collective becomes surrounded by a sheath, either secreted by the zygote or by the collective as a whole. This may serve to protect the developing aggregate but also effectively prevents the non-zygotic amoebae from escaping. The zygote gradually devours these captive cells, using the ingested material to grow increasingly larger as well as gradually building up a five-layered cell wall. The process, which can take several weeks, results in a dormant highly resilient macrocyst that can be difficult to germinate in the lab. Before germination occurs, the giant cell undergoes meiosis, from which only a single meiotic product survives. This is followed by multiple rounds of cell division so that upon germination, the macrocyst releases a mass of haploid trophic amoebae (Fig. 5; Okada et al. 1986).

Ultrastructure Solitary feeding amoebae have relatively broad hyaloplastic pseudopodia with acutely pointed subpseudopodia, sometimes referred to as filose (Fig. 7a; Olive 1975). These amoebae move in a slow, smooth manner, unlike the eruptive manner of acrasid amoebae (see ▶ Heterolobosea). Cells are somewhat rounded while feeding, with a size of about 10–15 μm in diameter, but they assume a distinctive elongated form during aggregation. The nucleus is characterized by a single peripheral nucleolus, which is digitate so that it appears as two to five dense masses of RNA devoid of dense chromatin and lying in tight contact with the nuclear membrane (Fig. 7a; Benichou et al. 1983).

Fructifications (sorocarps) may be clustered or branched or regularly whorled (Figs. 4, 8a–i, and 10). The aggregates of *Dictyostelium* (molecular Group 4) species usually remain together as a unit and give rise to a solitary fruiting body that is only rarely branched and, even then, mostly only sparely (Figs. 4a, b, and 8e). In contrast, other species throughout the tree tend to split up their aggregates into multiple sorogens, which may then subdivide even further to yield clustered fruiting bodies (Fig. 4e–i). The generally larger structures of *Dictyostelium* species are typically supported at their base by a basal disc or triangular supporter (Fig. 7c, e), which are derived from a third cell type, the anterior-like cells. In at least one *Dictyostelium* species, *D. discoideum*, this cell type diverges even further to produce two more structures, the upper and lower cup that serve to support the relatively large spore head. Thus *D. discoideum* and probably other *Dictyostelium s.s.* species differentiate five distinct cell types. The sorocarps of the crampon-based species of *Hagiwaraea*

also tend to be relatively large (Fig. 7f), suggesting a general correlation in Dictyostelia between sorocarp size and cell type diversity.

Genome The first dictyostelid genome, that of *D. discoideum*, was published in 2005 (Eichinger et al. 2005). It is 34 megabases (Mb) in size with six chromosomes encoding an estimated 12,500 proteins. Although most genes contain introns, these are small in size (150 base pairs on average), similar to many other microbial eukaryotes. The genome is extremely AT rich (70–80%). Many protein-coding genes carry long tracts of triplet repeats, and these are translated into repetitive amino acid tracts that are retained in the mature proteins (Eichinger et al. 2005). Such repeats are thought to contribute to evolutionary plasticity (e.g., Radó-Trilla et al. 2015), and while they are common in eukaryotes, including humans, the extent in *D. discoideum* is so far unrivaled (Scala et al. 2012). These sequences are generally poorly conserved, and there is little similarity in their size or location between *D. discoideum* and *D. purpureum* (Sucgang et al. 2011), which are both species of *Dictyostelium s.s.*, albeit distantly related (Fig. 9).

In addition to *D. discoideum*, full or advanced draft genome sequences are available for *D. purpureum* (Sucgang et al. 2011), *Ra. lacteum* (Du et al. 2015), *Cavenderia fasciculatum* (Heidel et al. 2011), *He. pallidum* (Heidel et al. 2011), and *A. subglobosum* (Urushihara et al. 2015). Thus, there are now genome data for at least one representative of each of the five largest molecular groups (Fig. 3). The genomes range in size from 31 to 34 Mb, except for *Raperostelium lacteum* which appears to be ~22 Mb (Du et al. 2015). The genomes seem to encode similar numbers of genes, and the differences in genome size are mostly due to varying levels of noncoding DNA such as intergenic spacers and introns (Du et al. 2015). It is interesting to note that these genomes are all considerably smaller than that of the solitary amoeba *Acanthamoeba castellanii*, which has a 45 Mb genome with 15,455 predicted genes (Clarke et al. 2013). Genome data have also recently been reported for representatives of the remaining major divisions of Dictyostelia – *Co. polycephalum*, *P. violaceum*, *Ro. ellipticum*, and *Synstelium polycarpum* (Singh et al. 2016).

Maintenance and Cultivation

Dictyostelids and their fruiting bodies are too small and sparse to be easily observed in nature. However, many are relatively easy to isolate and grow in the lab (reviewed in Douglas et al. 2013). The superficial layers (0–3 cm depth) of almost any forest soil will yield four to eight species that can be identified on isolation plates, although species have been found as deep as 20–30 cm (JES unpublished). Isolation involves placing diluted soil samples on nutrient-poor agar (e.g., hay infusion agar; Table 2), followed by incubation at room temperature for several days until aggregates and/or fruiting bodies begin to appear (slower-growing species, such as acytostelids, may require up to 6 days before aggregates appear).

Cavender (1990) lists five important factors for isolating dictyostelids from soil:

Table 2 Media used in culturing dictyostelids (Raper 1951)

Hay infusion (HI)		NTGY		Standard LP (0.1%)		MY	
Component	[g/li]	Component	[g/li]	Component	[g/li]	Component	[g/li]
Specific							
Weathered mature grass (*Poa* spp.) (filtered)	8.0	Tryptone	5.0	Peptone	1.0	Malt extract	0.002
$Na_2HPO_4 \cdot 12H_2O$	0.96	Glucose	1.0	Lactose	1.0		
General							
KH_2PO_4	1.5		1.0		–	(Optional)	0.75
Yeast extract	–		5.0		–		0.002
Agar (Difco)	15.0		15–20		15.0		15.0

1. A low nutrient medium lacking inhibitors
2. Some buffering capacity
3. A low aqueous soil dilution (< 1:50)
4. Provision of a pregrown bacterial food source
5. The use of fresh, undried, unfrozen surface soil and leaf mold
6. A few charcoal grains added to lids of inverted plates (optional)

Freezing kills trophic cells (Cotter and Raper 1968). However, this also provides a means of measuring percentages of active versus resting propagules. Dictyostelid species differ greatly in their abundance in soil and their sensitivity to culture media used for their isolation. According to Cavender (1990), dictyostelids fall into three general types in terms of ease and conditions for isolation.

Type A. Larger, More Vigorously Growing, and Easily Isolated Species These consume heavier growths of bacteria and tolerate higher concentrations of phosphate buffers and soluble nutrients. Examples are *D. discoideum*, *D. purpureum*, *D. sphaerocephalum*, *Dictyostelium giganteum*, *D. gargantuum*, and *P. violaceum*. It should be noted that it is possible to isolate some of these robust species of Dictyosteliaceae without added bacteria, as they may often carry their own (i.e., farming species; see above).

Type B. Much Smaller and More Delicate Species These consume only light growths of bacteria and are inhibited by nutrient and phosphate buffer concentrations suitable for type A species. Examples are *He. oculare*, *Co. polycephalum*, *Sy. polycarpum*, *Ca. stellatum*, *Ra. lacteum*, *Cavenderia deminutivum*, *Ra. minutum*, *Acytostelium leptosomum*, *Ro. ellipticum*, and *Acytostelium irregulosporum*.

Type C. Species of Intermediate Size and Sensitivity Examples include *D. rosarium*, *Cavenderia aureostipes*, *D. aureum*, Ca. *fasciculatum*, and *He. pallidum*. These grow best on conditions intermediate between types A and B.

A very weak hay infusion medium is recommended to isolate all three groups together (Table 2; Cavender and Raper 1965a; Douglas et al. 2013). It is preferable to use fresh agar plates (~24 h), although older plates (several weeks) have been used routinely for some *Dictyostelium* species (Fortunato et al. 2003a). Bacteria, typically *E. coli* (B/r, 281 K.B.R., or other common laboratory strain) or *K. aerogenes* (900 K. B.R.), are pregrown for 24 h at 30° on NTGY (*E. coli*) or SM medium (*K. aerogenes*). A 1:50 soil/water dilution is made using two dilutions (1:10, 1:25) to allow coarse particles to settle. Dilutions are gently shaken to avoid damage to trophic cells (Kuserk et al. 1977). An 0.5 ml aliquot of the 1:50 dilution is added to each hay infusion plate along with 0.4 ml of a heavy bacterial suspension (white in appearance). These are mixed over the surface by tilting, and the lid of the petri dish is set ajar until the excess water evaporates. If the agar surface is level, the suspension will remain uniformly spread.

Some species such as *A. leptosomum* and *Raperostelium tenue* need charcoal for optimal fructifications (Cavender 1990). Since charcoal is never detrimental to cultures of Dictyostelia, we recommend its routine use (Douglas et al. 2013). This seems to be related to the capacity of charcoal to absorb some gas, probably NH_3, which inhibits the formation of fruiting bodies (Bonner et al. 1986). Clones of cellular slime molds begin to develop in the bacterial lawn after 3–6 days at 22–25 °C. Overhead illumination at this time improves the development of dictyostelid clones, which are most distinct when other soil amoebae are limited in number (e.g., in acid forest humus). Media used to culture dictyostelids are shown in Table 2 (Raper 1951). Two-member culture methods have been reviewed by Raper (1984). A standard medium containing non-nutrient agar (NNA) is preferred to be able to compare morphological descriptions of all species.

Individual species are isolated by replating. To do this, the sorus of the desired isolate is touched with a glass needle and transferred to bacterial streaks made on a fresh NNA plate using a suspension of the host bacterium. Growth types A, B, and C all grow on NNA, although type B and C species generally respond favorably to charcoal crumbs placed in the lid of an inverted culture dish (Raper 1984). Culture plates are incubated in darkness or diffuse light at 20–25 °C. However, some species require different temperatures, such as *Dictyostelium septentrionalis* and *Raperostelium australe* (15–20 °C), *Co. polycephalum* (25–30 °C), and *Cavenderia antarctica* (15–18 °C), reflecting their environments of origin (Bonner and Lamont 2005). Submerged culture methods, first developed by Gerisch (1959), are routinely used for experimental studies. Axenic culture on defined media is possible for *He. pallidum* (Goldstone et al. 1966) and *D. discoideum* (Franke and Kessin 1977), allowing for isolation of auxotrophic mutants for genetic analyses. For suspension of pregrown amoebae, Bonner's salt solution (1947) is used.

Long-term preservation of spores is best achieved by freezing spores with glycerol buffer or with the medium HL5 (Franke and Kessin 1977). Spores can also be stored by lyophilization, dessicated in silica gel (Raper 1984), or frozen in glycerol. For further details on isolation and cultivation of dictyostelids, see Douglas et al. 2013.

Evolutionary History

The phylogenetic position of Dictyostelia has been controversial for much of its scientific history. Much of the early study of Dictyostelia was conducted by mycologists, who placed it within kingdom Mycetae (Fungi) (DeBary 1857). As a result, current dictyostelid nomenclature is based on the International Code of Nomenclature for Algae, Fungi, and Plants, and their systematics traditionally follows botanical rules. Early molecular studies were also problematic. The earliest 18S rRNA trees to include both *D. discoideum* and a myxogastrid, *Physarum polycephalum*, placed them as separate relatively early diverging branches of eukaryotes (Sogin et al. 1986). This was eventually recognized as an artifact due to a combination of

inadequate taxon sampling, uneven evolutionary rates, and the nucleotide compositional bias of *D. discoideum* (A+T rich) versus *Ph. polycephalum* (G+C rich) rRNAs (Spiegel et al. 1995; Baldauf and Doolittle 1997; Bapteste et al. 2002; Fiore-Donno et al. 2005). Taxon-rich multigene trees now unambiguously place Dictyostelia and Myxomycetes/Myxogastria together, in some cases with certain protostelid sister taxa (Baldauf and Doolittle 1997; Shadwick et al. 2009; Cavalier-Smith et al. 2016). The latter grouping was first designated as Eumycetozoa (Olive 1975), but this is now recognized as invalid because protostelids are not monophyletic see ▶ Protosteloid Amoebae). Dictyostelia is now confidently placed with Myxomycetes in Macromycetozoa (Fiore-Donno et al. 2010). This is a division of the Conosa branch of Amoebozoa, the bulk of whose diversity consists of solitary amoebae (Pawlowski and Burki 2009).

Within Dictyostelia, the acetyostelid morphotypes were long thought to be the earliest branch, diverging before the evolution of cellular differentiation. Meanwhile polysphondylids were thought to be very derived, because of the apparent complexity of their highly ordered sorocarps. However, molecular phylogeny places acytostelids embedded within a morphologically complex Acytosteliaceae, along with dictyostelid and polysphondylid morphotypes (Fig. 3). Thus, the simple morphologies of acytostelids appear to have evolved by loss of ancestral complexity. Meanwhile the polysphondylid morphology has evolved at least twice independently (within *Heterostelium* and Dictyosteliaceae; Fig. 3). Arguably the most "complex" dictyostelids are found in *Dictyostelium*; e.g., *D. discoideum* sorocarps contain at least five differentiated cell types (Schaap 2007).

The first rRNA phylogeny of Dictyostelia suggested molecular Group 1 (now, Cavenderiaceae) as the first major branch, albeit without significant statistical support (Schaap et al. 2006). This suggested a possible trend toward larger size and complexity in Dictyosteliaceae (Alvarez-Curto et al. 2005; Schaap 2007). However, due to the highly divergent nature of mycetozoan rRNAs, the distance between the ingroup and outgroup is immense. More recent attempts to root the tree with multigene data confidently place the root between Dictyosteliales and Acytosteliales (Romeralo et al. 2013; Sheikh et al. 2015; Singh et al. 2016). Although both families are morphologically diverse, Acytosteliales contains representatives of all three morphotypes including all acytostelids and most of the polysphondylids, while Dictyosteliales consists largely of dictyostelid morphotypes (Sheikh et al. 2015).

The fundamental split of Dictyostelia into Dictyosteliales and Acytosteliales indicates that the last common ancestor of Dictyostelia already possessed most of the notable traits of the group. These include streaming aggregation, acrasin signaling, cellular differentiation, and developmental regulation by extracellular cAMP signaling, microcysts, macrocysts, and a sexual cycle involving aggregation and cannibalism. Nonetheless, a few scenarios can be postulated with reasonable confidence. Microcysts were undoubtedly inherited from their amoebozoan ancestors, as this is a common survival trait among solitary amoebae (Du et al. 2015). Extracellular cAMP-controlled development probably evolved from intracellular cAMP signaling, which is used to regulate encystation in the single-celled amoebozoan

Acanthamoeba (Kawabe et al. 2015). Acrasin signaling may have evolved from prey detection pathways; e.g., the acrasin folate is also a common by-product of bacterial metabolism and promotes chemotaxis and phagocytosis in various Dictyostelia (Pan et al. 1972, 2016). The use of cAMP as an acrasin, however, appears to have evolved only in *Dictyostelium*, probably early in the evolution of the genus. This involved duplication of an ancestral cAMP cell surface receptor that is still used throughout Dictyostelia for developmental signaling (Alvarez-Curto et al. 2005).

Nonetheless, size has probably been an important force in dictyostelid fruiting body evolution. The most consistently large sorocarps are found among species of *Dictyostelium s.s.* These have the largest sori and the thickest and longest stalks. This larger size was probably facilitated by coevolution of additional cell types to help these larger sorocraps remain erect (Schaap 2007). The largest sorocarps in Raperosteliaceae, those of *Hagiwaraea*, have also evolved an additional support structure in the form of a digitate crampon-like base, which undoubtedly helps stabilize these structures. Increased branching or the presence of whorls may also help stabilize some larger sorocarps (Romeralo et al. 2013).

Among the major groups, *Dictyostelium* is of particular interest as it includes the model species, *D. discoideum.* The genus is molecularly shallow but species rich, and it is dominated by relatively robust species, many of which are abundant in a wide variety of habitats. The latter may be due to their generally robust sorocarps, which may better survive long dispersal times and/or avoid decomposition in humus soil (Schaap 2007). However, the frequent recovery of these species could also reflect, at least in part, their ease of cultivation in the lab. Another factor that may aid the development of larger sorocarps in *Dictyostelium* is stalkless migration, which in *D. discoideum* allows the slug to move a considerable distance away from its aggregation site without shedding cells along the way (Bonner 2006).

The evolution of the polyspondylid morphotype is intriguing, as this striking morphology has evolved at least twice independently (Schaap et al. 2006). The majority of polysphondylids, particularly the numerous species with small unpigmented sorocarps (e.g., *He. pallidum*), are now assigned to *Heterostelium*, where they are embedded within a scattering of small unpigmented dictyostelid morphotypes and possibly also acytostelids (Fig. 9). Meanwhile, the robust violet-colored polysphondylids, most notably the type species *P. violaceum*, are found clustered with a robust violet-colored dictyostelid (*P. laterosorum*) forming the genus *Polysphondylium* (Fig. 3; Romeralo et al. 2011). This suggests that pigmentation and sorocarp size are more evolutionarily conservative than branching pattern. The abundance of cryptic species throughout Dictyostelia (Romeralo et al. 2011) further suggests that few genes may be involved in specifying sorocarp branching patterns (Schaap et al. 2006).

The possibility that acytostelid simplicity is derived was first suggested by Bonner (1982). However, this scenario is further complicated by the fact that acytostelid morphotypes are not monophyletic, with *Ro. ellipticum* as the sister group to either *Heterostelium* (Fig. 9; Schaap et al. 2006; Romeralo et al. 2011) or to all other Acytosteliaceae (*Heterostelium* + *Acytostelium*; Singh et al. 2016). Either scenario requires that either acytostelid-type morphological reduction occurred twice

independently, once in an ancestor of *Acytostelium* and once on the lineage leading to *Ro. ellipticum*, or that multicellularity was re-invented early in the evolution of *Heterostelium*. Additional isolates and, if possible, closer relatives of *Ro. ellipticum* need to be examined to better understand what might have occurred and how.

Dictyostelia is an ancient and molecularly deep taxon. Understanding of the molecular, behavioral, and developmental biology of *D. discoideum* is very sophisticated, and this knowledge is now being extended across the diversity of the group. However, given the depth and antiquity of the taxon, there are still relatively few species known. This and the facts that the deepest branches tend to be occupied by small delicate elusive species and most localities across the world have been only sparsely sampled, if at all, suggest that much of the diversity of the group remains to be discovered. It will be especially useful to find taxa that break up some of the longer branches as well as relatives of the enigmatic *Co. polycephalum*, *Sy. polycarpum*, *Sp. caveatum*, and *Ro. ellipticum*, all of which occupy interesting junctures in the tree. New genomic data from these lineages (e.g., Singh et al. 2016) and the continued isolation of new species from the wild (e.g., Cavender et al. 2016) should help resolve their phylogeny and further understand evolutionary, ecological, and behavioral patterns in Dictyostelia.

Acknowledgments The authors wish to thank James Cavender and Eduardo Vadell, for careful reading of the chapter and valuable comments throughout, and Sanea Sheikh and Daniel Baldauf for invaluable help with preparing figures.

Choanoflagellatea

40

Daniel J. Richter and Frank Nitsche

Abstract

Choanoflagellates are a group of unicellular and colonial heterotrophic flagellates within the Opisthokonta. The characteristic choanoflagellate cell morphology, present in all species, is an ovoid to round protoplast with one apical flagellum surrounded by a collar of microvilli. Phylogenetic studies indicate that choanoflagellates are the closest known living relatives of animals, which has led to a focus on this group to reconstruct the history of animal evolution. Choanoflagellates display a worldwide distribution from the Arctic to Antarctica, in fresh, marine, and brackish water, and they have also been detected in soil ecosystems. In aquatic habitats they play an essential role in the microbial food web as highly efficient filter feeders. Historically, choanoflagellate taxonomy has been based on morphological features, but recent molecular sequence data have refined the taxonomy and revealed several prominent discrepancies. All choanoflagellates belong to one of two sister groups: the Acanthoecida, which construct a siliceous extracellular structure known as a lorica, and the Craspedida, which lack a lorica but may possess an organic extracellular structure called a theca. The loricate Acanthoecida are comprised of two well-described subgroups, distinguished by characteristic differences in how their loricae are constructed: the Acanthoecidae, or nudiforms, and the Stephanoecidae, or tectiforms. To date, two choanoflagellate genomes have been sequenced, both craspedids: *Monosiga brevicollis* and *Salpingoeca rosetta*. The life cycle of *S. rosetta* has been most thoroughly characterized, with sexual and

- **Stephanoecidae** (e.g., *Bicosta*, *Diaphanoeca*, *Pleurasiga*, *Stephanoeca*)

Introduction

General Characteristics

Choanoflagellates are unicellular and colonial microbial eukaryotes found ubiquitously in marine and freshwater environments, where they are prevalent in both pelagic and benthic communities. They are heterotrophic phagotrophs whose distinctive cell morphology is defined by a collar of microvilli surrounding a single apical flagellum. The undulation of the flagellum creates water currents that transport suspended food particles, primarily bacteria, to the collar, which is thought to serve as a filter (Lapage 1925; Pettitt et al. 2002).

There are two recognized groups within the Choanoflagellatea: the Craspedida (referred to as craspedids; roughly 210 described species) and the Acanthoecida (referred to as acanthoecids or loricates; roughly 150 described species). Craspedid cells either lack a firm extracellular investment, or they may be surrounded by a thin fibrillar coat called a glycocalyx, or they may possess an organic investment called a theca (Figs. 1a and 2). The theca is an organic structure, although its precise composition has yet to be characterized (Norris 1965; Leadbeater 1980; Parke and Leadbeater 1977). In contrast, all known acanthoecids produce a silica-based extracellular structure called a lorica, which is constructed from costal strips joined to form costae (Thomsen 1973; Leadbeater and Manton 1974) (Figs. 1b and 3). The acanthoecids are composed of two subgroups: the Stephanoecidae, or tectiforms, and the Acanthoecidae, or nudiforms. These two subgroups are distinguished on the basis of their morphology during cell division and on the point in the cell cycle when costal strips are accumulated and subsequently assembled into a lorica (Leadbeater 2008; see the section on "Life Cycle" below).

Occurrence

Choanoflagellates are globally distributed. Some environments in which choanoflagellates have been detected by microscopy are: the North Atlantic (Ellis 1929; Leadbeater 1972a, b, 1980, 1983; Leadbeater et al. 2008; Thomsen 1973, 1976, 1982; Throndsen 1970, 1974; Manton et al. 1975, 1976; Tikhonenkov et al. 2006), Thailand (Thomsen and Boonruang 1983; Thomsen and Moestrup 1983), New Zealand and Australia (Al-Qassab et al. 2002; Moestrup 1979), Taiwan and Japan (Hara and Takahashi 1987; Hara et al. 1996, 1997; Nitsche and Arndt 2008), the Galapagos Islands (Manton et al. 1980), the Mediterranean Sea (Leadbeater 1973, 1974), the Red Sea (Thomsen 1978), the North Pacific (Booth et al. 1982; Booth 1990), the South Atlantic (Bergesch et al. 2008), and the Antarctic (Buck 1981; Buck and Garrison 1988; Chen 1994; Hara and Tanoue 1985; Takahashi 1981b; Marchant and Perrin 1990; Leakey et al. 2002; Nitsche et al. 2007).

Literature

Early literature on choanoflagellates was published largely in book format (e.g., Stein's *Der Organismus der Infusionsthiere* and Kent's *Manual of the Infusoria* (Stein 1878; Kent 1880-1882)) or in the *Quarterly Journal of Microscopical Science* (now known as the *Journal of Cell Science*). Subsequent characterizations of choanoflagellate ecology and new species descriptions have been published in journals focusing on marine science or on the biology of microbial eukaryotes, principally *Journal of the Marine Biological Association of the United Kingdom, Archiv für Protistenkunde* (now known as *Protist*), *European Journal of Protistology*, and *Journal of Eukaryotic Microbiology*. Within the past 15 years, interest in choanoflagellates as the sister group to animals has engendered a number of publications in molecular biology journals such as *Molecular Biology and Evolution*, *BMC Evolutionary Biology*, and *Developmental Biology* and in general interest science journals including *PLoS ONE*, *Current Biology*, *Science*, *Proceedings of the National Academy of Sciences of the USA*, and *Nature*. Several review articles, guides, and book chapters have been written on choanoflagellates, including those by Zhukov and Karpov (1985), Leadbeater and Thomsen (2000), and the previous edition of this book (Buck 1990).

A comprehensive book covering all aspects of choanoflagellate biology, ecology, and evolution has recently been published (Leadbeater 2015).

History of Knowledge

The first description of a choanoflagellate, *Codosiga botrytis* (originally named *Epistylis botrytis*), was made by Ehrenberg (Ehrenberg 1831, 1838). Further light microscopy studies from the late nineteenth and early twentieth centuries increased

the catalog of morphologically described choanoflagellate species (Kent 1880-1882; Ellis 1929). Norris (1965), drawing on evidence from electron microscopy, established the basis of the current systematic hierarchy within the group. Studies on mitochondrial morphology (Leadbeater 1974) and kinetid structures (Hibberd 1975; Karpov 1982) provided initial information on the phylogenetic relationship of choanoflagellates to other eukaryotes, placing them within the now-retired protist phylum Zoomastigina and not in the groups Craspedophyceae or Chrysophyceae. The advent of molecular methods conclusively established choanoflagellates as the sister group to animals (Wainright et al. 1993; Snell et al. 2001; Lang et al. 2002; Shalchian-Tabrizi et al. 2008; Philippe et al. 2005; Steenkamp et al. 2006; Ruiz-Trillo et al. 2008; Carr et al. 2008). Molecular phylogenetic studies of diverse choanoflagellates have mainly been based on ribosomal small subunit RNA gene sequences but have also extended to a small number of protein coding genes (Snell et al. 2001; Carr et al. 2008; Nitsche et al. 2011; del Campo and Massana 2011). Interest in metazoan evolution has led to increased molecular characterization of choanoflagellates, a significant component of which has been analysis of genome and transcriptome data sets, and comparison to animals (King and Carroll 2001; Fairclough et al. 2013; King et al. 2003; 2008; Richter and King 2013).

Practical Importance

Choanoflagellates, part of the size/nutritional class of heterotrophic nanoflagellates (2–20 μm), are components of an essential link within aquatic food webs, consuming bacteria and hence propagating resources to higher trophic levels (Arndt et al. 2002). To date, no parasitic or endosymbiotic species have been reported nor has any form of toxicity or pathogenicity been described within the choanoflagellates.

Habitats and Ecology

The habitats in which choanoflagellates have been found vary broadly, consistent with the hypothesis that they are ubiquitously distributed in the environment. For example, marine choanoflagellates have been reported as members of the aquatic surface microlayer (neustonic) community (Norris 1965), within sea ice (Buck 1981; Takahashi 1981b; 1981a; Thomsen et al. 1997) and as plankton of coastal waters (del Campo et al. 2015) and oceanic regimes in the deep sea (Nitsche et al. 2007). Although most reports on planktonic habitats have been from coastal areas, several open ocean transect studies have documented choanoflagellates at all sampled stations and depths (Booth et al. 1982; Leakey et al. 2002; de Vargas et al. 2015). Choanoflagellates have also been detected in soil (Ekelund and Patterson 1997; Ekelund et al. 2001; Geisen et al. 2015).

Craspedid choanoflagellates are present in both freshwater and marine environments. Loricate (acanthoecid) choanoflagellates were considered to be strictly

marine until recent reports describing two new species in freshwater lakes: one in Mongolia (Paul 2012) and the other in Samoa (Nitsche 2014). Marine choanoflagellates have been found in habitats where the potential for salinity variation is great, such as tide pools, sea ice, hypersaline lakes (van den Hoff and Franzmann 1986; Couradeau et al. 2011), and coastal regions (see above). Other environmental tolerances may differ among choanoflagellate species: *Parvicorbicula socialis* has been found at 25 °C in the Mediterranean and in both polar regions at temperatures as low as −1.8 °C (Buck 1980; Manton et al. 1975), while *Bicosta antennigera* has not been recorded at temperatures exceeding 10 °C (Manton et al. 1980). Choanoflagellates have been cultured from hypoxic water masses (Wylezich et al. 2012). A study of the craspedid morphospecies *Codosiga botrytis* showed that a single morphotype may contain different genotypes which reflect adaptations to different habitats like estuaries, rivers, or soil (Stoupin et al. 2012).

Although choanoflagellates are generally found at low abundance in most aquatic ecosystems (e.g., Buck et al. 1996), they can be a major component of plankton in some specific environments (for example, exceeding 10^6 cells per liter the ice edge region of the Antarctic Weddell Sea (Buck and Garrison 1983)).

The mode of nutrition of choanoflagellates is phagotrophy by suspension feeding that is generally interpreted as a form of filter feeding (Lapage 1925; Pettitt et al. 2002). Choanoflagellates create water currents via an undulating movement of their single apical flagellum, which transports particles to the outside of their collar. These particles consist mostly of bacteria, picoplanktonic algae, and debris. These particles are transported along the microvilli of the collar near to the protoplast, whereupon cytoplasmic pseudopodia extend to engulf the food, which is subsequently digested within a food vacuole (Fenchel 1982; Pettitt et al. 2002; Leadbeater and Manton 1974). Choanoflagellates can handle many food particles simultaneously (Boenigk and Arndt 2000), and multiple different modes of feeding have been observed in craspedids (Zhukov and Karpov 1985).

In the craspedid *Salpingoeca rosetta*, a sulfonolipid constitutively produced by a coisolated prey bacterium is capable of inducing colony formation (Alegado et al. 2012). While the ecological significance of this interaction is currently unknown, *S. rosetta* may interpret the bacterial signal as an indication of prey presence (Alegado et al. 2012; Alegado and King 2014) by forming colonies around which the rate of fluid flow, and therefore the rate of contact with potential prey, is higher than that of single cells (Orme et al. 2001; Roper et al. 2013).

Characterization and Recognition

General Appearance and Ultrastructure

Choanoflagellates are identified by the presence of a single apical flagellum, whose length may vary between species and within species based on life history stage (Leadbeater 2015), surrounded by a collar of 20–50 actin-filled microvilli. In the craspedid *Monosiga brevicollis*, these microvilli are about 0.1 μm wide, 0.1 μm apart

at their bases and 0.6 μm apart at their tips (Mah et al. 2014). No organisms or cell types possessing a single flagellum surrounded by a collar of microvilli have been reported outside of the choanoflagellates, with the exception of the choanocyte cell type found in animals (reviewed in Alegado and King 2014). The cell body is in a size range of 1.2–10 μm in length and 2–10 μm in width (Mah et al. 2014; Leadbeater 2015). A symmetric wing-like vane spanning the proximal two thirds of the flagellum has been described in some choanoflagellate species (Fjerdingstad 1961; Hibberd 1975; Karpov and Leadbeater 1998; Karpov 2000; Mah et al. 2014). In the craspedid *Codosiga botrytis*, the vane was observed to be approximately 2 μm wide on either side of the flagellum, and to contain two sets of overlapping fine fibrils (Hibberd 1975). In addition to a basal body directly associated with the structure of the flagellum, all choanoflagellates also feature a second nonflagellar basal body whose length varies by species; to date, only *C. botrytis* has been observed to contain more than two basal bodies (Hibberd 1975; Karpov and Leadbeater 1998; Leadbeater 2015). A stacked microtubular structure consisting of two or more layers (depending on species) extends from one third to one half the length of the cell and supports the bases of the collar microvilli (Hibberd 1975; Zhukov and Karpov 1985; Karpov and Leadbeater 1998). Choanoflagellate mitochondrial cristae are generally flattened in shape, as in other opisthokonts (although tubular cristae have recently been observed (Wylezich et al. 2012)), but mitochondrial location, size, and shape varies among species (Leadbeater 2015). Typically, the Golgi apparatus, whose size and structure differs among species, is located adjacent to the second, nonflagellar basal body (Leadbeater 2015). The nucleus is generally located below the Golgi apparatus, and nuclear division has been examined in detail in both craspedid and acanthoecid species (Karpov and Mylnikov 1993; Leadbeater 1994b; Karpov and Leadbeater 1997).

Many craspedid choanoflagellate species possess an extracellular organic structure known as a theca. Theca shape is currently considered to be diagnostic for species identification. Furthermore, thecae from different species have been divided into classes by shape: cup shapes such as *Salpingoeca rosetta* (Dayel et al. 2011), flask shapes such as *Salpingoeca urceolata* (Kent 1880-1882), and tube shapes such as *Salpingoeca gracilis* (James-Clark 1868), with other classes of shapes remaining to be discovered. In contrast to the Craspedida, the Acanthoecida possess a distinct morphological characteristic, the siliceous lorica, which has received considerable taxonomic attention during the past five decades due to the relative ease of preparation of the lorica for electron microscopy and the species-specific conservation of the critical details of lorica morphology (reviewed extensively by Leadbeater 2015). The electron microscopy study of Norris (1965) was the first to show that the costae that make up the lorica of the Acanthoecida were themselves constructed of component costal strips. These costae are formed intracellularly within silica deposition vesicles from incorporated environmental amorphous silicon dioxide and are subsequently exocytosed during lorica formation; the highly choreographed steps of lorica construction are subject to a universal set of rules that are implemented in a species-specific manner (Leadbeater and Davies 1984; Leadbeater 1985, 1989; Marron et al. 2013; Leadbeater 2015; Leadbeater et al. 2009).

Life Cycle

Several cell types/life history stages have been described within choanoflagellates, including: (i) cells attached to a substrate, either directly, by a long stalk or pedicel, or within a theca or lorica; (ii) cells passively suspended in the water column, either naked or within a lorica; (iii) "normal" swimming cells that closely resemble attached cells; (iv) fast-swimming cells with shorter collars, often differently shaped from slower swimming cells and sometimes referred to as swarmers; and (v) colonies, either free-swimming or attached to a substrate, in which cells may be connected by fine intercellular bridges (Hibberd 1975; Karpov and Coupe 1998; Dayel et al. 2011; Fjerdingstad 1961). As with the theca, the presence or absence of cell types or life history stages within a culture may be condition-dependent, and only in a few cases are these conditions beginning to be understood (e.g., Alegado et al. 2012). Whether or not morphologically similar cell types are homologous among choanoflagellate species is currently unknown.

Asexual reproduction in choanoflagellates is by means of longitudinal fission in most species (Karpov and Mylnikov 1993; Karpov and Leadbeater 1997). The two primary subgroups of acanthoecids differ in the mode of lorica formation associated with asexual reproduction (Leadbeater 2008). In the Stephanoecidae, the daughter cell is supplied with a whole set of costal strips from the mother cell when it departs the parent lorica (tectiform replication, e.g., Leadbeater 1994a). In contrast, in the Acanthoecidae, the daughter cell leaves the mother cell naked and subsequently produces the costal strips by itself (nudiform replication).

Sexual reproduction and evidence for genetic recombination have been observed in the craspedid thecate choanoflagellate *Salpingoeca rosetta* (Levin and King 2013). In *S. rosetta*, sexual transitions from a haploid to a diploid state occur in nutrient-limiting conditions, and the converse transition from diploidy to haploidy, presumed to occur via meiosis, takes place in nutrient-rich conditions. Fusion of anisogamous haploid gametes occurs via a smaller, rounded cell (the "male" gamete) fusing and then entering a larger, ovoid cell (the "female" gamete). Sex in *S. rosetta* can occur within clonal cultures and between genetically differentiated cultures derived from the same initial isolate. In addition, choanoflagellates possess conserved eukaryotic genes involved in meiosis (Carr et al. 2010).

Choanoflagellates are capable of forming cysts, although the environmental triggers and molecular pathways for cyst formation remain uncharacterized (Zhukov and Karpov 1985; Leadbeater and Karpov 2000; Stoupin et al. 2012).

Nuclear and Mitochondrial Genomes

Two craspedid choanoflagellate nuclear genomes have been sequenced: *Monosiga brevicollis* (King et al. 2008) and *Salpingoeca rosetta* (Fairclough et al. 2013). *Monosiga brevicollis* has an estimated genome size of 41.6 Mb, with a GC content of 55%, 9,171 predicted protein-coding genes, and 6.6 introns per gene of average length 174 bp. The genome of *S. rosetta* is larger, with an estimated size of 55.4 Mb,

a GC content of 56%, and 11,629 predicted protein-coding genes featuring 7.5 introns per gene with a mean length of 255 bp.

The circular mitochondrial genome of *M. brevicollis* is 75,568 bp, with a very low GC content of 14%, and encodes 55 predicted genes which comprise 47% of the genome (Burger et al. 2003).

Choanoflagellate genomes may be heavily influenced by horizontal gene transfer from their prey; approximately 4.4% of the genes in the *M. brevicollis* nuclear genome have been estimated to result from lateral transfers from bacterial or algal donors (Yue et al. 2013).

Systematics and Nomenclature

The formal taxon name for choanoflagellates is Choanoflagellatea Cavalier-Smith 1998, emended by Nitsche et al. 2011. All described species fall into two groups: Craspedida and Acanthoecida, both proposed by Cavalier-Smith (1997) and emended by Nitsche et al. (2011). The group Craspedida contains at present only one subtaxon, the Salpingoecidae Kent 1880-1882 emended sensu Nitsche et al. 2011, whose type genus is *Salpingoeca* James-Clark 1867. The group Acanthoecida consists of two subtaxa, the Stephanoecidae Leadbeater 2011 and the Acanthoecidae Norris 1965, emended sensu Nitsche et al. 2011. *Stephanoeca* Ellis 1929 is the type genus of Stephanoecidae, and *Acanthoeca* Ellis 1929 is the type genus of Acanthoecidae.

Several choanoflagellate genus and species names are known to require revision (Nitsche et al. 2011). Early catalogs of choanoflagellate species were based on light microscopy (Kent 1880-1882; Ellis 1929) and were later supplemented with electron microscopy data. However, both molecular phylogenetic evidence and detailed observations of clonal cultures have demonstrated that characteristics of protoplast (cell) morphology and life history are not reliable indicators of species identity (Carr et al. 2008; Dayel et al. 2011; Nitsche et al. 2011). For example, *Choanoeca perplexa* and *Proterospongia choanojuncta*, which were originally described as two distinct species, have since been recognized as unicellular and colonial life history stages of the same species (Leadbeater 1983; Carr et al. 2008). Therefore, instead of relying on protoplast morphology or a single life history stage as a means of species recognition, choanoflagellates are currently identified using a combination of three separate methods: (1) the morphology of their extracellular structures such as the theca or the lorica (if either is present); (2) characterization of multiple life history stages in clonal culture; and (3) molecular sequence data, where the highest sampling depth exists for small and large subunit ribosomal RNA gene sequences. In cases where the first two methods have produced ambiguous results, molecular data are used as the arbiter for final identification.

The relationship among species with similarly shaped thecae is less well understood. Species belonging to the same class of theca shape are likely to be more closely related to one another than to species in a different class, but the exact nature of the relationship among shape classes awaits clarification, due to the fact that only

a handful of species within each shape class have been studied in detail, and because a choanoflagellate species capable of producing a theca may not do so under certain natural or laboratory conditions (Dayel et al. 2011).

The introduction of molecular methods of phylogenetic analysis demonstrated that the two groups of loricate choanoflagellates (Stephanoecidae and Acanthoecidae, which are distinguished by their mode of replication, described below under "Life Cycle") are distinct (Carr et al. 2008; Nitsche et al. 2011). However, molecular data also indicated that a taxonomy based solely on lorica morphology is not sufficient. For example, although the morphology of the loricae of *Acanthocorbis unguiculata* and *Helgoeca* (formerly *Acanthocorbis*) *nana* are strikingly similar, phylogenetic analysis showed that they belong to different groups (Leadbeater et al. 2008). Therefore, although the lorica is a suitable characteristic to determine identity at the species level, higher taxonomic levels cannot necessarily be determined by lorica structure alone (Nitsche et al. 2011).

Maintenance and Cultivation

Choanoflagellate cultures can be isolated from the environment either using a micropipette or by dilution (King et al. 2009). Choanoflagellates cannot currently be cultured in the absence of bacteria, which serve as their food source (a 1970 report [Gold et al. 1970] of choanoflagellates grown without bacteria has not been replicated). The process of isolation generally produces a culture with a single clonal choanoflagellate and a mixed culture of dozens or more species of bacteria. A combination of antibiotic treatment and selective dilution techniques can be used to produce a "monoxenic" culture grown with one species of bacterium (King et al. 2008, 2009; Dayel et al. 2011).

Choanoflagellates are cultured in organically enriched medium of the appropriate salinity. Media are frequently enriched with infusions of cereal grass or by directly adding individual autoclaved pieces of rice or other grains (King et al. 2009). Frequency of passaging cultures into new growth flasks depends on the growth rate of the cells within the culture, but is generally conducted between once per day and once per several weeks. Choanoflagellates growing attached to culture flasks may be detached using a plastic cell scraper. The rate and method of passaging can also be used to influence the proportion of different cell types within the culture (Dayel et al. 2011). Choanoflagellate cultures can be stored long-term as frozen stocks in liquid nitrogen (King et al. 2009), and over 20 species are available from the American Type Culture Collection (ATCC).

Evolutionary History

There is currently no fossil record of choanoflagellates. The most likely candidates for preservation would be those with a siliceous lorica, but the combination of their microscopic size and the lack of knowledge about how they might be preserved, if at

all, have prevented their detection to date. Living cells of *Codosiga botrytis* have been retrieved from permafrost cores estimated to be between 28,000 and 32,000 years old (Stoupin et al. 2012).

Choanoflagellates have been demonstrated to be the sister group to animals (Snell et al. 2001; Lang et al. 2002; Shalchian-Tabrizi et al. 2008; Philippe et al. 2005; Steenkamp et al. 2006; Ruiz-Trillo et al. 2008; Carr et al. 2008), and molecular dating methods have estimated the divergence of animals and choanoflagellates to have occurred somewhere from 600 million to over one billion years ago (Peterson et al. 2004; Douzery et al. 2004; Hedges et al. 2004; Parfrey et al. 2011). Substantial interest has focused on studying the choanoflagellates as a means to reconstruct the evolutionary history of animals (reviewed in Alegado and King 2014; Richter and King 2013).

Acknowledgements This work is a revision of the chapter on choanoflagellates originally written by Kurt Buck for the first edition of this book. We thank Kurt Buck, Sergey Karpov, Barry Leadbeater, Martha Powell, Alastair Simpson, and Helge Thomsen for providing critical comments on this revised chapter. D.J.R. was supported by a National Defense Science and Engineering Graduate fellowship from the United States Department of Defense, a National Science Foundation Central Europe Summer Research Institute Fellowship, a Chang-Lin Tien Fellowship in Environmental Sciences and Biodiversity, a postdoctoral fellowship from the Conseil Régional de Bretagne, and the French Government "*Investissements d'Avenir*" program OCEANOMICS (ANR-11-BTBR-0008).

Blastocladiomycota

41

Martha J. Powell

Abstract

The Blastocladiomycota are posteriorly uniflagellated zoosporic fungi found as saprotrophs and parasites primarily in freshwater and soil. Once considered Chytridiomycota, phylogenetically they are a monophyletic group divergent from other zoosporic fungi, clustering among the nonzoosporic fungi. Their thalli range from monocentric, polycentric, tubular, to hyphal and are unusual among fungi in exhibiting alternation of a haploid gametophytic generation with a diploid sporophytic generation. Thick-walled resistant sporangia are the sites of meiosis and aid in the survival of the organism when environmental conditions become adverse. The hallmark of the group is the ultrastructural architecture of their zoospores, which includes a single nucleus proximal to the kinetosome, an aggregated cluster of ribosomes capping the nucleus anteriorly, and a lateral microbody-lipid globule complex (MLC). In addition to being the center for utilization of stored energy, the MLC has been implicated in rhodopsin-based photoreception and signal transduction in response to blue-green light. Invertebrates, plants, algae, oomycetes, and other blastoclads serve as hosts of parasitic members. For example, *Paraphysoderma* is a highly destructive pathogen of algae grown in mass cultures for biofuels and pharmaceuticals. As a pathogen of mosquitoes, *Coelomomyces* has been explored as a biocontrol agent, but its life cycle requirement for alternation of hosts makes this a difficult system to maintain. The saprotrophs *Allomyces* and *Blastocladiella* are emerging as model organisms in developmental biology, genetics, physiology, and genomics.

●●Coelomomycetaceae
●●Catenariaceae
●●Blastocladiaceae
●●Sorochytriaceae

Introduction

General Characteristics

The Blastocladiomycota is a monophyletic phylum of zoosporic fungi (Hibbett et al. 2007; James et al. 2006a, b, 2014) commonly found as saprotrophs and parasites of vascular plants, algae, invertebrate animals, oomycetes, and other blastoclads in soil and freshwater (Sparrow 1960). Unwalled zoospores and zygotes function in dispersal and establishment of new thalli, typically surrounded by a chitin-containing cell wall. Thallus morphology ranges from a monocentric thallus composed of a single sporangium and attached rhizoids (Fig. 2c) to more extensive rhizomycelia (Fig. 3f) and hyphae (Fig. 2b) bearing multiple sporangia (Fig. 3a). Thalli are multinucleate (Fig. 2e) and aseptate, except for pseudosepta (Fig. 2a, e) that arise irregularly or septa that delimit sporangia and gametangia (Figs. 2c and 3a, c, d). The life cycle may include alternation between haploid gametothallus and diploid sporothallus generations, and in *Coelomomyces,* alternation of hosts as well. In sexual reproduction, pairs of uniflagellated gametes fuse, resulting in biflagellated

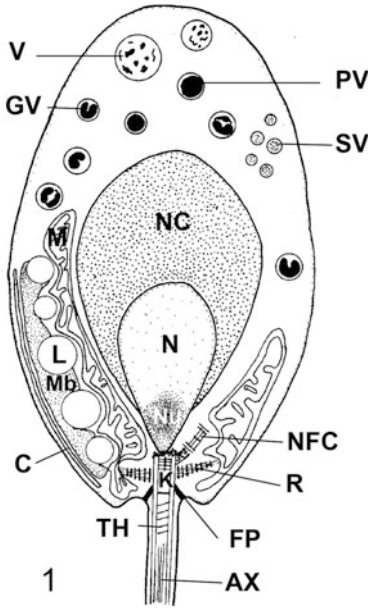

Fig. 1 Summary diagram of a longitudinal section of a blastoclad zoospore as visible with a transmission electron microscope. Characteristic structures include: the nuclear cap [(*NC*), the ribosomal aggregation surrounded by a cisterna continuous with the outer membrane of the nuclear envelope]; the cone-shaped nucleus (*N*) pointed toward the kinetosome (*K*); nucleolus (*Nu*); the nonflagellated centriole (*NFC*); a multilayered, striated rhizoplast (*R*); flagellar props (*FP*), spiral concentric fiber/transitional helix (*TH*); gamma-particle vesicles (*GV*); phosphate-containing vesicles (*PV*); secretory/adhesion vesicles (*SV*); vacuole (*V*); side body complex also known as the microbody-lipid globule complex [consisting of a backing membrane cisterna (*C*), microbody (*Mb*), lipid globules (*L*), and mitochondrion (*M*)]; flagellar axoneme (*Ax*). The anteriorly projecting cage of microtubules extending from the apical end of the kinetosome is not illustrated in the diagram

zygotes. In asexual reproduction, posteriorly uniflagellated zoospores (Fig. 1) are formed and released from thin-walled sporangia. One blastoclad is unusual in the production of amoeboid aplanospores rather than only flagellated zoospores (James et al. 2011; Letcher et al. 2016; Strittmatter et al. 2016). Resistant sporangia (=resting sporangia) usually germinate by an irregular cracking of the outer layer of their thick wall (Fig. 4a), releasing meiospores that give rise to gametothalli. Resistant sporangia are darkly pigmented with ornately sculptured (Figs. 2c and 3b), multilayered cell walls (Fig. 4a) and are highly characteristic of blastoclads.

The real hallmark of the Blastocladiomycota is its characteristic zoospore with distinguishing features visible with light microscopy and even more striking with electron microscopy (Fuller 1977). A prominent nuclear cap crowning a conspicuous cone-shaped nucleus pointed toward the posteriorly directed flagellum (Fig. 1) clearly distinguishes the elongate blastoclad zoospore from motile cells of other organisms. As a zoosporic group in the basal radiation of fungi from a protoctistian

(**c**) *Blastocladiella britannica* monocentric, eucarpic thallus consisting of a resistant sporangium (*RS*) and basal rhizoids (*R*) separated from sporangium by a septum (*S*). Notice the characteristic loose enclosure of the resistant sporangium within the thallus wall (notice space between resistant sporangium and septum). The pitted surface of the

ancestor (James et al. 2006b; Medina et al. 2003; Steenkamp et al. 2006), the blastoclads share certain features with chytrids, different from higher fungi, but also share characteristics with higher fungi distinct from chytrids (see section on "Evolutionary History"). Reflecting an ancient shared ancestry with chytrid fungi, yet also an evolutionary divergence from this group (James et al. 2006a, b), the zoospores of blastoclads may abruptly change directions as they swim, as do chytrid zoospores; however, they typically move in a gliding pattern rather than the hopping motion typical of a chytrid zoospore.

Occurrence

With a global distribution, blastoclads are known from freshwater and terrestrial habitats, but none have been cultured directly from marine habitats (Powell 1993; Sparrow 1960; James et al. 2014). One genus, *Blastocladia*, is composed entirely of obligate fermenters that thrive in stagnant water (Emerson and Natvig 1981). In still water, they are frequently found on submerged, partially decorticated, water-logged twigs or decaying fleshy fruit, especially of the rose family (Whisler 1987). Some members, such as *Blastocladiella*, are most frequently collected in soils from southern latitudes (Sparrow 1960), and *Allomyces* is commonly collected from slowly air-dried soil (Willoughby 1984). Saprotrophs in soil and water are collected on a variety of substrates including seeds, pollen, cellulose, feathers, hair, and chitin (e.g., Czeczuga et al. 2004; Whisler 1987). Others occur as parasites on microinvertebrates in aquatic habitats (e.g., *Catenaria, Coelomomyces, Polycaryum*) or terrestrial habitats (*Catenaria, Sorochytrium*). Still others parasitize terrestrial and aquatic vascular plants (*Physoderma*), algae (*Paraphysoderma*), and other blastoclads (*Catenaria*).

Literature

The most comprehensive analysis of the molecular phylogeny of the Blastocladiomycota revealed that the current classification is in need of revision (James et al. 2014; Porter et al. 2011). Although most monographic works on the

Fig. 2 (continued) resistant sporangium (*RS*) is visible at the edge of the thallus (*arrow*). × 800. (**d**) *Allomyces macrogynus* sporothallus. Bipolar germination of a zoospore. The encysted zoospore is a rounded cell (*C*) from which a rhizoid (*R*) and hypha (*H*) emerge in opposite directions. A nucleus (*N*) is located at the growing tip of the hypha at this stage. × 500. (**e**) *Allomyces macrogynus* sporothallus. Thallus development with hyphal tip branching dichotomously as the tips take on a tuning-fork arrangement. A pseudoseptum (*S*) has formed, and the rhizoidal system (*R*) that anchors the basal cell becomes extensive. The hypha is coenocytic, and scattered nuclei with prominent nucleoli have a "fried egg" appearance. × 500. (**f**) *Allomyces macrogynus* sporothallus. Developing thallus with extensive rhizoids (*R*), a trunk-like basal cell (*BC*) from which sprouts numerous bushy hyphae with characteristic dichotomously branched tips. × 250

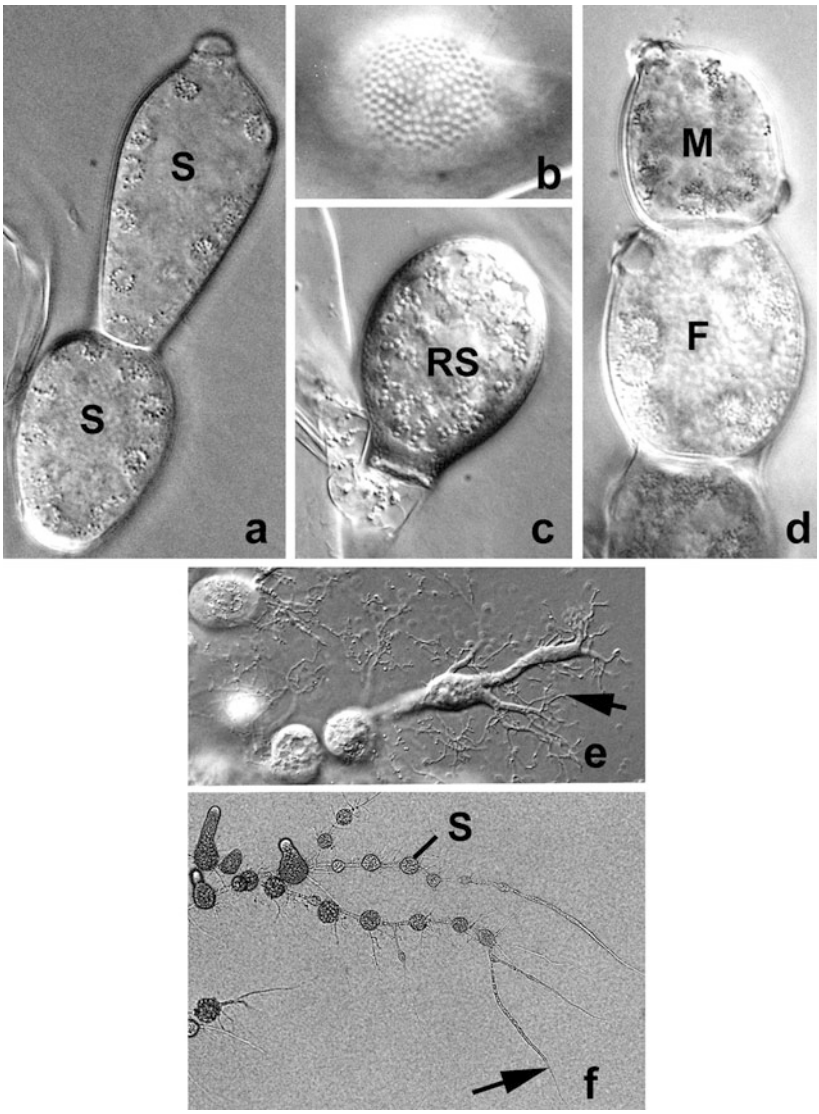

Fig. 3 (**a**) *Allomyces macrogynus* sporothallus. Two terminal sporangia (*S*) with "ring-like" arrangement of tiny lipid globules. A discharge papilla is visible at the apex of the terminal sporangium. × 500. (**b**) *Allomyces macrogynus* sporothallus. (**f**) Rhizomycelium of *Catenaria anguillulae.* Notice the catenulate organization of sporangia (*S*) separated by isthmus cells. The growing tips of the rhizomycelium are finely tapered and bifurcated. × 100

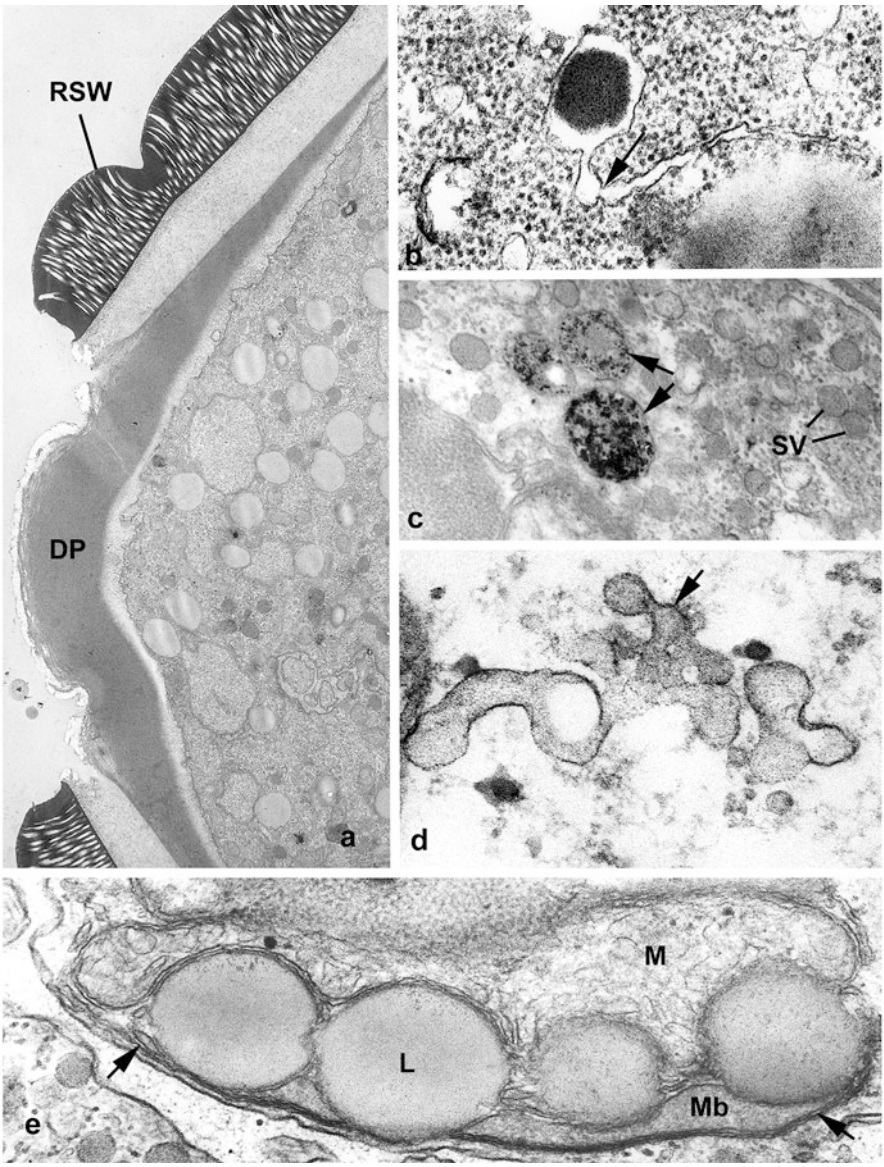

Fig. 4 (**a**) Electron micrograph of thin section through resistant sporangium of *Coelomomyces punctatus* illustrating the thick ornamented cell wall (*RSW*), inner layer of material, and lens-shaped discharge plug (*DP*) that has formed in the opened discharge crack in the wall. × 12,500. (**b**) Formation of a gamma-particle vesicle from a segment of rough endoplasmic reticulum (*arrow*) during zoosporogenesis in *Catenaria allomycis*. Smaller particles have coalesced into a spherical electron-opaque inclusion. × 75,000. (**c**) Cytochemical precipitation of free phosphate with 0.02 M lead nitrate, pH 5.2, into lead phosphate, a heavy metal that is detectable with electron microscopy. The scattered electron-opaque precipitates thus localize the presence of phosphorous in vesicles (*arrows*) in meiospores of *Coelomomyces punctatus*. Smaller secretory vesicles (*SV*) with a finely

Blastocladiomycota are dated, they still serve as invaluable reservoirs of knowledge. Sparrow's (1960) *Aquatic Phycomycetes* includes the most complete monograph of this phylum. In *Chytridiomycetarum Iconographia,* Karling (1977) described life histories, morphology, development, and characteristics of blastoclad species and presented a copious collection of drawings, helping to make this group tractable. Karling (1950) monographed the genus *Physoderma*, placing *Urophlyctis* into synonymy with *Physoderma*; but Sparrow (1962) later argued the morphological distinctions between these two genera. Emerson and Robertson (1974) provided keys to the five genera in the Blastocladiaceae and discussed issues with generic distinctions in this family. Couch and Bland's (1985) monograph of *Coelomomyces* is richly illustrated with light and scanning electron micrographs and is detailed in its review of knowledge of development of this obligate parasite of dipterans and copepods. The genus *Allomyces* has been extensively studied in developmental investigations and much of this work is summarized in Olson's (1984) "*Allomyces*-a different fungus." Longcore's "Chytrid Taxonomy since 1960" is a compilation of new taxa, combinations, and synonymies published since Sparrow's (1960) monograph and available at http://umaine.edu/chytrids/Chytrid-Bibliography/.

History of Knowledge

The recent recognition of the Blastocladiomycota as a Phylum distinct from the Chytridiomycota is based on molecular phylogenetic analyses and supporting biochemical and ultrastructural data (James et al. 2006b). As a relatively small group, it is not surprising that resurgent interest in biodiversity, fueled by molecular phylogenetics, is revealing new taxa and new taxonomic affiliations (Hoffman et al. 2008; James et al. 2014; Johnson et al. 2006a; Porter et al. 2011). The uniqueness of this group was first recognized when Petersen (1909) established the order Blastocladiales, based on a single genus, *Blastocladia* (Reinsch 1878), transferring it out of the Saprolegniales (oomycetes). The generic name is descriptive of the thallus and was derived from combining the Greek *blastos* (=germ or sprout) with *clados* (=branch). New genera were either added or described over the next 100 years until now there are 16 recognized genera (Table 1). Actually, the oldest recognized zoosporic fungus is *Physoderma* (Wallroth 1833), but its blastoclad affinity was not officially recognized until 1980 when, based on zoospore

Fig. 4 (continued) granular matrix are thought to function in cyst coat formation and adhesion during encystment. × 55,000. ultrastructure, Lange and Olson (1980b) transferred it to the Blastocladiales in a new family. Similarly, *Catenaria anguillulae* was classified in the Chytridiales until Couch (1945) transferred it to the Blastocladiales and established a new family.

Practical Importance

Because of the range of substrates used and adaptations for growth in soils and water, blastoclads are important in the biodegradation of organic matter and recycling of nutrients. In addition, the use of parasitic blastoclads to control invertebrates, including nematodes and insects, is a fertile area of investigation. Many years ago, Couch (1945) proposed *Catenaria anguillulae* as a biocontrol agent against root knot nematode of tomatoes, and a recent study has actually demonstrated the efficacy of *Catenaria anguillulae* in controlling the destructive impact of root knot nematode on rice (Singh et al. 2007). Tribe (1977) similarly highlighted the potential of C.

auxiliaris to control sugar beet cyst-nematode, and Castillo and Lawrence (2011) discovered *C. auxiliaris* attacking reniform nematodes on cotton. Under moist environmental conditions, *Myiophagus* is a possible control of scale insects (Karling 1948). Use of *Coelomomyces* as a bioinsecticide against mosquitoes and other dipterans is complex because of its obligatory requirement for an intermediate microcrustacean host and the difficulties in mass producing inoculum. With increased insect resistance to conventional chemical control, attempts to develop *Coelomomyces* for biological control continue (Lucarotti and Shoulkamy 2000; Scholte et al. 2004).

Parasitic blastoclads can also negatively impact agricultural production. *Physoderma* is a parasite of several vascular plants; *P. maydis* causes brown spot and has a significant impact on the commercial production of corn (Karling 1950; Lange and Olson 1980a). *Paraphysoderma sedebokerense* (James et al. 2011) is a recently discovered algal parasite, sister to *Physoderma* and capable of devastating microalgae mass-cultured in large outdoor ponds for commercial production (Hoffman et al. 2008). *Allomyces* and *Blastocladiella* have been reported growing on fish (Chukanhom and Kishio 2004; Czeczuga and Muszynska 1999), but their role as a primary infective agent of vertebrates has not been verified. Perhaps more important in fish production, *Polycaryum laeve* infection of *Daphnia* can adversely influence the access of fish to *Daphnia* as a food source, the long-term availability of *Daphnia* (Johnson et al. 2006b, 2009), and the nutrient content available to other animals that prey on *Daphnia* (Forshay et al. 2008).

One of the most important uses of blastoclads is as popular experimental organisms to study gene regulation during development (e.g., Ojha and Barja 2002; Silva et al. 1987) because of the ease of growing *Allomyces* and *Blastocladiella* in synchronous cultures and their clearly defined developmental stages (germination; vegetative growth; sporulation; motile spore stages).

Assemblages of sequenced genomes of *Allomyces macrogynus, Blastocladiella emersonii,* and *Catenaria anguillulae* are providing a framework for comparative exploration of gene functions (Avelar et al. 2014; Idnurm et al. 2010; Krishnan et al. 2012), adding to insights gained earlier with sequencing and annotation of mitochondrial genomes from *Allomyces macrogynus* (Paquin and Lang 1996) and *Blastocladiella emersonii* (Tambor et al. 2008).

Habitats and Ecology

Blastoclads are important in aquatic and terrestrial ecosystems as decomposers of organic materials and also as parasites (Powell 1993). In having to compete with other soil fungi and bacteria, terrestrial saprotrophic blastoclads could be expected to produce antimicrobial compounds. Interestingly, a preliminary study demonstrated that several fast-growing isolates of *Allomyces* could inhibit the growth of *Streptococcus* and *Staphylococcus* in culture (Lorelli and Held 1983), a result that invites additional exploration. Blastoclads are themselves hosts to very few other organisms, but may be subject to RNA-virus infections (Khandjian et al. 1977) or attack

by other zoosporic fungi such as *Olpidium* and *Rozella* as well as the blastoclad *Catenaria* (Karling 1977). Whether blastoclads are able to mount effective defenses against invaders or whether the evolutionary radiation of parasitic groups has not exploited these organisms as hosts are fascinating questions.

Parasitic blastoclads may impact or control populations in terrestrial and aquatic habitats (Gleason et al. 2010). For example, *Catenaria* species parasitize nematodes, rotifers, and midges (Sparrow 1960), while *Sorochytrium milnesiophthora* infects tardigrades inhabiting clumps of moss (Dewel and Dewel 1990). In mesocosm experiments, Johnson et al. (2006b) discovered that *Polycaryum laeve* increased the visibility of *Daphnia* and as a consequence increased their susceptibility to predation by fish in waters low in dissolved organic carbon, effectively reducing population levels of *Daphnia*. Additionally, *Coelomomyces'* attacks on mosquito larvae (including the vector for malaria) impact adult mosquito populations. Typically mosquito larvae infected with *Coelomomyces* die before they pupate and morph into adults. But lightly infected larvae may mature into adult mosquitoes, in which case, in females the fungus invades interstitial spaces of ovary tissue, preventing egg formation. The female's blood meal and resulting hormonal changes trigger the transformation of *Coelomomyces* thalli into resistant sporangia the size of normal mosquito eggs. Thus, when the female mosquito tries to oviposit eggs, fungal-resistant sporangia are released instead, further dispersing this pathogen (reviewed in Lucarotti and Shoulkamy 2000; Powell 1993; Scholte et al. 2004).

Many blastoclads are adapted to their environment because of responses to chemical and environmental signals. For example, it is advantageous to individual blastoclads to colonize new substrates when original substrates become crowded. Obviously, individual blastoclad sporangia cannot move, but their zoospores can. During zoosporogenesis, and only during this stage in *Blastocladiella emersonii*, sporangia release a soluble compound that maintains zoospore motility and blocks the activity of agents which induce encystment. In this manner, zoospores are most likely to swim into new areas and colonize new substrates devoid of other blastoclads (Gottschalk and Sonneborn 1985). As another example, Deacon and Saxena (1997) have shown that zoospores of *Catenaria anguillulae* exhibit chemotaxis to exudates from excretory pores and the anus of their nematode hosts, sites where they can readily infect the host. The attraction is so great that numerous zoospores congregate and encyst in these areas, and the collective onslaught aids the blastoclad in overcoming host defense mechanisms (Jansson and Thiman 1992). Finally the movement of zoospores toward light may increase their access to plant organic matter. Zoospores of several species of *Allomyces* exhibit phototaxis to light (Olson 1984; Robertson 1972). Physiological (Saranek and Foster 1997), and comparative genomic studies (Avelar et al. 2014; Idnurm et al. 2010; Krishnan et al. 2012) reveal that animal-like type II rhodopsins, distinct from opsin pigment genes found in other fungal lineages, may be involved in light sensing responses in blastoclads. Recently protein localization at the surface of the microbody-lipid globule complex (MLC) has implicated the blastoclad "side-body complex" in rhodopsin-based photoreception and signal transduction in response to blue-green light (Avelar et al. 2014).

Characterization and Recognition

Morphology and Life Cycles

Within the Blastocladiomycota, there is a great range in thallus morphologies and complexities of life cycles. Thallus types may be monocentric (Fig. 2c), polycentric-rhizomycelial (Fig. 3e and f), or hyphal (Fig. 2a and b). Life cycles vary in complexity, even within the same genus, but all life histories are variations on a general pattern (reviewed in James et al. 2014). Unusual among fungi, blastoclads exhibit alternation of generations with two forms of thalli, and in *Coelomomyces*, alternation of hosts as well. Emerson (1941) first elucidated the differences in complexity of life cycles and divided *Allomyces* into three subgenera (an approach Karling [1973] later followed in *Blastocladiella)*: (1) Subgenus *Euallomyces* includes all species of *Allomyces* with a long-life cycle consisting of isomorphic gametothallus and sporothallus. (2) In subgenus *Cystogenes*, the gametothallus is reduced to a holocarpic cyst (= the encysted meiospore released from the resistant sporangium on the sporothallus), which is totally consumed when it discharges four gametes. (3) *Brachyallomyces* remains for any species of *Allomyces* for which gamete fusion has not been found.

In the *Euallomyces* long cycle, the diploid sporothallus (Fig. 2f) bears thin-walled multinucleate zoosporangia (Fig. 3a) and thick-walled pigmented resistant sporangia (Fig. 3b and c). The zoosporangium produces diploid zoospores (mitospores) which regenerate the sporothallus. Meiosis occurs in resistant sporangia (Lange and Olson 1980a; Olson 1984; Olson and Reichle 1978a, b), which subsequently produce haploid zoospores (= meiospores). After a period of motility, meiospores encyst and germinate into haploid gametothalli.

In *Allomyces*, male and female gametangia are formed on the same gametothallus (Fig. 3d), but in *Coelomomyces* distinct male and female gametothalli are formed (Whisler et al. 1975). Male and female gametes may differ in size as in *Allomyces* or be the same size as in *Catenaria* and *Coelomomyces*. Unlike their colorless female counterparts, male gametangia and male gametes are orange because they contain carotene. Pommerville (1977, 1978) elucidated the role of chemical attractants in gamete recognition in *Allomyces*. Female gametes produce a sesquiterpene-type pheromone, sirenin (Pommerville 1977) that specifically attracts the male gametes; and male gametes similarly produce a compound, parisin (Pommerville and Olson 1987), that specifically attracts female gametes. In the presence of the hormones, gametes' swimming patterns are altered into ever narrowing arc paths until contact is made between male and female gametes (Pommerville 1978). Gametes fuse in pairs and swim as a biflagellated zygote, eventually withdrawing their flagella into the spore body, encysting, and germinating into a sporothallus.

Zoospore Ultrastructure

All flagellated spores of blastoclads (mitospores, meiospores, gametes, or zygotes) have similar and characteristic architectures with compactly organized organelles

(Fig. 1). Spores are nonassimilative and depend solely on endogenous reserves for energy, with little or no protein synthesis. The molecular machinery needed for zoospore motility and for zoospore germination, including undulopodia withdrawal, cyst-wall formation, and germ-tube initiation, is already packaged within the spore (Silva et al. 1987). The flagellar apparatus is in the posterior end of the zoospore and typically consists of the kinetosome, a nonflagellated centriole (=secondary centriole) lying at an angle and anterior to the kinetosome, a multilayered striated rhizoplast (root) positioned perpendicular to the plane of flagellar beat and connected to the basal mitochondrion (Aliaga and Pommerville 1990), and microtubules typically arranged in nine groups of threes extending symmetrically from dense material around the kinetosome as a cage around the nucleus and nuclear cap. All ribosomes are aggregated into a nuclear cap and surrounded by a cisterna that is continuous with the outer membrane of the nuclear envelope (Fig. 1). Messenger RNAs, arrested at the elongation stage, are sequestered among the ribosomes of the nuclear cap and are not translated until the ribosomes in the nuclear cap disperse during zoospore germination (Jaworski 1987; Jaworski and Stumhofer 1981). Minor variations on this basic design are found, such as the absence/reduction of a prominent rhizoplast in zoospores of *Physoderma, Sorochytrium,* and *Coelomomyces,* the lack of a nonflagellated centriole in *Coelomomyces*, and microtubules evenly spaced in *Sorochytrium* (Table 1).

Most blastoclad zoospores store a large amount of lipids that is metabolized with the coordination between microbodies and mitochondria (Powell 1978a). First called the side-body complex because of its conspicuous location in zoospores (reviewed in Fuller 1977; Fuller and Olson 1971), electron microscopy determined that this structure was an assemblage of microbodies, lipid globules, mitochondria, and membrane cisternae (the microbody-lipid globule complexes = MLC), an energy generation unit (Powell 1978a). In the MLC, lipid globules are sandwiched between microbodies and mitochondria (Fig. 4e), which extend toward and branch around the kinetosome. Typically there is also a single membrane cisterna (the backing membrane) associated with the MLC. Examination of zoospores of a range of species reveals that the basic organization of the MLC may vary in different genera (Dewel and Dewel 1990), but the association between these organelles is a consistent feature. However, in zoospores of the anaerobic genus *Blastocladia*, mitochondria and lipid globules are sparse, and microbodies and the backing membrane are absent (Lingle and Barstow 1983). There is evidence of stored glycogen in blastoclad zoospores, appearing to be most abundant in anaerobic members (Lingle and Barstow 1983).

Zoospores contain several classes of vesicles. One type is the gamma-particle vesicle enclosing a large electron-dense cup-shaped or globular particle that is synthesized during zoosporogenesis in the rough endoplasmic reticulum (Fig. 4b) as small particles which later coalesce (Barstow 1979). Biochemical analysis of the gamma particle shows that it is composed of two major proteins with high basic amino acid content (Hohn et al. 1984). The compact structure of the gamma particle breaks down during germination of the zoospore, suggesting the use of stored proteins during this process. A second type of vesicle contains an electron-dense

globule and is sometimes confused with the gamma-particle vesicle. However, energy dispersive X-ray analysis (Aldrich et al. 1984) and cytochemistry (Fig. 4c) demonstrated that this inclusion contained phosphorus and calcium and may be polyphosphate granules. Another group of vesicles, secretory vesicles, has a finely granular and homogenous matrix (Fig. 4c) and is implicated in zoospore adhesion or coat formation during encystment (Dewel and Dewel 1990; Martin 1971).

Systematics and Representative Genera

Thallus forms, host, and nutrition are used as primary characters for delimitation of the six families and sixteen genera of the Blastocladiomycota (Table 1). Formal assignments of *Polycaryum* and *Myiophagus* to families have not been made and await more extensive molecular characterization. These two genera are therefore currently considered *incertae sedis* within the Blastocladiomycota (Table 1).

1. Physodermataceae includes obligate parasites of plants, often in aquatic or moist environments, and forms a clade sister to other members of Blastocladiomycota in molecularly based phylogenies (James et al. 2006b, 2014; Porter et al. 2011). Unlike other members of the Blastocladiomycota, Golgi cisternae are stacked into dictyosomes (Fig. 27 in Lange and Olson 1980a). Karling (1950) placed *Urophlyctis* into synonym with *Physoderma*. Molecular phylogenetic analyses from herbarium specimens of *Physoderma* and *Urophlyctis*, however, place representatives of each genus as sisters in monophyletic clades (James et al. 2014; Porter et al. 2011), supporting the distinctiveness and monophyly of each genus and Sparrow's (1962) questioning of the validity of the earlier synonymy of *Urophlyctis* with *Physoderma* (Karling 1950). *Physoderma* produces two types of thalli on hosts, an epibiotic-monocentric thallus and an endobiotic-rhizomycelial thallus. The rhizomycelium of *Physoderma* generates a variety of intercalary enlargements, and resistant sporangia are formed from spindle-shaped or turbinate swellings (Karling 1950; Sparrow 1962). Resistant sporangia are characteristically large with sculptured walls, and at germination a large operculum is pushed open or a crack forms as the inner sporangial wall layer protrudes through the opening (Lange and Olson 1980a). As Sparrow (1962) discusses, *Urophlyctis* unlike *Physoderma* stimulates gall formation in hosts and can possibly be distinguished based on subtle morphological differences.
2. Paraphysodermataceae. *Paraphysoderma sedebokerense,* an algal parasite that produces amoeboid aplanospores within a monocentric, eucarpic thallus, has recently been described (James et al. 2011), and the new taxon is phylogenetically sister to the *Physoderma/Urophlyctis* clade (Hoffman et al. 2008; James et al. 2014; Porter et al. 2011). Rapidly swimming uniflagellate zoospores have also been observed (Strittmatter et al. 2016), but their role in the life history of this organism is not yet resolved. *Paraphysoderma sedebokerense* is highly destructive on *Haematococcus pluvialis* when the green algal host is grown in mass culture for the commercial production of astaxanthin, the red ketocarotenoid used

as a pigment and antioxidant in food, cosmetic, and pharmaceutical industries (Guerin et al. 2003; Strittmatter et al. 2016). The same species infects the green alga *Scenedesmus dimorphus* grown in mass culture for biofuel production (Letcher et al. 2016). On its host, *Paraphysoderma* produces an epibiotic thin-walled sporangium with a single rhizoid axis, and under certain conditions, it also produces resting sporangia with thick walls (Letcher et al. 2016). Typical of resting sporangial germination in the Blastocladiomycota, the outer wall cracks open during germination and discharge of spores. A recent ultrastructural study demonstrated the presence of synaptonemal complexes in thick-walled resting sporangia, indicating the site of meiosis (Letcher et al. 2016). In an ultrastructural study, both nonflagellated and flagellated spores were observed in resting sporangia (Letcher et al. 2016); thus, details of the life history of this organism remain to be elucidated.

3. Members of the Coelomomycetaceae are obligate parasites of mosquitoes, flies, ostracods, and copepods. *Coelomycidium* and *Coelomomyces* in the Coelomomycetaceae diverge from the Physodermataceae in molecular analyses and are sister to a clade containing Catenariaceae and Blastocladiaceae (James et al. 2006b; Porter et al. 2011). The life cycle of *Coelomomyces* requires an alternation between a dipteran primary host housing the sporothallus and a copepod or ostracod secondary host housing the gametothallus. The resistant sporangium is the only stage with a thick cell wall (Fig. 4a) and able to survive adverse environmental conditions.

   Zygotes typically infect mosquito larvae during the first or second instar stages (Travland 1979). The thallus begins as an unwalled protoplast discharged from the casing of an encysted zygote and gains entry into the host through the cuticle and epidermis. The thallus eventually moves into the coelomic cavity where it produces unwalled but carbohydrate-coated hypogens and branching filaments (Couch and Bland 1985; Powell 1976, 1994). The fungus acquires nutrients from the haemocoel and adjoining fat bodies, but can also invade other host tissues, eventually filling the larva with thick-walled resistant sporangia and killing the host. Resistant sporangia crack open (Fig. 4a) and release meiospores that infect a secondary copepod or ostracod host (Federici and Lucarotti 1986). Within the secondary host, distinctive colorless female gametothalli and orange-male gametothalli grow (Whisler et al. 1975). At maturity, the gametothalli cleave into gametes (Lucarotti and Federici 1984). Following death of the host, gametes escape and fuse in pairs forming biflagellated zygotes (Travland 1979). Zygotes then infect mosquito larvae and reestablish the sporothallus stage. Lightly infected larvae may pupate and morph into adults, in which case the female mosquito distributes resistant sporangia of the parasite rather than her own eggs (reviewed in Lucarotti and Shoulkamy 2000; Powell 1993; Scholte et al. 2004).
4. The two genera classified in the Catenariaceae (Table 1) are nutritionally diverse and include parasites of insects (especially midge egg masses), rotifers, nematodes, copepods, sheep liver flukes, and the blastoclad *Allomyces,* as well as saprotrophic members utilizing keratin and plant substrates (Couch 1945; Karling

1965; Martin 1991; Tribe 1977). *Catenophlyctis* (Karling 1965) is a commonly found soil keratinophilic blastoclad that produces both monocentric and polycentric thalli. Its resistant sporangia are amber to dark brown, but unlike those of *Catenaria,* do not lie free within the thallus wall. *Catenaria* produces a dendritic rhizomycelial sporothallus (Figs. 3e), eventually consisting of tubular, sterile isthmuses adjoining spherical zoosporangia (Fig. 3f) and resistant sporangia held loosely within the thallus. Rhizoids emanate from the surface of either the sporangium or the isthmuses, and the pointed tips of the rhizomycelium branch dichotomously (Fig. 3e and f). Early development of *C. allomycis* and *C. anguillulae* differs. *Catenaria allomycis* is an obligate parasite of *Allomyces*. It releases an unwalled spherical protoplast directly into the host cytoplasm (Powell 1978b). The round-cell stage produces a granular cell wall and then begins to elongate into a walled rhizomycelium. In response to the infection, the host proliferates an endoplasmic reticulum investment around the developing sporothallus of the parasite (Powell 1978b). The life cycle of *C. allomycis* is of the *Cystogenes* type, with a reduced gametothallus represented by a single cyst which releases four isogametes (Couch 1945). *Catenaria anguillulae* is a facultative parasite of nematodes, sheep liver flukes, and copepods. In *C. anguillulae*, the encysted spore germinates in a monopolar manner and produces a walled rhizomycelium directly within the host cell. No fusion of gametes (*Brachyallomyces* type) is known for this species, but detection of synaptonemal complexes in resistant sporangia of *C. anguillulae* suggests that meiosis occurs prior to resistant sporangium germination and release of meiospores (Olson and Reichle 1978a). The site of diploidization is not resolved.

Phylogenetically *Catenophlyctis variabilis* clusters with isolates identified as parasites of nematodes, *Catenaria anguillulae. Catenaria spinosa* and *C. uncinata*, parasites of midge eggs, however cluster in another clade. These results suggest that the genus *Catenaria* as currently circumscribed is not monophyletic (James et al. 2014; Porter et al. 2011).

5. The Blastocladiaceae is the only family composed entirely of saprotrophs. Thalli of the five genera in this family (Table 1) range from eucarpic, monocentric forms (Fig. 2c) to mycelial forms with indeterminate growth (Fig. 2b and e). Germination of the encysted zoospore or zygote is bipolar (Fig. 2d), and studies have demonstrated antigenic differences between the rhizoidal and hyphal surfaces of *Allomyces macrogynus* (Fultz and Sussman 1966). *Allomyces* is mycelial and grows as a saprotroph on decaying plant and animal matter. It has a characteristic basal cell, anchored with rhizoids, that is most obvious early in development (Fig. 2e). The apex branches in a tuning-fork manner (sympodially or dichotomously) (Fig. 2e and f). Sporangia (Fig. 3a), resistant sporangia (Fig. 3b and c), or gametangia (Fig. 3d) are typically formed at the hyphal apex. Pseudosepta are obvious along hyphae (Fig. 2a and e) as is also an apical structure that corresponds to the location of the Spitzenkörper (Fig. 2b) (defined below). Species of *Blastocladiella* (Couch and Whiffen 1942) bear a single zoosporangium, resistant sporangium (Fig. 2c), or gametangium at the apex of an unbranched basal cell and can appear simply as a monocentric thallus (Fig. 2c). There may be some space

between the resistant sporangium and the thallus wall (Fig. 2c). *Blastocladia* has a similar thallus with a trunk-like basal cell attached to the substrate with rhizoids, but the apex of the basal cell is lobed or branched. On natural substrates, *Blastocladia* grows in crisp white tufts or pustules. Significantly this genus is an obligate fermenter and functions as a facultative anaerobe. It requires a carbohydrate source, such as found in fleshy fruits or twigs, for fermentation. However, unlike obligatory anaerobic rumen fungi, *Blastocladia* cells contain mitochondria and not hydrogenosomes (Gleason et al. 2002; Lingle and Barstow 1983). The Blastocladiaceae is in need of revision because it is polyphyletic in molecular phylogenetic analyses with representatives of *Blastocladiella* failing to place in the clade with *Allomyces, Blastocladia,* and *Microallomyces* (James et al. 2014; Porter et al. 2011).

6. The Sorochytriaceae contains a single species, *Sorochytrium milnesiophthora*, a parasite of the moss-inhabiting tardigrade, *Milnesium tardigradum* (Dewel et al. 1985). This blastoclad produces two thallus forms. In the living host, it forms the parasitic endobiotic colonial phase consisting of a sorus with numerous sporangia that scatter within the host body cavity. When the host dies, *Sorochytrium* grows externally as a saprotrophic rhizomycelium. Eventually, the whole body of the tardigrade becomes filled with orange thick-walled resistant sporangia.

Maintenance and Cultivation

Whisler (1987) gave an insightful summary of techniques widely used to collect and isolate blastoclads, building on more classical narratives (Sparrow 1960). Approaches for isolation of zoosporic fungi from soil and water can also be found in more general but still detailed descriptions (Bills et al. 2004; Fuller and Jaworksi 1987; Shearer et al. 2004). Because many blastoclads produce thick-walled resistant sporangia that withstand desiccation, use of slowly air-dried soils is an effective approach to select for genera such as *Allomyces, Blastocladiella*, and *Catenaria* (Willoughby 1984). It is sometimes necessary to store a dried sporothallus for a period of time and rehydrate it to induce germination of resistant sporangia. Many blastoclads (*Coelomomyces, Catenaria allomycis, Physoderma*) are obligate parasites and have only been grown in two-membered or mixed cultures. Barr and Babcock (1994) developed a method for cryopreservation and long-term storage of cultures that has proved in practice successful with recovery of cultures frozen 20 years previously.

Flooding about a teaspoon of soil with sterile pond water or distilled water and baiting with a variety of substrates (keratin, chitin, cellulose, pollen, oil-rich seeds) can result in growth of saprotrophic blastoclads on these substrates. This "enrichment" technique allows the proliferation of organisms which can then be brought into pure culture by streaking thalli or zoospores on nutrient media containing antibiotics (250 mg/L penicillin and streptomycin). Dilute nutrient media at 20–50% strength are commonly used for initial isolation media. With repeated transfers, isolates become adapted to richer media on which they survive for longer

times. Two common media (Whisler 1987) used for maintenance of blastoclads are YpSs (20.0 g soluble starch, 1.0 g yeast extract, 1.0 g K_2HPO_4, 0.5 g $MgSO_4 \cdot 7H_2O$, 1 L distilled water, 20 g agar) and PYG (1.25 g peptone, 1.25 g yeast extract, 3.0 g glucose, 1 L distilled water, 20 g agar).

Because it is an obligate fermenter and facultative anaerobe, the genus *Blastocladia* is often collected on submerged twigs and fleshy fruits in small bodies of stagnant waters with reduced concentrations of dissolved oxygen (Gleason et al. 2002; Whisler 1987). A common method for collecting is to take a firm apple, prick its surface repeatedly with a needle, and place the apple in a wire cage. The cage is left submerged in a pond for several weeks to several months. The apple is then brought into the lab and inspected for the crisp white pustules of blastoclads. If pustules are present, the surface is washed vigorously to remove biofilms, and thalli are transferred with a fine needle to nutrient media containing antibiotics. To maintain *Blastocladia* in broth culture, it is necessary to neutralize the lactic acid it produces with a base. It is grown in broth in an Erlenmeyer flask with a side arm containing 0.5 M NaOH, added as needed to maintain the pH in the 6.7–7.0 range. Broth used contains 3.0 g glucose or glycerol, 1.25 g yeast extract, 1.25 g peptone, 1.36 g KH_2PO_4, 0.71 g Na_2HPO_4, 0.12 g $MgSO_4 \cdot 7H_2O$, 1.0 mg bromocresol purple, a color indicator of pH, 1 L distilled water (Gleason et al. 2002).

Evolutionary History

Early Devonian Rhynie Cherts in Aberdeenshire, Scotland, amassed some of the best preserved fossil remains of zoosporic fungi (Remy et al. 1994). Microscopic preparations of these materials have revealed the presence of thalli that resemble present-day blastoclads. For example, *Paleoblastocladia milleri* produced two types of dichotomously branching thalli bearing gametangia and sporangia in terminal chains. Thus, fully 400 million years ago blastoclads were present on earth and were in the process of their evolutionary radiation (Remy et al. 1994). Another approach to building the evolutionary history of fungi, which generally do not have as abundant fossil record as groups such as higher plants and animals, is the calibration technique (Berbee and Taylor 2007). In this method, groups of organisms with rich fossil records and with different times of first occurrence on earth are used to calibrate the evolutionary rates of base changes in genes through geological time. Estimates based on these models suggest that fungal and metazoan lineages diverged from a shared protoctistan ancestor over a billion years ago and that the basal zoosporic fungi radiated 800 million years ago (Berbee and Taylor 2007; Steenkamp et al. 2006). Thus, zoosporic fungi as members of the supertaxon Opisthokonta are more recent than oomycetes and other flagellated heterotrophs. The timing of the radiation of blastoclads suggests that the advent of plants and animals on land and in wetlands may have provided new hosts and sources of organic substrates for blastoclads, driving their evolution. Consistent with this view, in molecular-based phylogenies of blastoclads, members that are algal and plant parasites are basal (James et al. 2006b; Porter et al. 2011). Later divergences led to blastoclad

saprotrophs and blastoclad parasites of invertebrate animals (James et al. 2006b; Porter et al. 2011).

Numerous molecular phylogenetic studies have suggested that the Blastocladiomycota represent an early radiation of fungi from a protoctistian ancestor, diverging from other groups of zoosporic fungi including chytrids (James et al. 2006a, b; Steenkamp et al. 2006). Phylogenetic analyses of gene sequences place the filose-pseudopodial amoebae group, the nucleariids, as ancestors to the fungi and also diverging from a flagellated protoctistian ancestor (Medina et al. 2003; Steenkamp et al. 2006). Supporting this hypothesis, blastoclad zoospores are capable of amoeboid motion, even when they are undulopidated (Deacon and Saxena 1997). The recent description of a blastoclads capable of producing amoeboid spores (Hoffman et al. 2008; James et al. 2011) further supports the sister relationship of nucleariids to fungi.

As might be expected when techniques and approaches to analyses are still in refinement, alternate phylogenetic hypotheses exist, but consistently the blastoclads are resolved at the basal radiation of the fungi (Aleshin et al. 2007; Liu et al. 2006). Accordingly, in blastoclads and other fungi, cell walls contain chitin as a structural polysaccharide, the essential amino acid lysine is synthesized in the alpha-aminoadipic-acid pathway with distinct enzymes (Nishida and Nishiyama 2000; Vogel 1964), glycogen serves as the major storage carbohydrate, and mitochondria contain lamellate cristae. Consistent with their evolutionary radiation in a lineage leading to higher fungi and separate from chytrids, blastoclads have features found in higher fungi and not in chytrids. Similar to many higher fungi, the poles of the nuclear envelope remain closed during mitosis (Olson 1984) in contrast to open poles found in chytrids. For blastoclads with hyphal growth, the Spitzenkörper (Fig. 2b) is the organizational region for tip elongation (Vargas et al. 1993), but thus far a typical Spitzenkörper has not been identified in chytrids. It should be noted, however, that the Spitzenkörper of *Allomyces* consists of a granular/fibrillar matrix that excludes ribosomes and other organelles, whereas in regularly septate fungi, the Spitzenkörper contains an aggregation of apical and microvesicles (Vargas et al. 1993). Also similar to most fungi and unlike chytrids, most blastoclads (*Physoderma* and *Paraphysoderma* are exceptions) have been reported to produce Golgi equivalents (Fig. 4d; Bracker 1967) in their endomembrane system (Feeney and Triemer 1979; Sewall et al. 1989) rather than the stacked cisternae in dictyosomes characteristic of chytrids and most other eukaryotic organisms.

Blastoclads differ from chytrids in additionally significant ways. Meiosis in blastoclads is typically sporic (Lange and Olson 1980a; Olson 1984; Olson and Reichle 1978a, b), whereas in chytrids it is zygotic. Cleavage of blastoclad zoospores begins with the growth of the flagella into a flagellar vesicle followed by cytoplasmic cleavage (Renaud and Swift 1964), while in chytrids the zoospore body and flagella are cleaved at the same time. On the other hand, indicative of an ancient shared flagellar ancestor, both blastoclads and chytrids have cholesterol rather than ergosterol as their major sterol (Weete et al. 1989), nine flagellar props connect the zoospore kinetosome to the plasma membrane (Barr 1981; Barr and Hadland-Hartmann 1978), and the transition zone between the kinetosome and flagellum contains a spiral

concentric fiber sometimes called a transitional helix (Barr 1981, 1992) (Fig. 1). Morphological and developmental characteristics in Blastocladiomycota, thus, support the reliability of molecular-based phylogenetic hypotheses and define blastoclads as a zoosporic fungal group distantly related to, but distinctive from, chytrids.

Acknowledgments The author is grateful to Dr. Peter Letcher for assistance in assembling illustrations. This work was supported in part by All Fungal Tree of Life (AFTOL) DEB-0732599 and Partnerships for Enhancing Expertise in Taxonomy (PEET) DEB-0529694 grants from the National Science Foundation.

Chytridiomycota

42

Martha J. Powell

Abstract

The Chytridiomycota is a group of fungi characterized by the production of zoospores with a single posteriorly directed flagellum. The thalli of these fungi are typically microscopic and varied. The advent of molecular phylogenetics combined with analyses of zoospore ultrastructural characters has transformed our understanding of the relationship of these fungi and has revealed greater genetic diversity than expected. What was once the single order Chytridiales is now ten monophyletic orders. *Rozella*, *Olpidium*, and the Blastocladiomycota, organisms once thought to be within the Chytridiomycota, diverge in separate lineages and are no longer included in the Chytridiomycota. The Neocallimastigomycota are sister to Chytridiomycota, but they are distinct in their zoospore ultrastructure, behavior of nuclear envelope during mitosis, and specific adaptation as anaerobes to digestive systems of herbivores. Molecular characterization of environmental samples demonstrates that zoosporic fungi are widespread and can survive in a range of habitats, from oceans to freshwater and even harsh environments including under artic snow or in exposed soils in alpine regions. The importance of these organisms as parasites, saprotrophs of refractory materials, and components in food webs is discussed. Ways to collect, culture, and characterize these organisms are highlighted. Current classification based on molecular and ultrastructural analyses is described.

Introduction

General Characteristics

In the previous edition of *Handbook of Protoctista*, the Phylum Chytridiomycota *sensu lato* included all posteriorly uniflagellated zoosporic osmotrophs (Barr 1990). Multigene-based phylogenies, however, revealed unexpected genetic diversity among these organisms, as well as evidence that the Chytridiomycota was paraphyletic (James et al. 2006a, b). As a consequence, the Phylum Chytridiomycota was retained *pro parte* and redescribed, circumscribing a monophyletic group (Hibbett et al. 2007), and two new Phyla were established for excluded taxa. (1) The Phylum Neocallimastigomycota (neocallimastigos), a clade sister to the Chytridiomycota, was erected (Hibbett et al. 2007) for specialized obligate anaerobes that reproduce with zoospores bearing single to multiple posterior undulipodia and that inhabit the digestive systems of ruminate and other herbivores (Ho and Barr 1995; Mountfort and Orpin 1994; Trinci et al. 1994). (2) The order Blastocladiales was elevated to the Phylum Blastocladiomycota (James et al. 2006b) as a monophyletic lineage diverging among filamentous, non-zoosporic higher fungi, rather than with the Chytridiomycota. Morphological, developmental, and ultrastructural characters support the molecular distinctions of the three phyla of zoosporic osmotrophic opisthokonts, Chytridiomycota, Neocallimastigomycota, and Blastocladiomycota (Hibbett et al. 2007; James et al. 2006a, b; Powell and Letcher 2012, 2014a, b).

This chapter emphasizes the Phylum Chytridiomycota as currently described, including its two classes Chytridiomycetes (= chytrids) and Monoblepharidomycetes (= monoblephs) (Hibbett et al. 2007). Although Doweld (2001) raised monoblephs to a phylum, the group typically places sister to Chytridiomycetes in molecular phylogenetic analyses (Dee et al. 2015). Zoospore ultrastructure and the structure of the mitotic apparatus, with opening of the nuclear envelope only at the spindle poles (Dolan and Fuller 1985; McNitt 1973; Powell 1975, 1980; Roychoudhury and Powell 1991), further substantiate the relationship of these two classes. Thus, in this chapter we discuss monoblephs as a class in Chytridiomycota, following the precedent in Hibbett et al. (2007) and Dee et al. (2015).

This chapter also addresses general characteristics of the smaller but important sister group, the Phylum Neocallimastigomycota (= neocallimastigos) once classified in the Chytridiomycota. Zoospore structure of neocallimastigos is distinct (Gold et al. 1988; Heath et al. 1983; Li et al. 1991, 1993) from that of Chytridiomycota, and

in contrast to Chytridiomycota, the nuclear envelope remains intact during mitosis (Li et al. 1993).

Members of the Chytridiomycota characteristically produce thalli with coenocytic sporangia which discharge zoospores bearing single posteriorly directed flagella. Although basal to the higher fungi, their major sterol is cholesterol rather than ergosterol (Weete et al. 1989). Like fungi, Chytridiomycota gain nutrition as osmotrophs, store carbohydrates as glycogen, synthesize lysine by the α aminoadepic pathway (Vogel 1964), have mitochondria with flattened cristae (Fig. 1b), and construct cell walls containing the structural polysaccharide chitin. In the tree of life, Chytridiomycota are among the earliest radiation of fungi (Steenkamp et al. 2006). Over 1,000 species of Chytridiomycota have been described based on classical taxonomy and thallus structure, but recent molecular and ultrastructural studies indicate that the actual species richness of this group is largely untapped (Letcher et al. 2005, 2008a, b, c, 2012b). Adapting chytrids for survival in diverse habitats and substrates, a variety of thallus forms range from a holocarpic sporangium to eucarpic hyphae bearing numerous sporangia (see Characterization and Recognition). The most distinguishing trait of chytrids is their posteriorly, whiplash uniflagellated zoospore, deriving energy from stored lipid (Powell 1976b, 1978) and glycogen and swimming with a characteristic abruptly darting and hopping pattern, sometimes becoming amoeboid in its motion (Sparrow 1960). After a period of motility, zoospores retract their flagella, produce a wall (Fig. 1a), and develop into thalli that will eventually generate sporangia. For some orders of chytrids, such as the Spizellomycetales, sexual reproduction has never been reported; in others, such as the Chytridiales (Fig. 2c), events of sexual reproduction are well documented. Oogamous sexual reproduction characterizes the monoblephs; but some genera, such as *Harpochytrium,* appear to reproduce only asexually (Powell and Letcher 2012).

Occurrence

Karling's (1977) atlas of Chytridiomycota displays their astonishing shapes, forms, and seemingly unlimited modes of survival in and on living and decaying organisms. Monoblephs (Fig. 2h–j) are typically found in tropical and temperate regions, most commonly in permanent still bodies of freshwater with low silt. They occur primarily as saprotrophs on submerged, water-logged twigs; insect cadavers; and rosaceous fruits (Emerson and Natvig 1981; Emerson and Whisler 1968; Sparrow 1960; Whisler 1987).

Chytrids are essentially universal in aquatic and terrestrial habitats as saprotrophs, biotrophs, and necrotrophs (Fig. 2f) (Powell 1993), including living in higher plants and animals. They thrive in the temperate zone, especially in lakes, ponds, bogs, and acidic forest soils (Bills et al. 2004; Fuller and Jaworski 1987; Shearer et al. 2004; Sparrow 1960) and can readily be isolated from plankton tows, submerged muds, and floating plant and animal debris that accumulate along the shore line of lakes and ponds (Barr 1990, 2001; Sparrow 1960). Although less common than in freshwater,

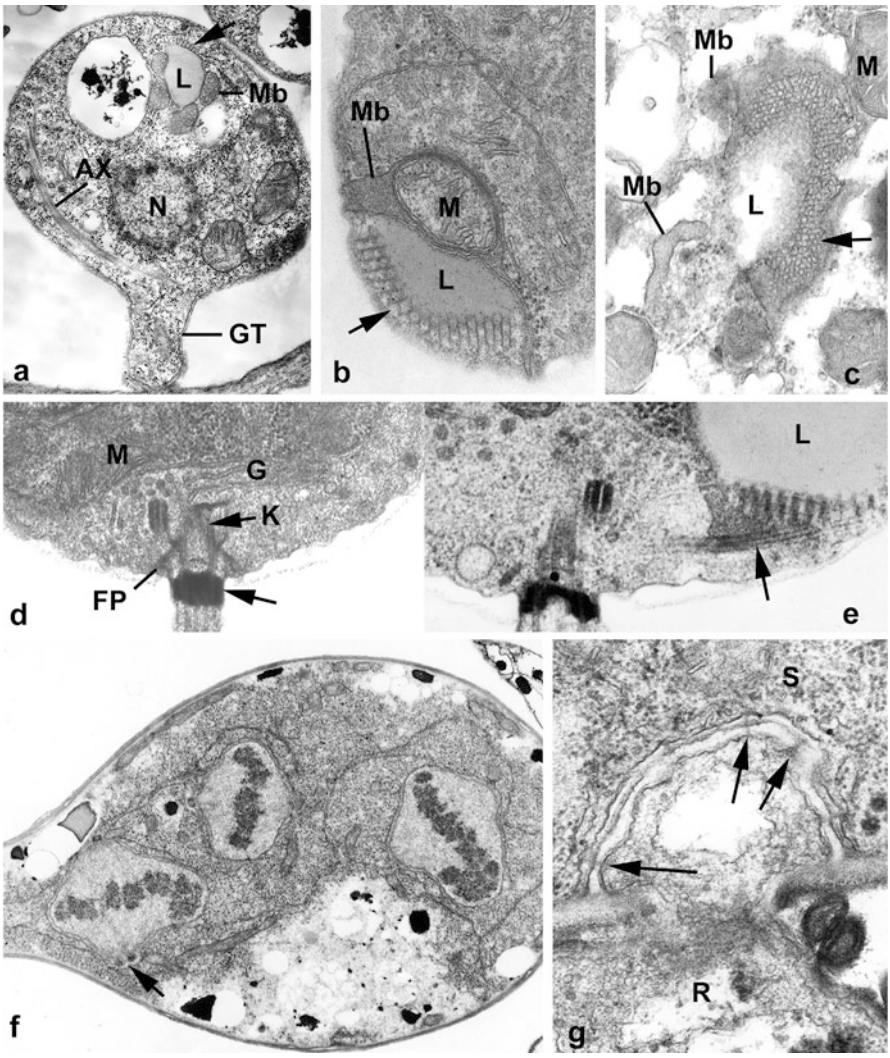

Fig. 1 (**a**) Electron microscopy of germination of a recently encysted zoospore that has generated a germ tube (GT). The nucleus (N) remains in the zoospore cyst. Remnants of the retracted axoneme (AX) microtubules are visible. Organelles in the microbody lipid globule complex have still not dispersed. Microbodies (Mb) are adjacent to the lipid globule (L). On the surface of the lipid the fenestrated cisterna (*arrow*) is still visible. ×13,000. (**b**) Microbody lipid globule complex (MLC) in zoospore of the chytrid, *Chytriomyces hyalinus*. The fenestrated cisterna (*arrow*) underlies the plasma membrane and is adjacent to the lipid globule (which is in contrast to the organization of the MLC of monoblephs where the fenestrated cisterna is adjacent to the microbody). A microbody (Mb) is appressed to the lipid globule (L) and is closely associated with the mitochondrion (M). Notice that mitochondria (M) have flattened cristae. The MLC is involved in energy production for zoospores. ×35,000. (**c**) Microbody lipid globule complex (MLC) in zoospore of the monobleph, *Monoblepharella*. Notice that the MLC organellar organization in the monobleph differs from that of the chytrid in (**b**). The fenestrated cisterna (= rumposome) (*arrow*) contacts the microbody

chytrids are also found in marine habitats, most frequently as parasites of algae (Johnson 1966; Lepelletier et al. 2014; Muehlstein et al. 1988; Müller et al. 1999; Nyvall et al. 1999). Reproduction with zoospores mandates that most chytrids depend upon water for dispersal. However, they are also adundant in dry soils, including halomorphic soils, tree–top canopy soils, grass land soils, and disturbed soil, (Booth 1971; Letcher et al. 2004a, 2014a; Longcore 2005; Lozupone and Klein 2002; Willoughby 1998). They are known to survive in harsh environments (Gleason 1976; Gleason et al. 2004, 2005; Letcher et al. 2004a, 2008b) and have been detected at the earth's Polan regions and high alpine mountains, even under blankets of snow or within sea ice (Freeman et al. 2009; Hassett and Gradinger 2016; Powell 1993; Schmidt et al. 2012; Simmons et al. 2009). With expanded exploration for life in extreme environments (Nagahama et al. 2011), it is expected that more chytrids, as ancient organisms, will be detected in these environments. Consistent with this view, chytrids are now known to inhabit herbivore dung (Davis et al. 2016b; Simmons et al. 2012; Wakefield et al. 2010).

Chytrids are microscopic and seldom observed directly from an environmental sample, other than one containing algae parasitized by chytrids. Thus, their occurrence is typically detected by incubating a sample in the laboratory with the addition of enrichment "baits" for a few days (Bills et al. 2004; Fuller and Jaworski 1987; Shearer et al. 2004). Intensive baiting of soil and aquatic samples has revealed an astounding amount of diversity of chytrids, even from a localized area (Davis et al. 2013). The phylogenetic tree generated from analysis of sequences from chytrids cultured in the Davis et al. (2013) survey had a tree topology corresponding with that from analyses of chytrids collected globally (North American, Latin American, Australia). Thus, these results demonstrate how widespread chytrids are, as well as the value and practicality of intensive sampling from a localized region (Davis et al. 2013).

Culture-independent molecular analyses of environmental samples have also revealed that chytrids are more abundant and more diverse than previously understood (Freeman et al. 2009; Lefèvre et al. 2007, 2008, 2012). PCR methodologies have unexpectedly recovered chytrid ribosomal genes (phylotypes) from novel sites, such as the intestinal system of mice (Scupham et al. 2006). Development of

(**f**) Typical synchronous mitotic division in multinucleate chytrid sporangium. Notice that at metaphase there is perinuclear ER. The nuclear envelope remains intact and opens only at the pole. Paired centrioles are at each end of the spindle poles (*arrow*). ×4,000. (**g**) Dome-shaped septum between sporangium (S) and rhizoid (R). Several plasmodesmata (*arrows*) traverse the septum. ×40,000

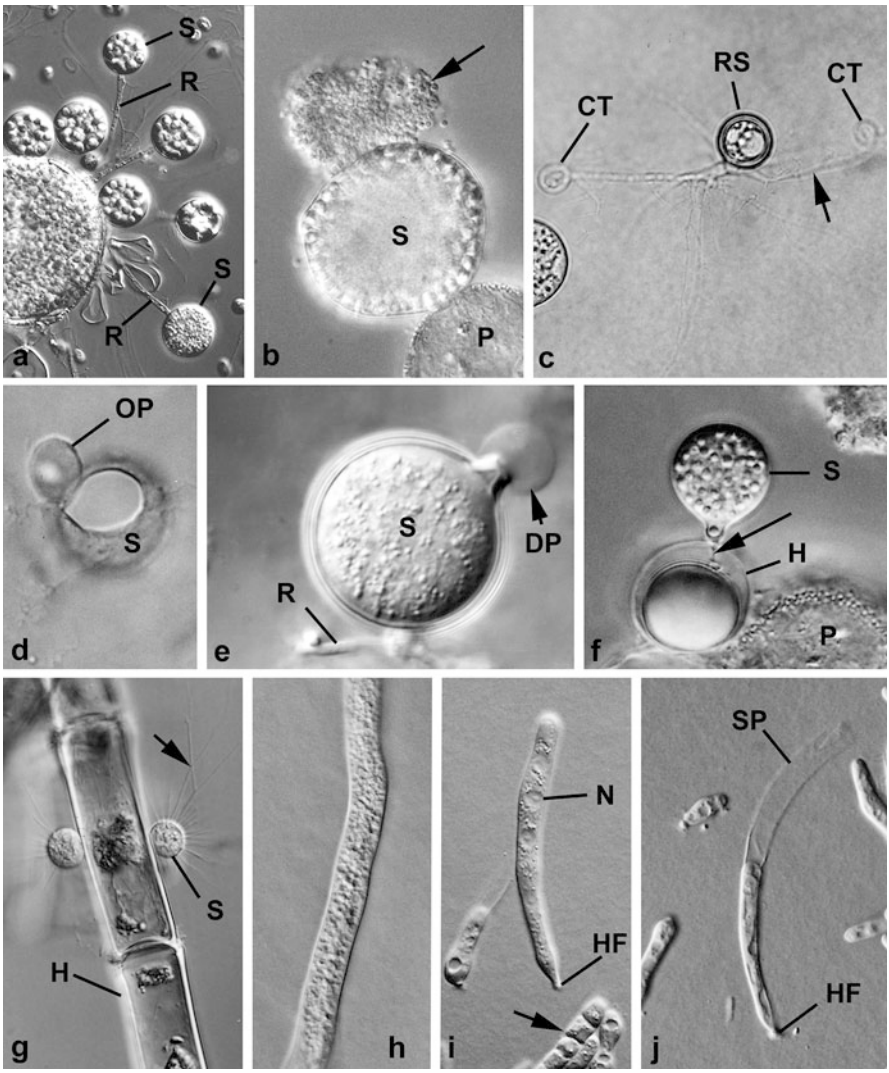

Fig. 2 (**a**) Epibiotic thalli on pollen. The sporangium (S) is on a long, pedicel-like rhizoid (R). ×600. (**b**) Monocentric thallus with a sporangium (S) grows on a pollen grain (P) and is releasing zoospores (*arrow*) in a cluster. The zoospores swarm in the vesicle, become active in swimming, and then they will swim away from the mass. ×800. (**c**) Sexual reproduction in *Chytriomyces hyalinus*. Rhizoids of two contributing thalli (CT) fuse and the contents of both pass through the rhizoids (*arrow*) and fuse. At the point of fertilization, a zygote forms and develops into a thick-walled resting spore (RS). ×700. (**d**) An operculum (OP) is folded back and opens the discharge pore in the sporangium (S). ×500. (**e**) A gelatinous discharge plug (DP) protrudes from an inoperculate discharge tube prior to zoospore discharge from a sporangium (S). Rhizoids (R) are at the base of the sporangium. ×1.000. (**f**) Chytrids may grow on other chytrids. The resting spore (H) of one chytrid is growing on a pollen grain (P), and another chytrid (S) grows on the resting spore, penetrating it with a delicate unbranched haustorium (*arrow*) ×1000. (**g**) Two thalli of a

molecular methods, such as colorimetric hybridization assays using species-specific peptide nucleic acid probes linked to dyes, enable rapid detection of individual chytrid species (Duy et al. 2015).

Literature

The most extensive monographic treatments of chytrids and monoblephs are Sparrow's (1960) *Aquatic Phycomycetes*, Karling's (1964) *Synchytrium*, and Karling's (1977) *Chytridiomycetarum Iconographia*. More recent approaches have focused on taxonomic revisions, as with *Diplochytridium* (Blackwell et al. 2002), or monographic synthesis of single genera, as with *Chytriomyces* (Letcher and Powell 2002a), *Karlingiomyces* (Blackwell et al. 2004), *Obelidium* (Blackwell et al. 2012), *Rhizophydium* (Letcher and Powell 2012), *Septosperma* (Blackwell and Powell 1991), and *Solutoparies* (Blackwell and Powell 1998). A summary of growing knowledge of chytrids based on molecular phylogenetics and comparative zoospore ultrastructure is *Chytrid Fungi on Line* http://nsfpeet.as.ua.edu/. Longcore (1996) maintains a compilation of taxonomic changes among Chytridiomycota since Sparrow's (1960) monograph at http://umaine.edu/chytrids/chytrid-bibliography/.

History of Knowledge

Sparrow (1960) provided a comprehensive historical account of the early systematics of chytrids and monoblephs. The history of chytrids began in 1851 with Braun's description of *Chytridium olla*, a monocentric, epibiotic biotroph of oogonia of *Oedogonium* (Sparrow 1960, 1973). The history of monoblephs began in 1871 when Cornu described *Monoblepharis*, a unique aquatic fungus with sexual reproduction involving nonmotile eggs in oogonia and motile sperms in antheridia. Because of its filamentous thallus, Cornu (1871) considered the new genus a member of the Oomycetes. For most of their history, Chytridiomycota were regarded as Phycomycetes (Fitzpatrick 1930), a collection of heterotrophic fungal and fungal-like organisms with coenocytic thalli that produced spores within sporangia. A major

Fig. 2 (continued) chytrid growing on a filamentous green alga. The chytrids have destroyed the host (H) cytoplasm and chloroplasts are clumped. (**j**) Thallus of *Harpochytrium* which has discharged zoospores, leaving the walls of the empty sporangium (SP) and the basal cell which retains its cytoplasm. Notice the hold fast (HF) of the thallus. ×1,000

advancement was made in understanding the relationships of zoosporic heterotrophs when Scherffel (1925) popularized the concept that the structure of the motile cell was of primary significance as a taxonomic character. Sparrow later adopted a classification scheme that grouped together organisms with posteriorly uniflagellate zoospores (Sparrow 1943), including chytrids and monoblephs as distinct orders (Sparrow 1960). Consistent with this earlier view of relationships, recent molecular and ultrastructural phylogenetic analyses support the related nature of chytrids and monoblephs as sister clades (Dee et al. 2015; James et al. 2006a, b); however, considering the striking differences in pattern of sexual reproduction, they are now classified as classes (Chytridiomycetes and Monoblepharidomycetes) in the Chytridiomycota (Hibbett et al. 2007). Doweld (2001) raised monoblephs to a phylum and created additional lower ranks (reviewed in Powell and Letcher 2012); but consistent with the most recent molecular phylogenetic understanding of monoblephs, we herein consider them as a class (Dee et al. 2015).

Practical Importance

Monoblephs are only known as saprotrophs, and none are recognized to form mutualistic or parasitic relationships. Some monoblephs, however, may be found growing as epiphytes on other organisms, such as snail shells, seeds, and algae (Emerson and Whisler 1968), but no other commensal relationships have been identified.

Chytrids are common in soil and aquatic habitats rich in organic substrates or suitable hosts where they play a vital role in nutrient recycling and control of populations of other organisms (Kagami et al. 2007, 2011, 2012; Powell 1993). The concept of the role of chytrids in a "mycoloop," where zoospores released from sporangia parasitizing inedible phytoplankton facilitate energy transfer as zooplankton feed on energy rich chytrid zoospores, highlights the importance of chytrids in aquatic food webs (Kagami et al. 2014). Chytrids can breakdown substrates that are resistant to decay by most other organisms, including cellulose, keratin, chitin, spores of mosses and ferns, and pollen. They are especially common as necrotrophs and biotrophs of cyanobacteria and algae (freshwater, terrestrial, and marine), oomycetes, protozoa, and microinvertebrates. The large genus *Synchytrium* contains obligate biotrophs of plants and algae (Karling 1964). *Synchytrium endobioticum*, the etiological agent of black wart on potatoes, is an especially troubling pathogen because its resting spores may remain viable for at least 30 years, rendering contaminated soils unsuitable for cropping with potatoes (reviewed in Powell 1993; Smith et al. 2014). This species also has the distinction of appearing on the United States Department of Agriculture Animal and Plant Health Inspection Service list as a "Select Agent" (Smith et al. 2014).

The most notorious chytrid is *Batrachochytrium dendrobatidis* (Bd), the first chytrid known to exploit vertebrate animals (Longcore et al. 1999, 2007). Attacking

frogs, toads, salamanders, newts, and caecilians, *B. dendrobatidis* causes chytridiomycosis and is associated with the alarming decline, extirpation, and extinctions of frogs (Daszak et al. 2004). Retallick et al. (2006) demonstrated that the same strain of Bd could infect both frogs and salamanders. The disease mechanism of Bd is not totally understood, but zoospores produce thalli within the keratinized epidermal cells of frog skins and tadpole mouth parts. Tadpoles do not appear to be adversely affected by the chytrid, but the skin in infected areas of adults becomes thickened (hyperkeratosis). Since amphibians depend in part on their skin for gas exchange and osmotic homeostasis, it is thought that Bd may produce toxic compounds or essentially suffocate the frog. To explore the molecular basis of infection, Rosenblum et al. (2008) compared stage-specific gene expression in sporangia versus zoospores using whole genome arrays. Significantly, they found that genes in a gene family associated with dermatophytous fungi, fungalysin metallopeptidase, was also expanded and differentially expressed in sporangia and zoospores.

Although awareness of *B. dendrobatidis* started in the 1990s, retrospective studies of museum preserved frog specimens indicate Bd has been active since 1932 in Africa where it coexisted with its host (Weldon et al. 2004). How genetically similar strains emerged at the same time all around the world is not known (Morehouse et al. 2003), but one theory is that Bd was carried to new sites with the increased spread of exotic species through the global pet trade (Daszak et al. 2004; Fisher and Garner 2007) and the worldwide distribution of *Xenopus laevis,* first for human pregnancy tests in the mid-1930s and later as a model research organism (Weldon et al. 2004). Infected frogs escaping captivity or interacting with other exotic frog species may have released the pathogenic chytrid onto highly vulnerable non-native hosts with no resistance to Bd. Since the pathogen seems to be most destructive in pristine areas, humans may also spread Bd from their own activities in studying these sites (Weldon et al. 2004). The frog chytrid does not survive high temperatures for long periods of time, growing between 4 °C and 25 °C, and temperature may restrict its spread in some areas (Piotrowski et al. 2004); although, it nonetheless continues to successfully spread on a global scale.

Comparative genomics of Bd strains from geographically diverse regions (Farrer et al. 2011) have revealed more genetic diversity than earlier detected (Morehouse et al. 2003) as well as ranges of pathogenicity, including a hypervirulent global panzootic lineage. Curiously, different strains contain different levels of heterozygosity, suggesting potential for recombination. Neither sexual reproduction nor resistant sporangia (which may be formed either asexually or sexually) has been discovered for this organism, although a case has been made that they do exist (Morgan et al. 2007). On the other hand, a polyploidy event of the total genome could have resulted in "hybrid vigor," which could contribute to its level of lethality.

Recently a second lethal species of *Batrachochytrium*, *B. salamandrivorans*, was discovered in the Netherlands infecting and causing mass die-offs of salamanders (Martel et al. 2014). This species poses a serious threat to the world's salamander and newt populations due to its virulence, host range, and the prevalence of international pet trade of salamanders (Martel et al. 2014).

Habitats and Ecology

Assessments of the importance of chytrids in the environment are increasing, including their roles in trophic transformations as a food source for microinvertebrates (Kagami et al. 2007, 2011, 2014), in the decline of zooplanktonic populations, in control of phytoplanktonic blooms (Beakes et al. 1988, 1993; Canter and Jaworski 1981; Doggett and Porter 1996; Ibelings et al. 2004), and in biodegradation of refractory materials and nutrient recycling (Midgley et al. 2006; Powell 1993).

Chytrid ecology is emerging as a new focus in studies of food webs and energy loops (Gleason et al. 2008; Kagami et al. 2007, 2014), especially in aquatic systems and with the use of molecular detection of chytrids (Lefèvre et al. 2007, 2008, 2012). Ecological studies suggest that chytrids can serve as a food source for microinvertebrates. In an investigation of *Daphnia*, one of the keystone crustacean species in aquatic habitats, researchers found that this filter-feeder readily consumed cholesterol-rich zoospores of chytrids which grew on diatoms. Thus, although the large, silicon-covered diatoms were not palatable to *Daphnia*, chytrids transformed the biomass of these primary producers into chytrid biomass, which *Daphnia* could readily utilize (Kagami et al. 2007). This is only one of multiple potential scenarios where chytrids may have a role in facilitating trophic energy transfer (Gleason et al. 2008).

Canter and colleagues (Beakes et al. 1988, 1993; Canter and Jaworski 1981) conducted foundational work and established the role of chytrids in the regulation of algal and other phytoplankton blooms (reviewed in Ibelings et al. 2004; Kagami et al. 2007; Park et al. 2004; Powell 1993). Light and nutrient levels directly impact the severity of infection, and under some circumstances chytrids can decimate algal populations (Ibelings et al. 2004). The complexity of these interactions (Kagami et al. 2007) is exemplified in Canter and Jaworksi's study (1981) on the requirement of light for zoospores of *Rhizophydium planktonicum* to adhere to their desmid algal host.

As saprotrophs, chytrids play a vital role in decay of refractory materials from plant and animal organic debris and in the recycling of nutrients. Molecular detection of chytrids, coupled with culture studies, will facilitate future studies of the distribution and abundance of chytrids in soil and aquatic habitats (Lefèvre et al. 2007, 2008, 2012). Most of our understanding of abundance and distribution of saprotrophic chytrids has come from baiting and culture studies from environmental samples. The most significant factors that influence chytrid distribution in soil are temperature, moisture, presence of essential ions, availability of substrate or host, pH, and salinity (Booth 1971; Gleason et al. 2004, 2005; reviewed in Letcher and Powell 2001). Certain chytrid species are cosmopolitan and grow within a broad continuum of environmental conditions (Letcher and Powell 2001, 2002b; Letcher et al. 2004a). Other species are more fastidious in their growth requirements, tolerating a narrower range and set of environmental conditions. For example, *Lacustromyces hiemalis* is isolated from ponds and lakes on submerged chitin bait most frequently when the temperature is below 11 °C, and the chytrid can tolerate temperatures only up to 23 °C (Longcore 1993).

Several survey studies have focused on the structure and dynamics of chytrid communities in terrestrial habitats. In a study of chytrid distribution in four forest communities with similar characteristics, Letcher and Powell (2001, 2002b) found that eight common species characterized the community structure. For each site, however, a number of other chytrid species were present but were scarce to rare. Although these less abundant species contributed to the species diversity of a community, they most likely occupied highly specific ecological niches and were more limited in nutrients that they could use. Supporting the concept that resource availability helps shape the pattern of chytrid distribution, Midgley et al. (2006) demonstrated that in soils containing limited amounts of orthophosphate chytrids differed in their abilities to use different forms of phosphorous. Whereas all chytrids studied grew on orthophosphate as the sole phosphate source, species exhibited varying capabilities to use other sources of phosphorous, such as phytic acid and DNA. Thus, limited sources of orthophosphate could affect the distribution of chytrid species in soils.

Other studies showed that distribution of chytrids in the soil is influenced by microhabitat and micro-landscape factors, rather than larger scale influences (Letcher and Powell 2002b). Chytrids are commonly found in soil under clumps of mosses, most likely due to the retention of moisture and accumulation of organic material. In a study of the distribution of chytrids under two species of mosses, significant differences in the diversity and abundances of chytrids were found (Letcher and Powell 2002b). Interestingly, chytrid diversity in soil proximal to the moss reflected the composition of chytrids under the mosses. Thus, chytrids under mosses may provide a point source of inoculum for soils adjacent to mosses, spreading when capillary water is present in the soil.

Potential mutualistic interactions of chytrids with other organisms are underexplored. What appears to be a cross-feeding interaction between a chytrid and alga results in improvement of growth for both organisms and suggests additional dynamics for chytrids in the environment (Picard et al. 2009, 2013). Differences in distribution of chytrids may also be related to the mechanism by which chytrid zoospores detect potential substrates or hosts. In aquatic systems, some, but not all, chytrid zoospores exhibit taxis to light and to specific food sources (Kazama 1972; Moss et al. 2008; Muehlstein et al. 1988). A positive chemotactic and phototactic response offers the advantage of bringing zoospores closer to potential usable plant and animal substrates. Whether or not zoospores of different chytrid species respond to different environmental clues, keeping them out of competition with other chytrid species, has not been explored.

Chacterization and Recognition

As Chytridiomycota, chytrids and monoblephs share numerous characteristics, including the basic architecture of their zoospores (Fig. 1b versus Fig. 1c) and the structure of their mitotic apparatus, which opens only at the spindle poles (Fig. 1f) and discards the mid-zone at telophase (Dolan and Fuller 1985; McNitt 1973; Powell

1975, 1980; Roychoudhury and Powell 1991). The oogamous mode of sexual reproduction among the monoblephs is a clear distinction from the variety of methods for genetic recombination found among the chytrids (Sparrow 1960).

Thallus Forms

Chytrids exhibit a range of microscopic thallus forms which adapt them for life as necrotrophs or biotrophs and as saprotrophs of organic materials. The simplest thallus form is the holocarphic thallus consisting solely of the sporangium (without rhizoids), which occurs within a host or substrate (Fig. 3e). The eucarpic thallus consists of both a sporangium and root-like structures called rhizoids. If the thallus has only a single sporangium, it is considered monocentric (Figs. 2a, b, e and 3c), but polycentric if there are several sporangia (Fig. 3h). The size of sporangia can range in diameter from less than 10 μm (Longcore et al. 2016) to over 100 μm (Sparrow 1960). The eucarpic thallus can be found internal (Fig. 3d) or external to its food source (Fig. 2b); and when epibiotic, the rhizoids anchor the thallus to its substrate (Fig. 2a). Rhizoids, thought to be involved in uptake of nutrients, can be minute and delicate (Fig. 3c) or extensive and coarse (Fig. 3f), increasing the capacity for food absorption. Rhizoids are rich in mitochondria, endoplasmic reticulum, vacuoles, and vesicles but they lack nuclei. When the thallus is developing, there is an unobstructed opening between the rhizoids and sporangium; but as the sporangium matures and comes closer to zoospore formation, a septum containing plasmodesmata (Fig. 1g) forms (Powell 1974; Powell and Gillette 1987). Thus, a route for nutrient uptake remains, but a portal for organellar movement is blocked at this point. The extent of the rhizoids for the eucarpic-monocentric thallus determines how expansive the thallus is (Fig. 3c versus f); consequently, the monocentric thallus has determinate growth and tends to be localized. Its ability to compete with filamentous forms in colonizing a substrate depends on numbers of thalli produced.

Some chytrids form a more complex thallus with multiple sporangia (polycentric) joined by mycelial/rhizoidal segments, the rhizomycelium (Fig. 3h). In contrast to the monocentric thallus, polycentric rhizomycelial growth is indeterminate where growth can be extensively branched and effective in radiating out into the substrate (Fig. 3g). Chytrids with rhizomycelia are common on cellulosic substrates but can be found on chitin and keratin as well (Longcore 1993; Longcore and Simmons 2012; Mozley-Standridge et al. 2009).

Most monoblephs produce a filamentous hyphal-like structure (Fig. 2h), often with a basal holdfast (Fig. 2i, j). The cytoplasm is highly vacuolated (Fig. 2h), giving the hypha a distinctive foamy appearance. Sporangia appear at the apex of these filaments. The thallus is greatly reduced in *Harpochytrium* (Fig. 2i, j) and *Oedogoniomyces*, consisting of a holdfast cell and sporangium (Fig. 2j). *Hyaloraphidium curvatum,* a recently recognized monobleph, earlier thought to be a colorless relative of algae (Forget et al. 2002; Ustinova et al. 2000), has a similarly simple thallus, but its sporangia produce non-motile spores (autospores).

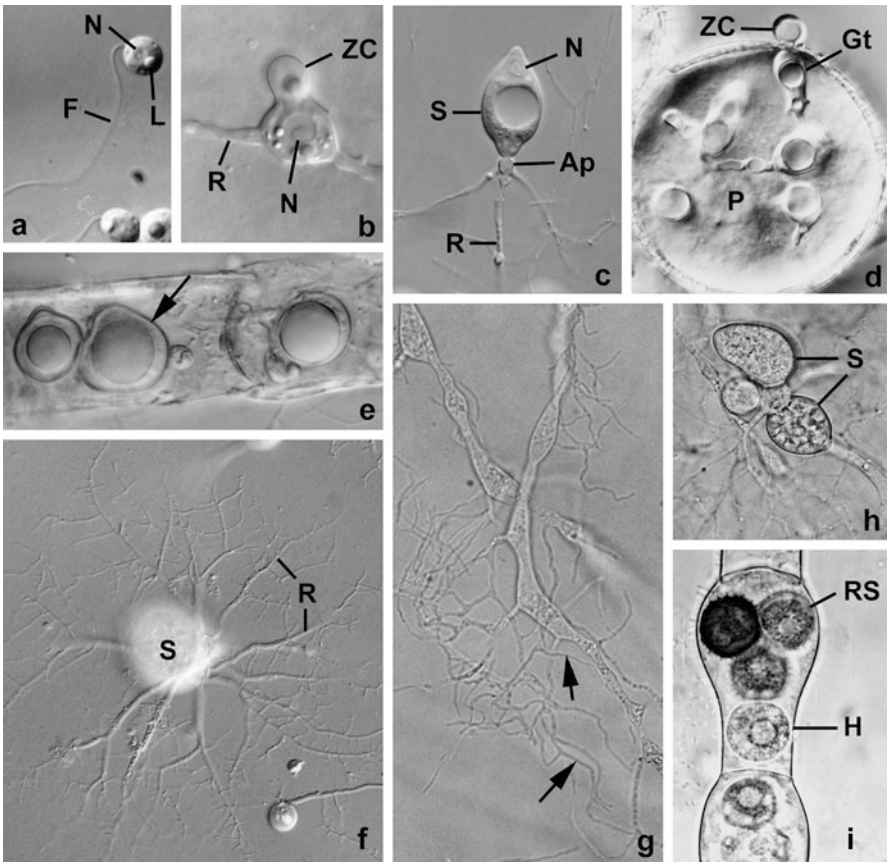

Fig. 3 (**a**) Chytrid zoospore with single nucleus (N), prominent single lipid globule (L), and single, posteriorly directed flagellum (F). Notice the symmetry of the flagellar beat is as a sine wave. ×1,200. (**b**) Thallus development in which the nucleus (N) has migrated from the zoospore cyst (ZC) into the germ tube. The germ tube is enlarging into a sporangium from which rhizoids (R) emanate. ×1,200. (**c**) Thallus development in which the nucleus (N) remains in the zoospore cyst which enlarges into the sporangium (S). The germ tube develops into the apophysis (Ap) and delicate rhizoids (R). ×800. (**d**) Formation of eucarpic, monocentric endobiotic thalli in a pollen grain (P). The zoospore cyst (ZC) is at the surface of a spherical pollen grain (P) and has germinated with a germ tube (Gt), which has penetrated the pollen grain and has just started enlarging into a sporangium as rhizoids branch at the end of the germ tube. The zoospore cyst does not enlarge. ×1,100. (**e**) Endobiotic, holocarpic thalli (*arrow*) within the filament of a green alga. The thallus consists only of the sporangium and no rhizoids are produced. ×750. (**f**) Eucarpic thallus with coarse and extensively branched rhizoids (R) extending from the spherical sporangium (S). ×500. (**g**) Rhizomycelium of *Polychytrium* sp. The area of absorption is enlarged with the fine bifurcations (*arrows*) radiating from the broadly tubular portion of the thallus. ×900. (**h**) Polycentric rhizomycelium of *Polychytrium* sp. with sporangia (S) developing. ×500. (**i**) Resting spores (RS) of *Rozella allomycis* have spiny walls and serve as the only walled stage in the life history of this organism. Notice the hypertrophy of the host (*Allomyces* sp.) hypha (H). ×500

Asexual Reproduction

Zoospores (Figs. 1b–e and 3a) discharged from sporangia (Fig. 2b) are the primary means of dispersal for Chytridiomycota. Zoospores contain a single nucleus (Fig. 3a) and are unwalled, but sometimes covered with a carbohydrate coat (Dorward and Powell 1983; Powell 1994). Zoospores are not an assimilative phase, but rather, they use their endogenous reserves stored as glycogen and prominent or smaller, scattered lipid globules for energy (Powell 1976b, 1978) (Figs. 1b, c and 3a). Powell (1976b) demonstrated that an assemblage of organelles, including microbodies, lipid globules, mitochondria, and a membrane cisterna (the microbody-lipid globule complex – MLC), had the capacity to transform the energy stored in lipid globules. Cytochemical studies showed that MLC microbodies in both monobleph and chytrid zoospores contained catalase (Dorward and Powell 1980; Powell 1976b, 1978), and biochemical analysis revealed that isolated microbodies contained marker enzymes for glyoxysomes (Powell 1976b). The close spatial association of organelles in the MLC and the proximity of the MLC to the flagellum suggested that the MLC served as a "battery" for zoospores, with glyoxysomes and mitochondria working in consort to transform the energy stored in lipid globules into ATP for zoospore motility. Additionally, cytochemical localization of calcium in the MLC cisterna and the proximity of the cisterna to the plasma membrane and flagellum suggested a role in signal transduction and the regulation of zoospore motility (Dorward and Powell 1982; Powell 1983, 1994).

Chytrid zoospores range in shape from spherical to oval and are characteristically small, in the 3–5 μm diameter range. However, some chytrids with oval zoospores, such as *Polyphagus* (Powell 1981a), and most monoblephs may be up to 13 μm in length. The swimming pattern of the zoospore is distinct and can be distinguished from flagellated cells of other organisms. Zoospores swim in a darting motion, abruptly changing directions in what can appear to be a hopping pattern. The single flagellum beats in a single plane with a sine-curve wave, and the zoospore body may spin on its axis while swimming or glide in a single plane.

After a period of swimming for what may be a few minutes to over 24 h, depending upon species, the zoospore contacts a suitable substrate or host, withdraws its flagellum by one of several mechanisms (Koch 1968), and secretes a wall around itself (Fig. 1a). Much of the differences in complexity of thalli depends on the fate of the nucleus after the zoospore encysts (Blackwell et al. 2006; Powell and Koch 1977a, b). The encysted zoospore develops into the thallus (Fig. 3b–d), and coenocytic sporangia produce numerous zoospores which are discharged from operculate (Fig. 2d) or inoperculate (Fig. 2e) discharge openings (Powell 1976a; Taylor and Fuller 1981).

Sexual Reproduction

Well-authenticated studies of sexual reproduction among Chytridiomycota are limited. Sparrow (1960, pp. 69–85) reviewed classical reports of sexual reproduction,

most based on cytological studies of nuclear behavior. Sexual reproduction among the monoblephs is oogamous. Fusion occurs between a nonmotile egg and a motile sperm in three of six genera of monoblephs. Sperms with single flagella are produced in antheridia, and oospheres are produced in oogonia. Sperms fertilize oospheres, and the zygote produces a thick wall and becomes an oospore, which functions in perennation. In *Monoblepharis*, the zygote is motile after fertilization, propelled by the sperm's flagellum; but zygotes of *Monoblepharella* and *Gonapodya* immediately produce thick walls and develop into oospores after fertilization. Favored temperature and light regimes regulate the reproductive cycle, typically with asexual reproduction in light and at lower temperatures (8–15 °C) and sexual in the dark at higher temperatures (Marek 1984; Sparrow 1943, 1960).

The best documented ultrastructural studies of chytrid sexual reproduction are of *Chytriomyces* and *Zygorhizidium*. The presence of synaptonemal complexes in meiotic nuclei at the time of zygote germination in *Zygorhizidium planktonicum* is evidence that the life cycle of chytrids involves zygotic meiosis (Doggett and Porter 1996). The demonstration of nuclear migration and fusion in a zygote leading to a resting spore in *Chytriomyces hyalinus* suggests that genetic recombination occurs (Miller and Dylewski 1981). Light microscopic studies of *Siphonaria variabilis* (Karling 1945) and *Polyphagus euglenae* (Wager 1913) give additional evidence that nuclear fusion precedes resting spore formation in chytrids. A range of strategies for genetic recommendation has been reported (Sparrow 1960) and include:

1. Fusion between motile gametes, as in plant pathogenic species of *Synchytrium*.
2. Gametangial copulation where one gametangium transfers its protoplasm to another gametangium, as described in *Sporophlyctis rostrata*.
3. Gametangial contact where the contents from one gametangium migrates through a conjugation tube into the other gametangium and the zygotic resting spore forms, as in *Zygorhizidium*.
4. Somatogamy with fusion between rhizoidal filaments, as in *Chytriomyces hyalinus* (Fig. 2c) and *Siphonaria variabilis*.

Systematics

Early classification of chytrids was controversial because researchers were inconsistent in assignment of priority to characters. Sparrow (1960) regarded the manner by which sporangia opened prior to the release of zoospores, either operculate or inoperculate, as most important and used this feature for two series of chytrid. On the other hand, Whiffen (1944) and Karling (1977) regarded mode of sporangial discharge secondary to the pattern of thallus development and complexity. Additionally, features of the rhizoids such as presence/absence of subsporangial swelling (Fig. 3c) (= apophysis; Sparrow 1960; Karling 1977), the extent of the rhizoid system, or tapered versus rounded tip morphology have been used in systematics (Barr 1980).

The physical appearance of the mature thallus is clearly a convergent feature. Chytrids with different patterns of development can produce thalli at maturity that look the same (Blackwell et al. 2006). Because of the limited reliability of thallus appearance and the great range of morphological plasticity in characters, such as the presence or absence of an apophysis, comparative zoospore ultrastructure has guided chytrid systematics since the 1970s (summarized in Barr 1978, 1990, 2001; Powell and Letcher 2014a). Molecular phylogenetic analyses substantiate that zoospore ultrastructure can be used reliably to place taxa into orders (James et al. 2006b; Letcher and Powell 2014; Letcher et al. 2006, 2008a, c). The chytrid zoospore is an intricately designed cell with remarkable diverse architectures. Koch (1961) was the first to clearly describe unique subcellular organization in chytrid zoospores and suggest zoospore characteristics as a more reliable source of phylogenetic valid characters. Electron microscopic studies gave the first fine view of the remarkable diversity in zoospore organellar architecture (Barr 1978, 1981a; Lange and Olson 1979; Powell 1978). Structure of organelles, microbody-lipid globule complex (MLC) (Fig. 1b, c) (Powell 1976b, 1978; Powell and Roychoudhury 1992), and ciliary apparatus (Fig. 1d, e) (Barr 1978, 1980, 1981a; Barr and Désaulniers 1988; Barr and Hadland-Hartmann 1978a; Powell and Letcher 2012; Roychoudhury and Powell 1992) were used to define zoospore types and to characterize orders. Barr acted on the view that a zoospore "type" could characterize an order and removed from the Chytridiales a new order, Spizellomycetales, for chytrids in which ribosomes were dispersed and the nucleus was spatially associated with the kinetosome (Barr 1980, 1984b). The advent of molecular phylogenetic analyses has provided a clearer picture of deeper branch relationships, and tree topologies validate the reliability of chytrid zoospore ultrastructure in systematics (Letcher and Powell 2014; James et al. 2006b). Results of molecular analyses have stimulated even greater scrutiny of ultrastructural details, resulting in new views of taxonomically important structural characters, such as kinetosome associated structures (KAS) and kinetosome to nonflagellated centriole bridges (Letcher and Powell 2014; Letcher et al. 2006, 2008a, c; Powell and Letcher 2014a).

Molecular phylogenetic analyses have also revealed that many of the morphological characters classically used as primary taxonomic characters actually arose numerous times in different chytrid lineages. Thus, both operculate and inoperculate members radiate among the Chytridiales (Letcher et al. 2005), Rhizophydiales (Letcher et al. 2006; Powell et al. 2011), Cladochytriales (Mozley-Standridge et al. 2009), and Lobulomycetales (Seto and Degawa 2015; Simmons et al. 2009). Monocentric and polycentric thalli may be found within the same lineage, such as the polycentric genus *Physocladia* and the monocentric genus *Chytriomyces* in the Chytridiales lineage (Letcher et al. 2005).

A significant outcome of molecular-based phylogenetic studies was the realization that Chytridiomycota was not monophyletic and represented a tremendous amount of untapped biodiversity. This realization stimulated increased investigations of chytrid diversity. Chytridales has been redefined (Hibbett et al. 2007; Letcher and Powell 2014; Letcher et al. 2005; Vélez et al. 2011), and new monophyletic orders have been established for most recognized clades (James et al. 2006b) in the

Chytridiomycetes (Fig. 4), each correlated with a distinct type of zoospore and a constellation of distinguishing characteristics (reviewed in Letcher and Powell 2014; Powell and Letcher 2012, 2014a, b).

The class Chytridiomycetes currently includes ten orders (Fig. 4), delineated based on molecular phylogenetics and comparative character analyses of zoospore structure:

1. Chytridiales (Barr and Hadland-Hartmann 1978a; Barr and Hartmann 1976; Davis et al. 2015; Dorward and Powell 1982, 1983; Leshem et al. 2016; Letcher and Powell 2005b, 2014; Letcher et al. 2005, 2012a, 2014a, b; Longcore 1992b, 1995; Picard et al. 2009; Powell 1983; Powell et al. 2013; Vélez et al 2011, 2013)
2. Cladochytriales (Barr 1986; Barr and Désaulniers 1986, 1987; Barr et al. 1987; Lucarotti 1981; Mozley-Standridge et al. 2009; Steiger et al. 2011)
3. Rhizophydiales (Barr and Hadland-Hartmann 1978b; Lepelletier et al. 2014; Letcher and Powell 2005a; Letcher et al. 2004b, 2006, 2008b, c, 2012b, 2015a; Longcore 2004; Longcore et al. 2011; McNitt 1974; Powell et al. 2011, 2015)
4. Lobulomycetales (Longcore 1992a; Seto and Degawa 2015; Simmons et al. 2009, 2012)
5. Rhizophlyctidales (Barr and Désaulniers 1986; Barr and Hartmann 1977; Davis et al. 2016a; Letcher et al. 2008a)
6. Spizellomycetales (Barr 1980, 1981b, 1984a, b; Barr and Allan 1981; Davis et al. 2016b; Longcore et al. 1995; Powell 1976b, 1978; Simmons 2011; Simmons and Longcore 2012; Wakefield et al. 2010)

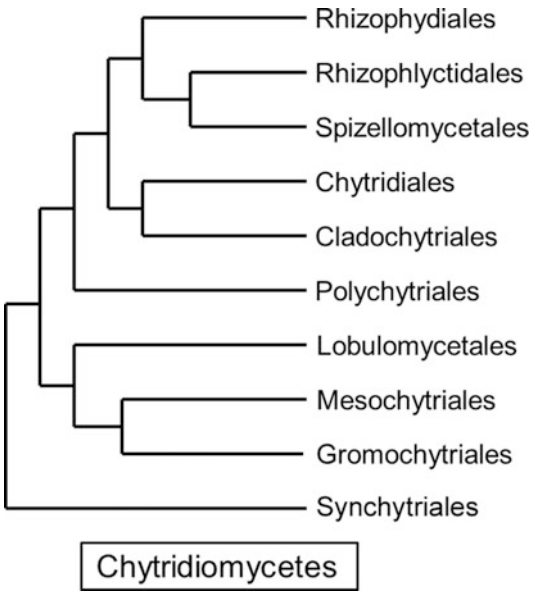

Fig. 4 Based on molecular and ultrastructural analyses, new orders have been described for monophyletic lineages within the Chytridiomycetes. The Rhizophlyctidales has been separated from the Spizellomycetales. The Rhizophydiales, Lobulomycetales, Cladochytriales, Polychytriales, and Synchytriales have been separated from the Chytridiales. The Mesochytriales and Gromochytriales are newly discovered sister lineages which include no previously described chytrid species

7. Polychytriales (Longcore 1993; Longcore and Simmons 2012)
8. Gromochytriales (Karpov et al. 2014a)
9. Mesochytriales (Karpov et al. 2010, 2014a)
10. Synchytriales (Lange and Olson 1978b; Longcore et al. 2016; Montecillo et al. 1980; Smith et al. 2014)

Several species of chytrids have been examined ultrastructurally, but their molecular phylogenetic placement is uncertain, and these remain as *incertae sedis*: *Caulochytrium* (Powell 1981b); *Entophlyctis apiculate* (Shin et al. 2001); *Polyphagus euglenae* (Powell 1981a); *Rhizophydium planktonicum* (Beakes et al. 1993); and *Zygorhizidium* (Beakes et al. 1988).

Because *Rozella allomycis* (Fig. 3i), *Olpidium brassicae,* and *O. bornovanus* (Barr and Hadland-Hartmann 1977; Barr and Hartmann 1977; Lange and Olson 1978a) place outside of the Chytridiomycota in molecular phylogenetic analyses (James et al. 2006b; Sekimoto et al. 2011), they are excluded from the phylum Chytridiomycota. The endophyte of oomycetes and chytrids, *Rozella* has recently been classified in Cryptomycota, a new phylum based primarily on phylotypes from environmental samples (Jones et al. 2011). As a clade sister to Fungi, the Superphylum Opisthosporidia (Karpov et al. 2014b) now includes Cryptomycota along with endoparasites of algal cells (Aphelida: Karpov et al. 2013; Letcher et al. 2013, 2015b) and animal cells (Microsporidia).

Recent molecular phylogenetic analyses (Dee et al. 2015) support three monophyletic orders in the class Monoblepharidiomycetes. Interestingly, the three hyphal monobleph genera (*Monoblepharis, Monoblepharella, Gonapodya*) place in a clade sister to nonhyphal members, supporting origin of hyphae in the monobleph lineage independent from other fungi. Electron microscopy of spores has also been studied in monobleph genera.

1. Harpochytriales (*Harpochytrium, Oedogoniomyces*) (Gauriloff et al. 1980a, b; Reichle 1972; Travland and Whisler 1971)
2. Monoblepharidales (*Monoblepharis, Monoblepharella, Gonapodya*) (Dorward and Powell 1980; Fuller and Reichle 1968; Gauriloff et al. 1980a; Mollicone and Longcore 1994, 1999; Reichle 1972)
3. Hyaloraphidiales (*Hyaloraphidium*) (Ustinova et al. 2000)

Maintenance and Culture

Fuller and Jaworski (1987) edited an excellent compendium of methods for manipulating development of a variety of chytrid taxa in culture. Techniques for isolating and culturing chytrids have been summarized for both aquatic and terrestrial chytrids (Barr 1983, 1987; Bills et al. 2004; Lange and Olson 1983; Shearer et al. 2004). Some chytrids, such as most species of *Synchytrium,* are obligate biotrophs and have not been grown outside their hosts (Barr 1983; Lange and Olson 1983).

The most common approach for bringing chytrids into pure culture is to add natural substrates (cellulose, chitin, keratin, pollen, heat-killed algae) directly to water collected containing organic material or to soil flooded with water. Unlike hyphal fungi, most chytrids do not exhibit filamentous growth and cannot grow appreciably away from their substrate and other contaminating organisms. The easiest method to obtain chytrids in pure culture is to observe chytrids on their bait through a microscope, and when zoospores are released, pipette up a 100 µl suspension and spread it on nutrient media containing antibiotics (0.5 g/L penicillin G and 0.5 g/L streptomycin sulfate). Large thalli and polycentric thalli can be dissected from the substrate on which they are growing and transferred to antibiotic-containing media. It is critical that incubation plates are observed closely for the first 48 h so that growing chytrids can be transferred onto clean nutrient plates, away from contaminating organisms.

Typically media low in nutrients is used for initial isolations, and with time, chytrids tend to grow better on richer media. Fuller and Jawaroski (1987) list numerous formulations for growth of chytrids and monoblephs, but a range of media may be needed to bring a chytrid into culture because some have unusual nutritional requirements (Gleason 1976) and media with other carbon, nitrogen, and ions are needed. There are a couple of multipurpose media on which most chytrids grow; these have the advantage of relative transparency, allowing clear observation of chytrids directly in culture: PmTG (1.0 g peptonized milk, 1.0 g tryptone, 5.0 g glucose, 10 g agar, 1 L water) or mPmTG (0.4 g peptonized milk, 0.4 g tryptone, 2.0 g glucose, 10 g agar, 1 L water). Other commonly used media include YpSs (15.0 g soluble starch, 4.0 g yeast extract, 1.0 g K_2HPO_4, 0.5 g $MgSO_4 \cdot 7H_2O$, 20 g agar, 1 L distilled water) and ARCH (2.0 g peptone, 3.0 g malt extract, 5.0 g glucose, 8.0 g agar, 1 L water).

One of the challenges in culturing chytrids is long-term maintenance of cultures. Because chytrids do not preserve well with freeze-dry methods, cryomethods have proved the most reliable (Boyle et al. 2003). The Barr and Babcock (1994) Q-tip technique is the most time-tested cryomethod for chytrids, but other more recently developed protocols using other cryoprotectants and controlled freezing step-downs show promise of success (Boyle et al. 2003). In the Q-tip method (Barr and Babcock 1994), 2 cm lengths are cut from the tips and sterilized. Several severed Q-tip heads are then added to nutrient broth in an Erlenmeyer flask. Cotton fibers of the Q-tips increase the surface area on which chytrids grow and facilitate transfer of thalli into cryovials. Cultures are grown on rotary shakers after inoculation for 6–10 days until vigorous growth is achieved. One Q-tip segment is then sterilely transferred to each 2 ml cryotube containing 10% glycerol as a cryoprotectant and stored at −80 °C. Some cultures have been successfully stored for over 10 years. To recover cultures, cryopreserved cultures are warmed to 35 °C quickly (30–60 s), and the thawed Q-tip transferred to broth culture. Soil chytrids appear to recover from freezing at a greater rate than aquatic chytrids.

Evolution and History

Molecular calibration of age correlated with fossil records suggests that the lineage leading to the Chytridiomycota diverged from another opisthokont lineage leading to metazoans over 1 billion years ago (Berbee and Taylor 2007). The best preserved fossils of chytrids come from the 400 million year old Devonian Rhynie Chert (Taylor et al. 1992). Chytrids resembling extant chytrids were found in thin sections on a *Nitella*-like organism. Although both holocarpic and eucarpic forms were found, no polycentric forms were detected. Well-preserved fossil chytrids have also been identified from Pennsylvainian age coal balls and included epibiotic and endobiotic forms (Millay and Taylor 1978). Thus, it is clear that the capacity of chytrids to invade living host and refractory organic materials was already developed in the Paleozoic, suggesting the evolution of wide-ranging enzymatic capabilities.

Chytridiomycota are sister to the radiation leading to higher fungi (James et al. 2006a, b). Molecular phylogenetic analyses (James et al. 2006a, b) reveal that the lineage leading to the neocallimastigos, monoblephs, and chytrids forms a monophyletic group, which diverges from the clade containing blastoclads, zygos, *Olpidium*, and higher fungi. *Rozella* (Fig. 3i), once considered a member of the order Spizellomycetales (because of the connection or proximity of the zoospore nucleus to the kinetosome), is basal to this divergence and appears to radiate with Microsporidia and Aphelidea (Karpov et al. 2013, 2014b; Letcher et al. 2013, 2015b). Like Microsporidia and Aphelidea, *Rozella* infects its host as an unwalled protoplast (Held 1981). Interestingly, *Rozella* appears to phagocytize host protoplasm (Powell 1984) as reported among Aphelidea. Distinct from Microsporidia, *Rozella* produces zoospores with single flagella (Held 1975), contains mitochondria (rather than mitosomes), and does not infect animal cells (Held 1981).

During the evolutionary radiation of chytrids, spore motility has been lost repeated times along multiple lineages of chytrids and monoblephs. For example in the chytrid radiation, nonmotile spores or autospores are found in chytrids such as *Sporophlyctis rostrata* (Sparrow 1960) and in monoblephs such as *Hyaloraphidium curvatum* (Ustinova et al. 2000). *Septosperma* exhibits a reduction in dependency on zoospores as the sole means of dispersal. Commonly found in forest soils that experience periodic inundation with water from floods or rains, *Septosperma's* rocket-shaped resting spores disarticulate from their basal cells, which facilitate their passive transport as water percolates through soil (Powell and Blackwell 1991). Fossil evidence suggests that chytrids may have undergone evolutionary radiations at the same time as land plant and animal radiations (Taylor et al. 1992). The availability of new niches and motile hosts, as well as adaptation to drier terrestrial environments, may have been factors driving evolutionary loss of spore motility. Discovery and recognition of new organisms at the base of the fungal evolutionary radiation will help disentangle the roles of symbiosis and environment in driving adaptation and divergence of Chytridiomycota (James et al. 2006a).

Characteristics of the Neocallimastigomycota

The Neocallimastigomycota are obligate anaerobic symbionts living in the rumen and other portions of the gastrointestinal tract of herbivorous mammals and reptiles (Gruninger et al. 2014; Ho and Barr 1995; Mountfort and Orpin 1994; Orpin and Letcher 1979; Trinci et al. 1994). They produce monocentric (one sporangium) and polycentric (many sporangia) thalli typically with extensive rhizoids penetrating and dissolving refractory, cellulose-containing fibrous plant materials (Ho and Barr 1995). They release posteriorly, single to multiple flagellated, unwalled zoospores from sporangia. These zoospores vary in size, even in the same isolate, with single flagellated spores typically being smaller. Sexual reproduction with fusion of gametes has never been reported among these organisms. However, Wubah et al. (1991) found evidence of aero-tolerant, resistant structures in *Neocallimastix* sp. and potential diploidization during their formation.

Occurrence

These organisms are adapted for growth in the rumen and digestive tracts of animals including, sheep, goats, cows, horses, deer, elephants, camels, and buffalo. They are not restricted to growth in ruminant animals and have been found in non-ruminant herbivores including reptiles (Liggenstoffer et al. 2010). They are not typically aero-tolerant but can survive outside of their hosts in feces (Wubah et al. 1991) and have been detected in anoxic landfills rich in cellulosic materials (Lockhart et al. 2006). Molecular analyses of environmental samples reveal that the diversity of this group is much greater than currently characterized and includes undescribed novel lineages (Kittelmann et al. 2012; Liggenstoffer et al. 2010).

Literature

Ho and Barr (1995) monographed this group, providing a key to species of five genera. Light micrographs of thallus morphology "permit the functional identification of genera and species" (Ho and Barr 1995). Since this monograph, three new genera been described (Callaghan et al. 2015; Dagar et al. 2015; Ozkose et al. 2001); consequently, there are now a total of eight genera and just over 20 species. Chen et al. (2007) produced a maximum parsimony analysis of the group based on ITS1 gene sequences and provided a key to six genera in the group and to the two species of *Caecomyces*. Knowledge of this group is relatively recent, but because of their importance in feed-utilization in herbivores, their physiology and growth have been widely studied (reviewed in Mountfort and Orpin 1994; Tachezy 2008; Trinci et al. 1994).

History of Knowledge

Although known since the early 1900s, Orpin (1975) first recognized the systematic affinity of *Neocallimastix* to fungi because of the detection of chitin in their cell walls. Heath et al. (1983) formally classified them in the order Spizellomycetales among Chytridiomycetes based on their production of thalli consisting of sporangia and rhizoids and discharge of posteriorly flagellated zoospores from sporangia. Comparative ultrastructural and molecular analyses, however, demonstrated their striking distinctions from chytrids, and Li et al. (1993) raised this group to an order, Neocallimastigales. Later, multigene phylogenetic analyses revealed that they were sister to the Chytridiomycota (James et al. 2006a, b); and with the recent formal establishment of the now recognized phylum Chytridiomycota, they were elevated to a phylum, Neocallimastigomycota (Hibbett et al. 2007).

Practical Importance

Neocallimastigos are significant in feed efficiency of plant materials by herbivores. They interact with other rumen microbes in the breakdown of fibrous material that would otherwise be indigestible to the host. They are early colonizers, and their extensive rhizoidal system penetrates plant fibers helping to physically breakdown cellulose and other compounds in plant walls. They secrete a wide range of degradative enzymes, including esterases, endo- and exo- glucanases, hemicellulases, mannanases, proteases, and xylanases (Orpin and Letcher 1979). Although it has not been shown that they actually break down lignin, they can solubilize lignin-containing fibers, and their zoospores exhibit chemoattraction to phenolic compounds and to sugars (Orpin and Bountiff 1978). There is current focus on these organisms because of the diversity of polysaccharide-degrading enzymes they produce which are potentially useful in biofuel production as well as food and textile industries (Gruninger et al. 2014).

Characterization and Recognition

This is a relatively small group with eight genera (*Anaeromyces, Buwchfawromyces, Caecomyces, Cyllamyces, Neocallimastix, Oontomyces, Orpinomyces, Piromyces*) and just over 20 species (Callaghan et al. 2015; Chen et al. 2007; Dagar et al. 2015; Ho and Barr 1995; Ozkose et al. 2001). They are distinguished primarily based on thallus complexity (monocentric or polycentric), degree of rhizoidal development, and number of undulipodia on zoospores. The presence of a transitional helix (= concentric fiber, Heath et al. 1983; Li et al. 1991) is a symplesiomorphic character shared with chytrids and blastoclads. Although sister to the Chytridiomycota in most molecular phylogenetic analyses (James et al. 2006a, b), the Neocallimastigomycota

are distinctive in numerous features. For example, instead of mitochondria, they contain hydrogenosomes that produce ATP by substrate-level phosphorylation (van der Giezen et al. 2003). Significantly, zoospore flagella lack props and a secondary centriole (= nonfunctional centriole or nonflagellated centriole) is absent (Heath et al. 1983; Li et al. 1991). Unique kinetosome-associated structures are complex in organization and include circumciliary rings, a spur, struts, and scoop (Gold et al. 1988; Heath et al. 1983; Li et al. 1991). Microtubules radiate from the kinetosome in a fan-shaped array and underlie the plasma membrane. Rather than retracting their flagella when zoospores encyst as in chytrids, they shed them and discard their kinetosomes, carrying forward no organized centrioles into their vegetative cells. During development of the coenocytic sporangium, the nuclear envelope remains totally intact at metaphase (reviewed in Li et al. 1993). In addition, no plasmodesmata (Powell 1974) have been found in septa that delimit their rhizoids and sporangia (Heath et al. 1983). A final difference is that as the sporangium undergoes zoosporogenesis, flagella elongate into vesicles prior to cytoplasmic cleavage (Heath et al. 1983), rather than forming simultaneously with cytoplasmic cleavage as in chytrids (1974).

Cultivation

Neocallimastigos must be cultivated under anaerobic conditions. They are isolated from herbivore feces or from filtered rumen fluids collected through a fistula and cannula into the rumen. Rezaeian et al. (2004) have summarized in detail methods for culturing and maintaining these anaerobes.

Evolutionary History

The neocallimastigos are zoosporic opisthokonts and are evolutionarily a highly derived, secondarily amitochondrial group. The presence of molecular import mechanisms in their hydrogenosomes, similar to those of mitochondria, and reports of two surrounding membranes support the concept that their hydrogenosomes were derived from mitochondria. These organelles, however, possibly have not retained any of the mitochondrial genome (van der Giezen et al. 2003). Evidence also suggests that neocallimastigos share a common uniflagellated aerobic ancestor with chytrids but diverged from chytrids in a lineage that adapted them to an anaerobic habitat. In this divergence, some of their enzymes may have been acquired by horizontal gene transfer from rumen bacteria. For example, glycosyl hydrolases are important in the ability to degrade fibrous cellulosic plant material. Similarities between glycosyl hydrolases in neocallimastigos and those found in rumen bacteria suggest that they were gained by horizontal gene transfer (Garcia-Vallvé et al. 2000). The neocallimastigos are an important group for additional investigations to understand the basal radiation of zoosporic osmotrophic opisthokonts and to exploit their economic potentials.

Acknowledgements This work was supported in part by the following grants from the National Science Foundation: PEET (0529694), REVSYS (949305), DEB (1455611). I am appreciative to Dr. Peter M. Letcher for assistance assembling photographic plates and for discussion of concepts, Dr. Joyce E. Longcore for providing cultures of *Harpochytrium* sp. and *Polychytrium* sp. used for photographic observations, and Dr. Will H. Blackwell for help collecting algae infected with chytrids and for conversations about systematics.

Microsporidia

43

Ann Cali, James J. Becnel, and Peter M. Takvorian

Abstract

Microsporidia are unicellular, obligate intracellular, spore-forming eukaryotes classified among the protists. As parasites, they have been reported from every major group of animals from other protists to mammals and man. They are economically and medically important and can be found environmentally in terrestrial, marine, and freshwater ecosystems. This phylum consists of over 200 genera and approximately 1,300 species producing benign to lethal infections. While they are extremely diverse, they all share the diagnostic and unique resistant spore. It contains a polar filament complex which begins the life cycle by extruding this filament injecting the spore contents, the sporoplasm, into a host cell. As intracellular parasites, they are dependent upon their host for access to nutritional products and have evolved several ways to obtain the required metabolites which in turn have reduced their need to produce many of the biochemicals necessary for their development. As a result of this reduced need to produce their own metabolites, there has been a reduction in their physiological machinery, as well as formation of unique organelles and biochemical pathways. Gene sequencing data has indicated diversity in genome size that ranges from 50+Mbp to the smallest eukaryotic genome reported to date (2.3 Mbp).

Summary Classification

The Microsporidia have undergone several changes in their taxonomic status. However, this group is now accepted as the Phylum Microsporidia Weiser 1977 (formerly known as Microspora and Microsporida) (Sprague and Becnel 1998). As a phylum of eukaryotic microorganisms, it has been considered a "sister" to the fungi (Weiss and Becnel 2014; Weiss 2005; James et al. 2006) but not in any fungal group. Microsporidiologists place them in Protista. Meiosis was first reported in 1976 (Loubes et al. 1976), and has subsequently been demonstrated several times, and has been reviewed in Vavra and Sprague (1976) and Weiss and Becnel (2014).

Introduction

The Phylum Microsporidia consists entirely of eukaryotic unicellular, obligate intracellular, spore-forming parasites. Their spores range in size from 1 to 20 μm but most are about 1–5 μm. Their hosts include all major animal phyla, even some protists, such as the phyla Ciliophora, Myxozoa, and Apicomplexa (in gregarines). Arthropods, then vertebrates, are their most common hosts. While they are known from all five classes of vertebrates, they are primarily reported in fish and mammals. Since the 1980s, they have been identified as significant opportunistic parasites of humans (Cali and Owen 1988; Didier and Weiss 2008; Weber et al. 1994; Weiss and Becnel 2014) with only a few reports prior to that time (Strano et al. 1976).

In general, the life cycle consists of three phases (Fig. 1): proliferative, sporogonic, and environmental. The proliferative phase is primarily responsible for the increase in numbers of organisms within each host cell; proliferative cells, sometimes referred to as meronts, divide repeatedly by binary or multiple fission. The sporogonic phase is composed of a division sequence called sporogony (three completely different sequences in the polymorphic genera). Meiosis, when it occurs, is initiated in sporont cells, prior to spore formation. Spores fill

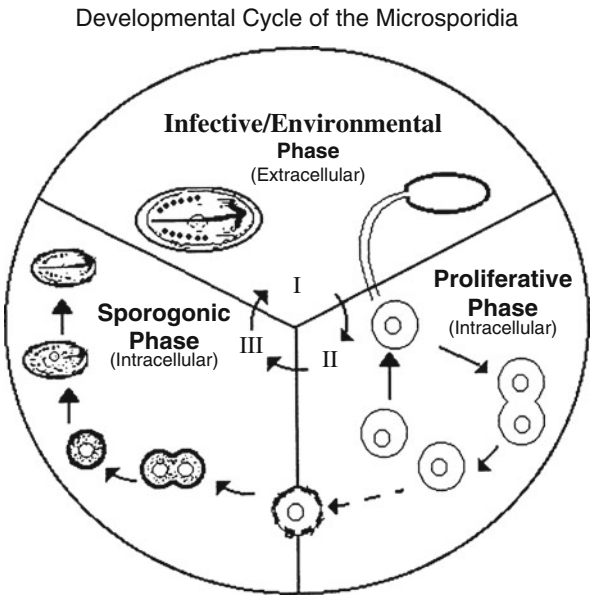

Fig. 1 A typical microsporidial developmental cycle can be divided into three Phases. Phase **I**, the infective/environmental phase, is the only extracellular part of the cycle. It is represented by mature spores shed into the environment from previously infected hosts. Under appropriate conditions, the spores germinate (e.g., if the spores are ingested by an appropriate host, they are activated by the digestive tract environment), this results in the explosive expulsion of the polar filament (which everts becoming a hollow tube). If the polar tube pierces a host cell, the spore contents, the sporoplasm, is injected into it and phase II begins. Phase II is the proliferative phase, the first phase of intracellular development. During this part of the microsporidian life cycle, organisms are usually in direct contact with the host cell cytoplasm or in a parasitophorous vacuole as they increase in number. The transition to Phase III, the sporogonic phase, represents the organisms' commitment to spore formation. In many life cycles this is morphologically indicated by parasite secretions through the plasmalemma producing a "thickened" membrane (many also form a surrounding sporophorous vesicle, SPOV). The number of cell divisions that follow varies, depending on the genus in question, and results in sporoblast cells that develop into spores (Reprinted from Cali and Takvorian 1999)

host cells (Fig. 2) and may either autoinfect after immediate germination within the infected host cell or they may require environmental exposure (environmental phase). These spores pass out into the environment during the life of the infected host, in its waste products or at its death, and are dispersed as a source of infections in new hosts.

Sporont cells are usually distinguished from proliferative stages (meronts) by the presence of an electron-dense surface coat secreted onto the plasma membrane during transition from proliferative cells to sporonts. In some species, an additional layer also develops around the sporonts. This layer forms the sporophorous vesicle (SPOV) enclosing the plasmodium which divides, forming groups of organisms that develop into mature spores. The SPOV and (usually) the presence of the thickened

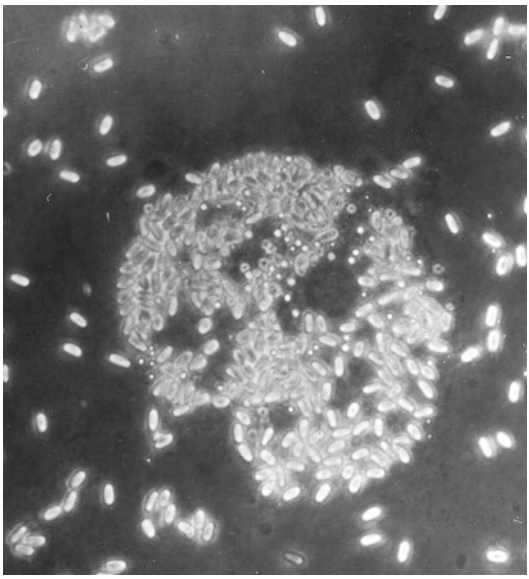

Fig. 2 *Nosema apis* spores in an intestinal epithelial cell of the honey bee. The spores appear highly refractile when observed in a fresh squash preparation by phase contrast microscopy. Spores are 4 × 2 μm (Reprinted from Cali and Owen 1988)

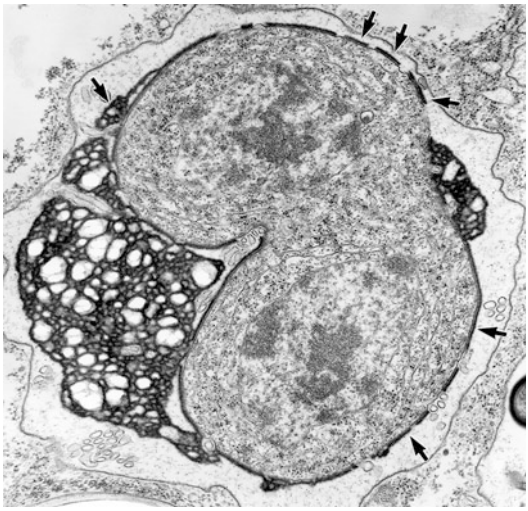

Fig. 3 *Vairimorpha necatrix.* Electron micrograph of a developmental cell in sporogony inside a SPOV. The SPOV contains a multinucleate sporogonial plasmodium surrounded by tubules. An electron dense coat is forming on its cell surface (*arrows*) (Reprinted from Mitchell and Cali 1993)

surface coat (Fig. 3) indicate that the cells are irreversibly committed to spore production and are thus sporonts. The products of sporont division are sporoblasts, which are cells that undergo morphogenesis, resulting in the formation of spores. The microsporidial spore, containing the unique polar filament complex (Fig. 4), is the diagnostic stage for the identification of organisms in this phylum. A glossary of

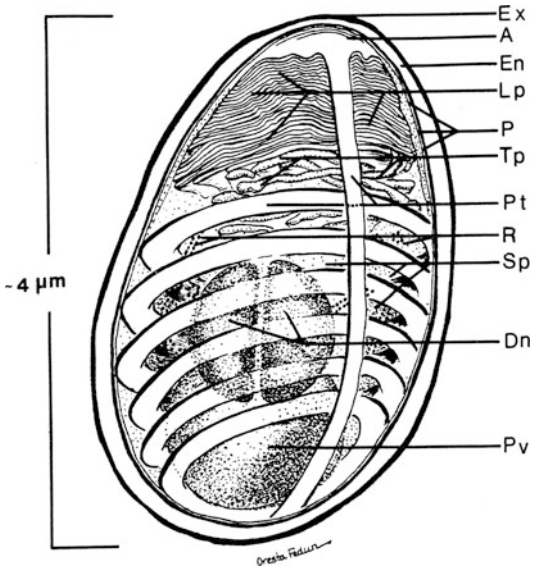

Fig. 4 Diagram of internal structure of a microsporidial spore. The spore coat has an outer electron dense region called the exospore (Ex) and an inner thicker electron lucent region, endospore (En). A unit membrane (P) separates the spore coat from the spore contents. The extrusion apparatus: Anchoring disc (A), polar tubule (Pt), lamellar polaroplast (Lp), and tubular polaroplast (Tp) dominate the spore contents and are diagnostic for microsporidial identification. The presence of a posterior vacuole (Pv) is variable. The spore cytoplasm is dense and contains ribosomes (R) in tightly coiled helical arrays. The nucleation may consist of a single nucleus or a pair of abutted nuclei, diplokaryon (D). The spore size depends on the species and varies from less than a micrometer long to over ten. The number of polar tube coils is also variable from a few to 30 or more (Reprinted from Cali and Owen 1988)

terms employed in describing microsporidial biology has been compiled by Sprague and Becnel (1999).

The mechanism, by which Microsporidia actively infect host cells is unique. It involves penetrating the plasma membrane without its destruction or the formation of a phagosome. A spore organelle, the polar filament (called polar tube after germination), is only 0.1 µm in external diameter and often exceeding 100 µm in length, within the intact spore it is coiled and anchored by the anterior attachment complex (Fig. 4). When the spore germinates, the activated polar structure is everted through the spore wall at this attachment. The sporoplasm (the infective agent) consisting of nucleus and cytoplasm bounded by a membrane passes through the tube and is inoculated into the host cell cytoplasm if the polar tube pierces a cell (Figs. 5 and 6). This process ensures that the parasite initially lies directly within the host cell cytoplasm, not in a phagosome vacuole derived from host plasma membrane, as is generally the case with parasites internalized by phagocytic processes. This provides protection against the lytic action of cells, but, even in cases where a vacuolar membrane is later formed around the dividing parasites, fusion of

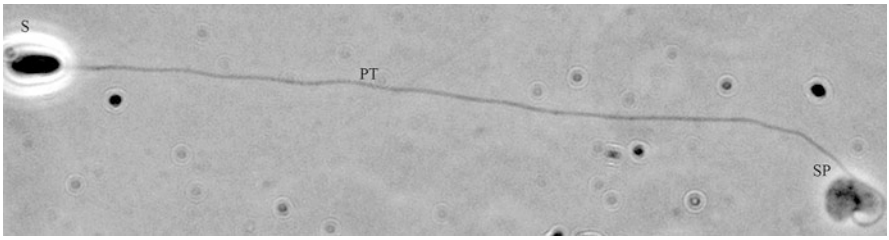

Fig. 5 *Anncaliia algerae.* Germinated spore (S) with the extruded polar tube (PT) and the discharged sporoplasm (SP) still attached (Reprinted from Cali and Takvorian 2001)

Fig. 6 Electron micrograph of an *Anncaliia algerae* sporoplasm in the cytoplasm of a host cell. The sporoplasm nucleus (Nu), some endoplasmic reticulum, numerous whorled vesicles, and a well-defined limiting membrane are present. The surface of the sporoplasm is adorned with fibrous protrusions and assorted vesicles (*arrowheads*) (Reprinted from Takvorian et al. 2005)

lysosomes does not occur. Additionally, a more traditional means of entry, via phagocytosis, has been reported. The entire spore may be engulfed by the host cell with subsequent spore activation and germination resulting in the polar tube extrusion and inoculation of another host cell (Cali and Takvorian 1999; Franzen 2004; Takvorian et al. 2005).

As obligate intracellular parasites, the microsporidia were considered primitive but are now accepted as evolved and well-adapted specialized organisms, with a lifestyle incorporating several unique features. A Golgi is present that while functionally similar (histochemically) to the classic organelle has evolved a very specialized function in the formation of the polar filament (Takvorian and Cali 1994, 1996) and a morphology resembling a vesicular mass (Beznoussenko et al. 2007). The microsporidia were considered amitochondriate until the early 2000s when it was discovered that more than a dozen genes encoding mitochondrion-derived proteins have been identified and localized to a body now identified as a mitosome (Vavra 2005; Vivares et al. 2002; Williams et al. 2002, 2008a) not resembling a

typical mitochondrion but suggesting a mitochondrial ancestry. The microsporidia are eukaryotic but have prokaryotic-sized ribosomes (being of the 70S sedimentation type with subunits of 23S and 16S). They also lack a 5.8S ribosome subunit, but its sequences are found at the beginning of the 23S subunit a feature found in bacteria, not eukaryotes (Weiss and Vossbrinck 1999). Centrioles, a usual feature of eukaryotes, are lacking in the microsporidia. During karyokinesis, the nuclear envelope remains intact and an intranuclear spindle forms, emanating from spindle plaques on the nuclear envelope. Phylogenetic analysis of their β-tubulin genes suggests a relationship between the microsporidial tubulin and the fungi (Akiyoshi et al. 2007; Edlind et al. 1994, 1996; Lee et al. 2008). However, their lineage remains challenging because their molecular sequences are so divergent and they have lost so many genes as well as the cellular and metabolic features that go with them, that they cannot be simply placed with them (Keeling and Fast 2002; Keeling et al. 2014). At 2.3 Mbp, the smallest eukaryotic genome known is that of the microsporidium, *Encephalitozoon intestinalis* (Peyretaillade et al. 1998). The microsporidial genome varies among their genera, from 2.3Mb to 50+Mbp (Keeling et al. 2014).

Occurrence

Microsporidia are commonly occurring parasites. There are approximately 1,200 known species distributed among 209 genera infecting virtually all major animal phyla. They exhibit varying degrees of host specificity from those infecting a narrow host range to some which can infect both invertebrate and vertebrate hosts. Appearance of infection can vary from no external signs of infection to macroscopic cysts causing deformities (Fig. 7a, b).

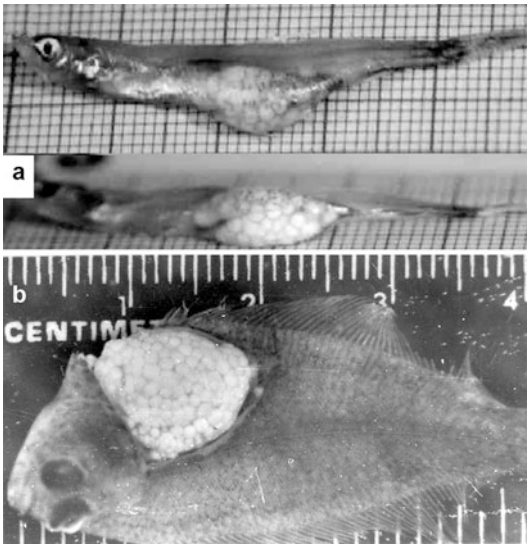

Fig. 7 The location and appearance of *Glugea* infections in fish vary depending upon parasite species and host, but all induce the formation of Xenomas (cyst-like structures). In smelt, they often cause deformities that can be seen externally, while in flounder, the Xenomas are not visible externally. (**a**) Young-of-the-year smelt infected with the microsporidium, *Glugea hertwigi* (Reprinted from Pekan-Hekim et al., 2005). (**b**) Young-of-the-year winter flounder infected with *Glugea stephani* (skin cut away)

Microsporidial percent occurrence within a given species can vary dramatically. The microsporidium, *Glugea hertwigi*, has been reported with prevalence that range from almost 100% in Baltic smelts (Weissenberg 1913) to 1–59% in northern Russian lakes (Anenkova-Khlopina 1920) in North America, smelt infection ranged from 4.6% to 100% and affected young-of-the-year as well as adults (Canning and Lom 1986). Experimental infection of young-of-the-year Winter flounder demonstrated 63% mortality from a single exposure to *Glugea stephani* (Cali et al. 1986) and 88% from two exposures (unpublished personal observations).

The Microsporidia are important parasites in many commercial economic and medical host groups. Although, the vast majority is known from insects and fish, currently 17 species have been identified in humans (Fayer and Santin-Duran 2014). The occurrence of human infecting microsporidia has resulted in studies generating a broader understanding of the geographic, zoonotic, epidemiologic, and environmental distribution of the Microsporidia and their interrelationships (Fig. 8) (Cali and Takvorian 2004). The spore stage is variable in its resistance and may survive years in the environment. Spores kept in the laboratory, in a water suspension or dry, may survive months or years, and other species may be stored in liquid nitrogen or lyophilized (Maddox and Solter 1996). Some Microsporidia are maintained in cell

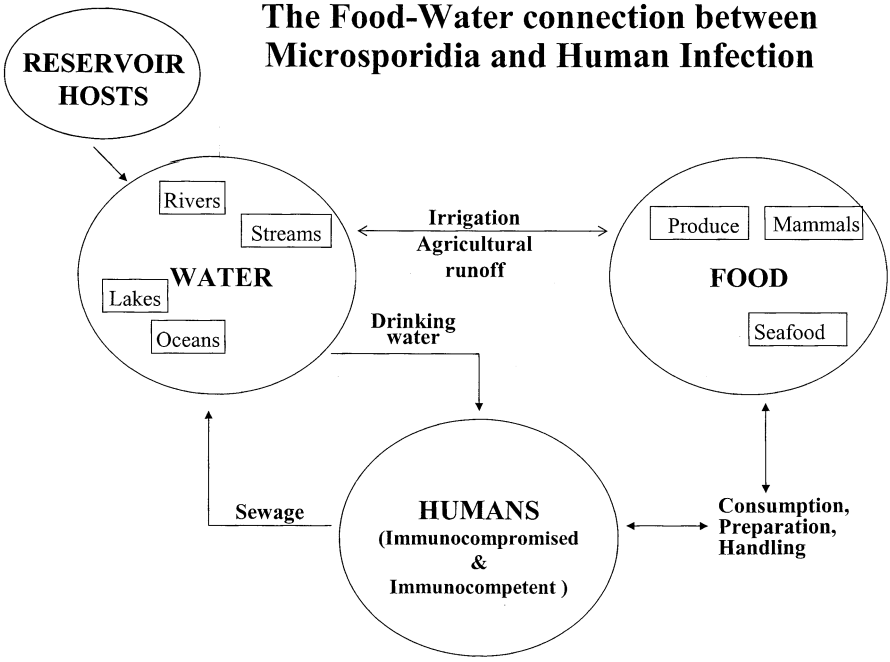

Fig. 8 The food-water connection between Microsporidia and human infection is important in helping to understand the occurrence of human-infecting Microsporidia. Epidemiological studies have provided a broader understanding of geographic, zoonotic, and environmental distribution of the Microsporidia and their interrelationships (Modified from Cali and Takvorian 2004)

cultures and are available from American Type Culture Collection (ATCC). Other species can be maintained in the laboratory in their natural or other related hosts.

Literature

In 1884, Balbiani published a book (*Lecons sur les Sporozoaires*) devoting a chapter to Microsporidies (pp. 150–168). Subsequently, in 1909, Stempell established Order Microsporidia with three families in a major review of the known microsporidial biology of that time (Stempell 1909). The monograph, by Kudo (1924), was the first volume devoted to general microsporidian biology and taxonomy. It was followed by four edited publications: one by Bulla and Cheng (1976, 1977 – two volumes); one edited by Beyer and Issi (1986); one edited by Wittner and Weiss (1999); and the most recent one edited by Weiss and Becnel (2014). These volumes contain articles by many authorities in the field.

There are numerous reviews and/or chapters on specific groups or aspects of the Microsporidia, including a treatise on the Microsporidia of insects by Weiser (1961 and updated in 1977), on infections in vertebrates by Canning and Lom (1986), in fish by Lom and Nilsen (2003), in mosquitoes by Andreadis (2007), and in insects by Solter et al. (2012). A few reviews/chapters on genera identification across the phylum include one by Larsson (1986) who reviewed the ultrastructure and adopted a cladistic approach to an analysis of the relationships of genera, by Sprague et al. (1992), by Larsson (1999), by Voronin (1999 in Russian), by Canning and Vavra (2000). Human infection reviews include Strano et al. (1976), Cali and Owen (1988), Bryan et al. (1991), Webber et al. (Weber et al. 1994), and Didier and Weiss (2008).

Journals carrying the bulk of original papers are *Journal of Invertebrate Pathology*, *Journal of Eukaryotic Microbiology (formerly J. Protozoology)*, *Protistologica*, *Věstník Československé Společnosti Zoologické*, *Acta Protozoologica*, *Folia Parasitologica* (Praha), and *Parazitologyia* (St. Petersburg). Increasing numbers of papers on fish Microsporidia are found in the *Journal of Fish Diseases*, and smaller numbers on general topics are found in *Zeitschrift für Parasitenkunde*, *Protist (formerly Archiv für Protistenkunde)*, *Parasitology*, and *Journal of Parasitology*. Japanese and Chinese sericultural and fisheries journals also carry some papers. Human infecting microsporidial reports are scattered through the medical as well as some of the abovementioned journals; however, the current computer search engines provide access to all current literature.

History of Knowledge

The first microsporidian to be named was *Nosema bombycis* Nägeli, 1857. He considered it to be a fungus but never classified it beyond the genus. It was the etiological agent of "pebrine" or silkworm disease, an epidemic of which occurred in Europe in the mid-nineteenth century, commanding the attention of many eminent

scientists, most notably Pasteur (1870). In spite of preventive measures, the disease played an important role in the decline of the silk industry in Europe.

The Microsporidia, as a distinct group for these organisms, was established in 1882 by Balbiani. They were grouped with the Myxosporea as Microspora in the Cnidosporidia, which at that time belonged in the class Sporozoa (Doflein 1901). A number of classification schemes were proposed for the Microsporidia; all were within the framework of the phylum Protozoa. Honigberg et al. (1964), in a major revision of the Protozoa, elevated them from an order to a class within the subphylum Cnidospora. In the1980 revision of the Protozoa (Levine et al. 1980), they concurred with the elevation of various groups (including the microsporidia) to the level of phylum.

Notable early workers include Thélohan, Gurley, Léger, Stempell, Hesse, Pérez, Fantham and Porter, Debaisieux, Duboscq, and Paillot. They concentrated on host/parasite relationships and on elucidating life cycles, but, because of the diminutive size of the organisms, many conflicting results were reported. This period of activity culminated in the monograph of Kudo (1924), summarizing the biology and taxonomy of the group as it was then known. Kudo listed 14 genera and about 150 species. In an annotated list compiled by Sprague (1977b) he recognized 44 genera, and he established the use of a collective group, *Microsporidium*, for ambiguous or uncertain forms. In the 1999 microsporidia volume edited by Wittner and Weiss, 143 genera were recognized, and in 2014 microsporidia volume edited by Weiss and Becnel, 200 genera were reported and currently (this chapter) 209 genera have been reported.

One of the most significant observations made in the early years was that the polar filament serves as a tube for the passage of the sporoplasm to the exterior of the spore (Oshima 1937). Oshima's observation was confirmed years later in stained smears by Kramer (1960) and in electron micrographs, e.g., Huger (1960), Kudo and Daniels (1963). The electron microscope has been instrumental in resolving early questions of parasite structure and host/parasite interface.

Another significant observation has been the demonstration of synaptonemal complexes in several microsporidial genera indicating that meiosis occurs (Loubes 1979). It has been demonstrated at both the light and electron microscopic level, in both single nucleated and diplokaryotic species. Some genera that utilize meiosis include *Amblyospora*, *Gurleya*, *Duboscqia*, *Parathelohania*, and *Vairimorpha*; however, it is not a general feature of the Microsporidia (Loubes et al. 1976; Maddox et al. 1981; Hazard and Brookbank 1984; Solter and Maddox 1998; Andreadis 2007). This subject has been reviewed in Vavra and Larsson (1999). Meiosis has been well documented and illustrated in the *Amblyospora connecticus* life cycle (Becnel and Andreadis 1999), and more recently (Fig. 9) in other *Amblyospora* spp. (Andreadis 2007).

A significant landmark in microsporidial biology is the genome sequencing of the microsporidium, *Encephalitozoon cuniculi* (Katinka et al. 2001). This has been followed by several other microsporidial genome sequences reviewed by Keeling et al. (2014). This has provided information for the application of genomic and proteomic molecular tools contributing to a better understanding of these organisms

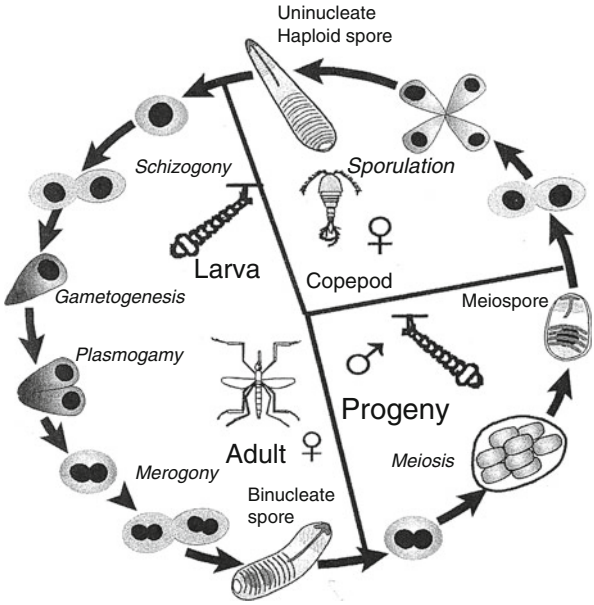

Fig. 9 Meiosis in Microsporidia: In *Amblyospora* spp., spores are produced in adult female mosquitoes and are passed by transovarial transmission to the next generation. The haploid uninucleate spores that develop in sporophorous vesicles produced in mosquitoe larvae are not infective to adults. These uninucleate spores are infective to copepods in which another cycle of development takes place, producing a third type of spore (diploid) infective to mosquitoes (Reprinted from Andreadis 2007)

(Williams et al. 2002, 2008a, b). Both morphology and molecular biology are currently in use for taxonomic purposes to define both genera and families. Consequently, depending on ones' approach, conflicting taxonomic schemes have been generated: "Molecular versus morphological approach to microsporidian classification" (Larsson 2005) and "Molecular phylogeny of the microsporidia: ecological, ultrastructural and taxonomic considerations" (Vossbrinck and Debrunner-Vossbrinck 2005). The time is approaching when a unified and integrated taxonomic system can be developed.

Practical Importance

The threat presented by microsporidia to hosts of economic importance, like silkworms, has already been mentioned. The same threat applies to bees infected with *Nosema apis* or *N. ceranae* and to fish, which are hosts to many species (Shaw and Kent 1999). Fish farming has increased the risks of epizootics. Alternatively, Microsporidia may play a beneficial role in nature: There is little doubt that some of the more virulent microsporidian pathogens in insects play a part in the natural control of host populations. There is encouraging evidence that some species can be exploited in biological control of pests, probably in conjunction with low levels of chemical insecticides: examples are *Nosema locustae* against grasshoppers (Henry 1971; Henry et al. 1973) now known as *Paranosema* (Sokolova et al. 2003) and/or *Antonospora* (Slamovits et al. 2004) and *Vairimorpha necatrix* against lepidopteran larvae (Maddox et al. 1981).

Identification of mammalian microsporidial infection is more recent: *Encephalitozoon cuniculi* Levaditi et al. 1923, was not accepted as a microsporidium until the 1960s and then it was placed in the genus *Nosema* (Weiser 1964). In 1970, its differences from the genus *Nosema* were demonstrated ultrastructurally and *Encephalitozoon* was made a microsporidial genus (Cali 1970). It has subsequently been recognized that it is quite widespread in mammals. *E. cuniculi* has been reported from over 30 different mammalian hosts including rodents, rabbits, carnivores, and nonhuman and human primates and is probably the most studied microsporidium (Cali and Owen 1988; Wilson 1979).

In humans, 17 species of microsporidia, causing a variety of pathologies and fatalities, have been identified (Cali and Owen 1988; Cali et al. 2011; Didier and Weiss 2008; Fayer and Santin-Duran 2014; Sobottka et al. 2012; Weber et al. 1994). They are opportunistic in that they are not self-limited in immunocompromised individuals. Worldwide prevalence rates have ranged from 0% to 50% depending on a variety of factors (Didier et al. 2004). While several organisms have been recognized, the majority of human infections are caused by four species of microsporidia in the two genera, *Enterocytozoon* and *Encephalitozoon.* The discovery of these parasites in AIDS patients has led to their identification in other immune deficiency situations such as organ transplants, rheumatoid arthritis, and cancer treatment. Since microsporidia are ubiquitous in nature and have a variable host range, reservoir hosts play an important role. Many animal hosts have been recognized for the genus *Encephalitozoon*, and more recently animal hosts have been documented for *Enterocytozoon* and many of the other human-infecting microsporidia (Bryan and Schwartz 1999; Cali et al. 2005; Coyle et al. 2004; Matos et al. 2004).

Habitats and Ecology

As obligate intracellular parasites, the microsporidial spores, the environmentally transmittable stage is the only extracellular stage in their life cycle, and they are very resistant in the external environment. Their survival outside the host varies according to species. In general, ultraviolet radiation and high temperatures are detrimental and quickly kill spores. Drought is also detrimental, more so for species parasitizing aquatic hosts than those in terrestrial hosts. Spores of the latter can often survive for weeks or months if protected by the dried-out cadavers or feces of their hosts. Spores in water can often survive for years. When spores enter a host and are stimulated to germinate they must inoculate a host cell with their sporoplasm in order to begin development. Their intracellular development is extremely variable and dependent upon the microsporidial genus.

The immediate environment for all microsporidial development is within the host cell. Initially the sporoplasm lies directly within the host cell cytoplasm, with the exception of a few fish and/or crustacean infecting genera: *Nucleospora*, *Enterospora*, and *Desmozoon* which develop within the host cell nucleus (Docker et al. 1997; Freeman and Sommerville 2009; Hedrick et al. 1991; Stentiford and

Bateman 2007; Stentiford et al. 2007). The others remain in the cytoplasm throughout their development, and they avoid intracellular lysis as normally occurs when lysosomes fuse with phagocytic vacuoles containing foreign organisms. Various methods are apparent by which Microsporidia avoid the lethal responses of their hosts.

The following section includes many variations of the intracellular environment (Table 1).

Table 1 Interfacial relationships of the microsporidia

Type I. Direct contact
The parasite plasmalemma is in direct contact with the host cell cytoplasm, e.g., *Nosema* and *Enterocytozoon*, or in the host cell nucleoplasm, e.g., *Nucleospora* and *Enterospora*
Type II. Indirect contact by parasite-produced isolation
The parasite secreted surface material present throughout parasite development, e.g., *Anncaliia*, *Brachiola*, and *Tubulinosema*
The parasite secreted elaborate envelope that surrounds parasite cells throughout development. It becomes an SPOV in sporogony when the parasite plasmalemma pulls away from the secreted envelope and then the plasmalemma thickens, e.g., *Pleistophora*
The parasite develops in direct contact with the host cell cytoplasm during early development, but then a parasite-formed membrane (SPOV) isolates the sporogonic stages from host cytoplasmic contact, e.g., *Vairimorpha*
The parasite appears in direct contact with the host cell cytoplasm during early development; however, the parasite produces an outer layer, somewhat like a glycocalyx, that provides for a zone of separation between the parasite plasmalemma and the host cell cytoplasm. This material "blisters" off the plasma membrane and pulls away, forming an SPOV in sporogony, e.g., *Pseudoloma*
Type III. Indirect contact by host-produced isolation
Host ER double membrane surrounds parasite cells throughout development. In the proliferative phase, the host ER double membranes follow the plasmalemma of the dividing cells so that no obvious vacuole is formed. In sporogony, the host ER does not divide with the sporonts and instead forms a double-membraned parasitophorous vacuole surrounding the cluster of organisms formed in sporogony, e.g., *Endoreticulatus*
Type IV. Indirect contact by host- and parasite-produced isolation
The host and parasite contribute to the formation of a thick interfacial envelope that surrounds all stages of parasite cells, e.g., *Trachipleistophora*
A host-formed parasite modified single membrane surrounding the developing parasite cell cluster, the parasitophorous vacuole. This is present during both the proliferative phase and the sporogonic phase; however, the parasite relationship to it changes, e.g., *Encephalitozoon cuniculi*
Host-formed parasitophorous vacuole surrounds the developing parasite cluster, and parasite-secreted material surrounds each parasite cell inside the parasitophorous vacuole, e.g., *Encephalitozoon intestinalis*
Host ER closely abuts the parasite plasmalemma in the proliferative phase (merogony). In sporogony, the parasite produces an SPOV. It may also contain tubules, e.g., *Loma* and *Glugea*
Parasite-induced infected host cell growth and hypertrophy, with parasite and host organelle proliferation combined with isolation by extracellular means, xenoma formation, e.g., *Glugea*, *Loma*, *Ichthyosporidium*, and *Microsporidium cotti* (In these genera a host response to the massively hypertrophying infected host cell includes host isolation of this cell by collagenous or other deposits around the cell. This complex is called a xenoma, ranging in size from microscopic to >5 mm in diameter.)

Some Microsporidia develop with their plasmalemma in direct contact with the host cell cytoplasm, e.g., *Nosema* and *Enterocytozoon* (Table 1 type I). They appear to interact with host cell organelles (Dionisio 2012). A more common relationship is parasite produced isolation, which is quite variable from a thickened plasmalemma to a secreted envelope (Table 1 Type II). The secretion from the parasite plasmalemma maintained on the surface of the parasite cells without separation occurs in some genera such as *Anncaliia*, *Brachiola*, and *Tubulinosema*. However, a phenomenon associated with many microsporidial genera is the separation of a secretion envelope of electron dense material external to the parasite's plasma membrane at the onset of sporogony. This produces a sporophorous vesicle, SPOV (Table 1 Type II), within which the plasmalemmal surface of the sporonts thicken and with various cell division cycles (characteristic of the genera) spores are produced, e.g., *Vavraia*, *Pleistophora*, *Trachipleistophora*, and *Vairimorpha*. The mechanism by which a second membrane can separate at the surface of an organism is obscure. Whatever its nature, after its separation it appears to function as a barrier to exchange between parasite and host cell. Frequently the cavity becomes filled with, tubules, fibers, and/or "metabolic products" of the parasite in the form of granules. The structure was known as the pansporoblast, but Canning and Hazard (1982) advocated the use of the term sporophorous vesicle (SPOV) for this microsporidial structure to make clear the distinction between it and the pansporoblast of the Myxozoa, which has a quite different origin and is composed of living cells.

An alternative is when the parasite cells may become secondarily invested by host membrane systems, such as the double membrane system of the host ER surrounding the developing parasitic organisms as they multiply, e.g., *Endoreticulatus* (Table 1 Type III).

In some microsporidia both the host and parasite contribute to the interface. A single membrane (possibly of both host and parasite origin) forms a parasitophorous vacuole, within which the parasites multiply and produce spores, e.g., *Encephalitozoon* (Table 1 Type IV). Although lysosomes are sometimes observed at the edge of the parasitophorous vacuole, lysosomal fusion is not triggered and the parasites are unaffected. *Encephalitozoon cuniculi*, a parasite of epithelial cells, endothelial cells, macrophages, and certain types of cells in the brain and kidney, provides the best example of intravacuolar development.

In genera such as *Glugea* and *Loma*, the host ER closely abuts the parasite plasmalemma in merogony but then the parasite starts production of "blisters" on its surface. An envelope forms, becoming the SPOV in sporogony (Table 1 Type IV). Inevitably, nutrients are provided for growth and multiplication of the parasites at the expense of the host cell cytoplasm. These different interfacial relationships demonstrate the diversity found among the many genera of the microsporidia (Fig. 10). Ultimately, there may remain little more of the host cell than its membrane around a large aggregate of spores (Fig. 2). Breakdown of heavily parasitized cells is common. If the cells are gut epithelial, excretory tubule or bladder cells, the spores can be discharged into the external environment. If there is no direct exit, spores released

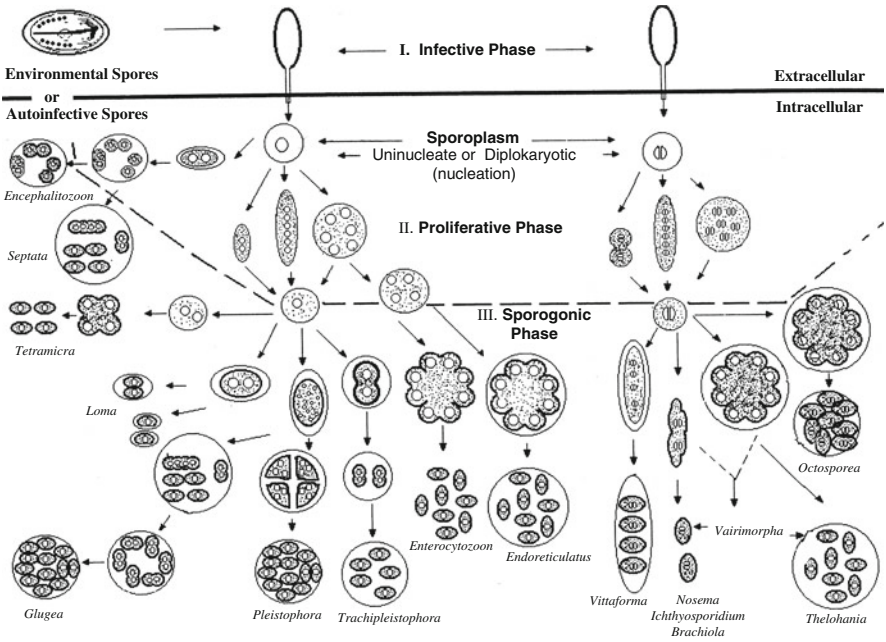

Fig. 10 Diagrammatic representation of some horizontally transmitted microsporidian life cycles, illustrating developmental diversity. In the **infective phase**, the proper environmental conditions are required to activate mature spores, resulting in polar tube extrusion. The polar tube of each spore is illustrated as piercing the host cell plasmalemma, represented by the solid black line. Below the line, is the intracellular cytoplasmic area. The sporoplasm travels through the everted polar tubule and is deposited inside the host cell. This begins the **proliferative phase** of development. The sporoplasm on the left is uninucleate and the cells that are produced from it represent the developmental patterns of several microsporidia with isolated nuclei. The sporoplasm on the right is diplokaryotic and it similarly produces the various diplokaryotic developmental patterns. Cells containing either type of nucleation will produce one of three basic developmental forms. Some cycles have cells that divide immediately after karyokinesis by binary fission (e.g., *Anncaliia* formerly *Brachiola*). A second type forms elongated moniliform multinucleate cells that divide by multiple fission (e.g., some *Nosema* species). The third type forms rounded plasmodial multinucleate cells that divide by plasmotomy (e.g., *Endoreticulatus*). Cells may repeat their division cycles one to several times in the proliferative phase. The intracellular stages in this phase are in direct contact with the host cell cytoplasm or closely abutted to the host ER. There are two types of exceptions. a) The proliferative cells of *Encephalitozoon* and *Septata* are surrounded by a host formed parasitophorous vacuole throughout their development (possibly *Tetramicra*). b) The proliferative plasmodium of the genus *Pleistophora* is surrounded by a thick layer of parasite secretions in the proliferative phase that separates and becomes the sporophorous vesicle in the sporogonic phase. Below the dashed line are the stages of the **sporogonic phase**. A few cycles maintain direct contact with the host cell cytoplasm in the sporogonic phase, *Nosema*, *Ichthyosporidium*, *Anncallia*, *Tetramicra*, and *Enterocytozoon*. The remaining genera form a sporophorous vesicle as illustrated by the circles around developing sporogonial stages. It should be noted that in the *Thelohania* cycle and the *Thelohania*-like part of the *Vairimorpha* cycle, the diplokarya separate and continue their development as cells with isolated nuclei (Reprinted from Cali and Takvorian 1999)

from cells are now vulnerable to the phagocytic processes of the host. This may provide the vehicle for transport to other parts of the host body as in disseminating Microsporidia such as the *Encephalitozoon* species in which the phagocytic cell does not kill the parasite; instead it multiplies in it (Orenstein et al. 1992). In insects, spores liberated into the hemocoele may be encapsulated by hemocytes and by subsequent deposition of melanin. In vertebrates, the aggregates of free spores are broken up by infiltrating cells and removed by phagocytes.

The relationship between parasite and host cell is not always a simple one of gain and loss, but a mechanism appears to operate by which the cell is imbued to a greater or lesser extent with the ability to compensate for the utilization of its cytoplasm by the parasites (Desjardins et al. 2015). There are indications that the parasites can, in some respects, control the metabolism of the cell, e.g., by the close relationship between the parasites and host mitochondria, endoplasmic reticulum, Golgi, and microtubules. In *Encephalitozoon*, host mitochondria accumulate close to the surfaces of parasites and lie at the edge of parasitophorous vacuoles, while in *Enterocytozoon* the host mitochondria appear to abut the parasite plasmalemma (Scanlon et al. 2004). Perhaps the most remarkable is the association between host endoplasmic reticulum and the merogonic stages in genera such as *Endoreticulatus* (Cali and Garhy 1991) and *Glugea* in which each meront is completely encased in a cisterna of endoplasmic reticulum and when meront division takes place, the endoplasmic reticulum follows the constrictions, which separate the offspring cells, and divides with them. This invariable association with host endoplasmic reticulum suggests that the host's proteins are being utilized by the parasite, but the manner in which they cross the membrane barriers is obscure. It has recently been demonstrated that in *Anncaliia* infected HeLa cells, microtubule organizing centers become disrupted resulting in fragmented Golgi associated with the developing Microsporidia (Santiana et al. 2015).

In genera such as *Glugea* and *Endoreticulatus* the host ER closely parallels the parasite plasmalemma. In general, the Microsporidia rely on the host organelles for nutrition. The host cell nucleus is rarely invaded; it is frequently hypertrophic and clearly survives long enough to exert control over synthesis of new proteins, which enables the host cell to enlarge and accommodate the growing parasites. Often the host cell survives, expands to accommodate the parasites, and, to all intents and purposes, itself becomes parasitic on the surrounding host tissues (Diamant et al. 2014). The term xenoma is used for this host/parasite cell complex. The xenomas induced by the *Glugea* species in fish show this interaction between host cell and parasite to a high degree. *Glugea* xenomas each represent a single greatly hypertrophic host cell (Takvorian and Cali 1981), reaching several millimeters in diameter (Fig. 7). Typically, the host reacts by producing a collagenous multilayered envelop, to isolate the xenoma. The plasma membrane of the *Glugea* xenoma displays pinocytotic activity in accord with its function to absorb nutrients from the surrounding tissue for its growth and that of the parasites within. The host nucleus becomes highly branched, ramifying through the peripheral layers of the cytoplasm, and numerous nucleoli, seen in every branch of the nucleus, are consistent with increased synthetic activity.

Different types of single-cell tumors are induced by other genera parasitizing fish. In *Ichthyosporidium giganteum* infections of *Leiostomum xanthurus*, the host cell is devoid of strengthening layers but is provided with extensive ramifications into surrounding host tissue (Sprague 1966). In *Loma morhua* parasitizing Atlantic cod, *Gadus morhua*, the host cell is enclosed by the thick basement membrane of the pillar system in the gills, and the plasma membrane interdigitates with it (Morrison and Sprague 1981). In *Spraguea lophii* infections of angler fish, *Lophius budegassa*, the infected ganglion cells are hypertrophic and surrounded in the ganglion by flattened cells. The colonies of parasites are strictly localized in the distal region of the ganglion cell body, close to the point of exit of the axon.

Characterization and Recognition

Phylum Microsporidia Balbiani 1882, *stat. nov.*, Weiser 1977.

Definition: Microsporidia are obligate intracellular parasites with spores of unicellular origin, containing a single uninuclear or binuclear sporoplasm, surrounded by a polar filament which becomes tubular upon discharge (eversion). As the spore germinates, the sporoplasm is transferred from the spore, via the polar tube, into a prospective host cell.

Microsporidia were once thought to be very primitive, subsequent research has demonstrated that, as parasites, they have degenerated/evolved, resulting in the loss or modification of some eukaryotic organelles, (see general characteristics for details). Additionally, their nucleation is represented by isolated (unattached) or abutted paired (attached) nuclei, called a diplokarya. During karyokinesis, their nuclear envelope remains intact. Typical centrioles, composed of microtubules are absent but centriolar plaques, consisting of electron-dense material deposited on the nuclear envelope, at the site of spindle attachment are present (Fig. 11). The plaques appear as 1–5 stacked bar–like structures that lie outside the nuclear envelope, with polar vesicles (mitosomes). These structures lie outside the nuclear envelope, but often in a depression of it. In genera containing meiosis, it occurs early in sporogony. Microsporidial spores are of single cell origin and are highly characteristic (diagnostic), containing a sporoplasm surrounded by a coiled single polar filament which is everted in the germination process, thus becoming tubular, allowing the passage of the sporoplasm through it, thus host cells may be infected by "inoculation" (Fig. 12). Due to their small size, electron microscopy is often used for confirmation of their microsporidial nature. The intracellular development consists of proliferative (merogony) and sporulation phases. In some genera, three different sporogonic sequences lead to a marked spore polymorphism.

Life Cycle

Microsporidial spores may survive in the environment for indeterminate periods of time and will not become activated until they encounter the proper stimuli necessary

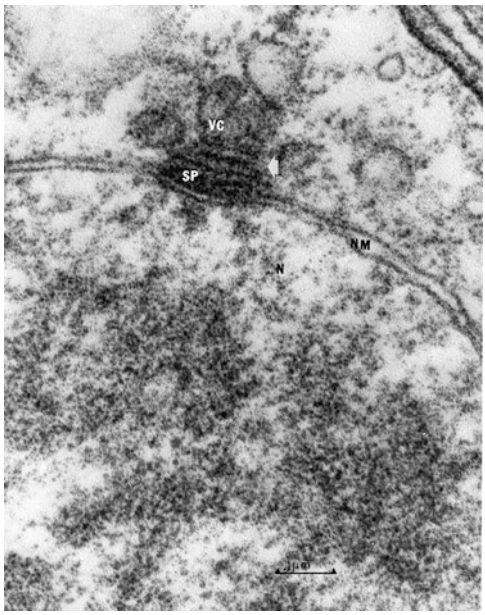

Fig. 11 Mitosome and spindle-plaque of *Glugea stephani.* The spindle-plaque (SP) the site of microtubule production and spindle attachment consists of stacked electron-dense bar-like structures on the cytoplasmic side of the nuclear membrane (NM). Membranous vesicles (VC) are the mitosome or relic mitochondria. Both of these structures are on the outside (cytoplasmic side) of the nucleus (N)

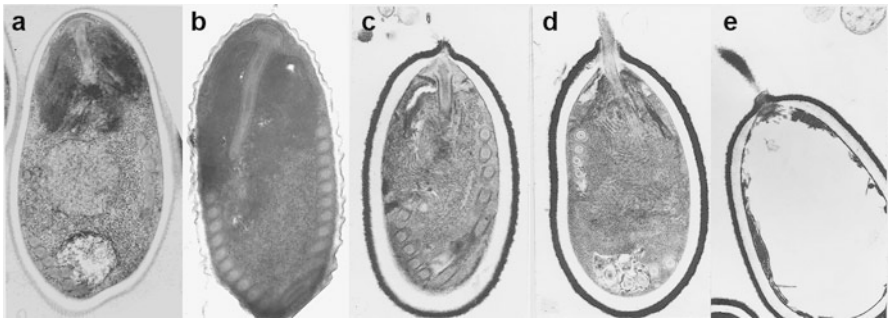

Fig. 12 Electron micrographs of mature spores comparing the morphological organization of inactive spores with those in the process of germination. (**a**) An inactive spore containing a very prominent anchoring disc followed by extensive lamellar polaroplast membranes and tubules in its anterior end. Below the polaroplast is the sporoplasm containing a well-defined nucleus in its cytoplasm. The posterior vacuole, not always present, is visible in this section. (**b**) An inactive spore illustrating the anterior straight portion of the polar filament as well as the cross-sectional views of the coiled portion in the medial to posterior part of the spore. (**c–e**) Changes associated with activation, polar filament eversion, forming the everted polar tube, and sporoplasm discharge. (**c**) Activated spore just starting to evert its polar filament through the rupturing apical portion of the spore. The polar filament coils are still present but are starting to reposition. (**d**) Activated spore with a large portion of its polar tube extruded and the remainder passing through the apical portion of the spore coat. The remaining part of the polar tube is repositioned. (**e**) Empty spore shell with the remnant of the polar tube still attached, the sporoplasm and associated structures have been transported out of the spore

for their particular germination (Fig. 12). This is most often in the digestive tract of a proper host. After activation of the spore, the germination process results in the transfer of its contents, the sporoplasm, into a host cell. If successful, the life cycle begins.

The Sporoplasm Sporoplasms (Fig. 6) have been observed in studies of emergence from spores (Fig. 5) in tissue culture (Cali et al. 2002; Takvorian et al. 2005; Weidner 1972; Weidner and Trager 1973). They have also been seen after spore germination in the natural host (Avery and Anthony 1983; Scarborough-Bull and Weidner 1985). Detailed studies of *Anncaliia (Brachiola) algerae* reveal the presence of a unique "network" MIN (multilayered interconnecting network) surrounding the cytoplasm and immediately inside the plasmalemma. It is connected to the polar tubule and disappears within minutes after extrusion, with only whorled vesicles remaining (Cali et al. 2002; Takvorian et al. 2005). The MIN has been identified as Golgi (Takvorian et al. 2013). These cells contain nuclei, little cytoplasmic differentiation, and whorled vesicles (Fig. 6). The surface membrane has been variously reported as simple, adorned with fibrous protrusions, or double, with the outer layer continuous with the polar tube sheath.

The proliferative phase (sometimes referred to as merogony) contains cells generally having a simple ultrastructural organization containing one to several single or abutted nuclei (diplokarya). In many Microsporidia, karyokinesis is not immediately followed by cytokinesis, resulting in multinucleate cells (Fig. 13).

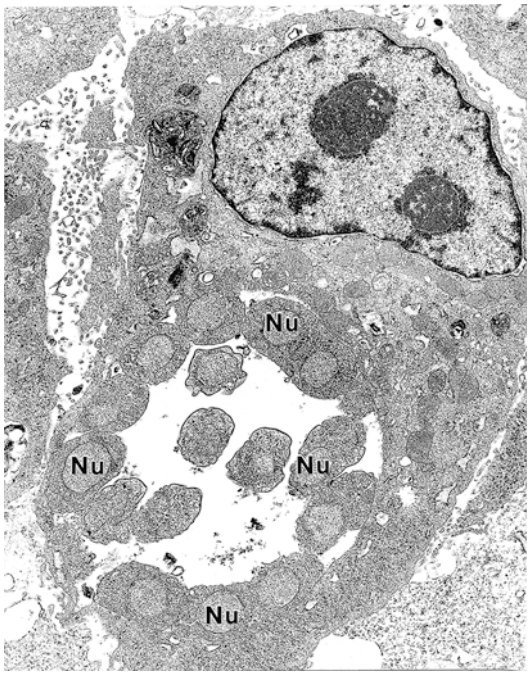

Fig. 13 *Encephalitozoon cunuculi.* Parasitophorous vacuole containing proliferative cells with large round isolated nuclei (Nu). Note that karyokinesis has not been immediately followed by cytokinesis, resulting in multinucleate cells tightly abutted to the periphery of the vacuole (Reprinted from Cali and Takvorian 1999)

These cells have a relatively simple cytoplasm containing some ER, ribosomes, and a medium dense appearance when viewed by electron microscopy. The plasma membrane is usually an unadorned unit membrane. In some microsporidia, the surface of the proliferative cells is covered with an electron-dense surface coat which is variously adorned with close-packed tubules, ridges, and/or vesicles (Cali et al. 1998), e.g., *Anncaliia* (*Nosema*, *Brachiola)* species (Fig. 14). An electron-dense surface coat is also present throughout the development of *Orthosomella*. In *Pleistophora* (*P. typicalis and P. ronneafiei*), there is a very thick amorphous coat, which divides with the proliferative cells but separates from the plasma membrane and becomes the sporophorous vesicle wall in sporogony (Fig. 15) (Cali and Takvorian 2003; Canning and Hazard 1982; Canning and Nicholas 1980).

Division of proliferative cells may be by binary fission of stages, which contain isolated nuclei (*Encephalitozoon*, *Unikaryon*) or diplokarya (*Nosema*, *Anncaliia*), and which elongate before constriction. Often they are multinucleate cylindrical (*Glugea*) or rounded plasmodia (*Alfvenia*, *Pleistophora*), also with diplokarya or isolated nuclei. The multinucleate stages may divide by simultaneous fission into unikaryotic or diplokaryotic products, or into smaller multinucleate segments by plasmotomy. In some taxa more than one morphological type of proliferation has been described. The heavy infections typical of most microsporidia demonstrate the abundance of some kind of multiplication process in proliferative development. The proliferative stages may not be morphologically distinguishable from sporonts; the proliferative phase may be short and linked to a cycle that includes autoinfective spores, extruding their polar tubes immediately after formation in an infected host

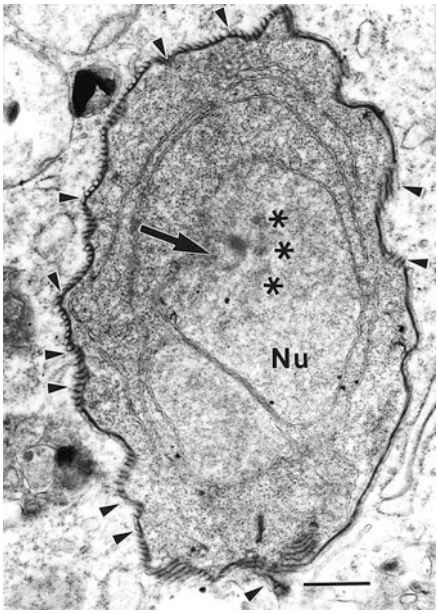

Fig. 14 *Anncaliia* (*Brachiola) algerae.* Proliferative cell in direct contact with the host cell cytoplasm. Parasite contains diplokaryotic nuclei (Nu) undergoing karyokinesis. Persistent nuclear membrane invaginates and contains a spindle plaque on the envelope (*arrow*) and chromosomes (*) within the nucleoplasm are present. Note the presence of vesiculotubular material (*arrow heads*) on the thickened plasmalemma (Reprinted from Takvorian et al. 2005)

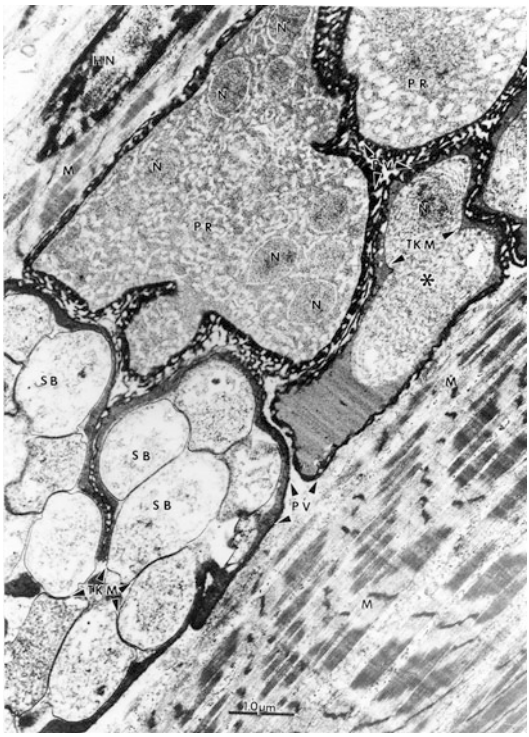

Fig. 15 Electron micrograph of *Pleistophora ronnefiei* developing in the skeletal muscle of a patient with AIDS. The proliferative stages (PR) and sporoblasts (SB) are enclosed in thick walled sporophorous vacuoles (PV). The proliferative forms are multinucleated, with many isolated nuclei (N). Early sporont has plasmalemma pulling away from the sporophorous vacuole (PV) and the plasmalemma has started to thicken (TKM) (Reprinted from Cali and Takvorian, 2003)

cell, and resulting in the infection of many more cells within the same host. Immediate germination of first-generation spores has been observed in several Microsporidia (Iwano and Ishihara 1989).

The Sporonts and Sporogony In those microsporidia that have a simple plasma membrane during their proliferative development, certain changes are observed which are associated with the entry into the phase of sporogony. These changes are morphologically characterized by secretions through the plasmalemma, giving it the appearance of an electron dense material that may first appear as "localized thickenings" like a scalloped surface (Fig. 16) and culminating in the formation of a "thickened membrane" (Fig. 17). Many genera produce appendages during this development or earlier. They vary in size and shape and are usually associated with the formation of the "thickened membrane" (Cali et al. 1998; Takvorian and Cali 1983). Uniquely, protoplasmic extensions have been demonstrated on *Brachiola vesicularum* (Cali et al. 1998) (Fig. 18). It is thought that these structures function in providing for nutritional needs after plasmalemmal thickening. Sporogony culminates in the production of spores, which are either (a) packaged in varying numbers within sporophorous vesicles or (b) are dispersed freely in the host cell cytoplasm.

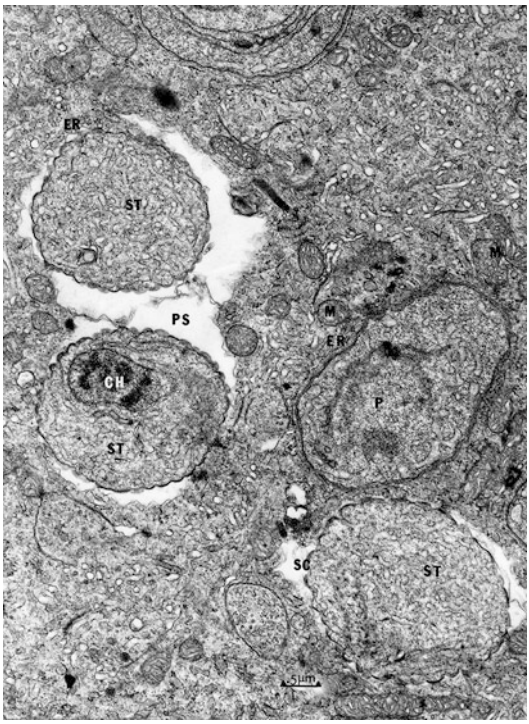

Fig. 16 *Glugea stephani* cells undergoing transition from proliferative (P) to sporogonic (ST) development. The most obvious morphological changes associated with the transition are a change from their association with the host cell cytoplasm and a concurrent change of the parasite cell surface. The proliferative plasmalemmal membrane is tightly embedded in the host cytoplasm, and the sporont plasmalemma is characterized by secretions of an electron dense material that appears as "localized thickenings" forming a scalloped surface (SC). As scalloping progresses, the plasmalemma becomes uniformly "thick" and the parasite cell is isolated from direct contact with the host cytoplasm by vacuole formation

(a) Development in Sporophorous Vesicles (formerly pansporoblasts)

In many of the genera, the parasite contracts within an envelope laid down de novo external to its plasma membrane (Fig. 19). Usually this is a fine, membrane-like structure as is present in *Vairimorpha* (Fig. 3) (Mitchell and Cali 1993); however, in *Pleistophora* and *Vavraia*, it is a thick layer already present during the proliferative phase (Canning and Hazard 1982), which acquires electron-dense additions, and then as the plasma membrane pulls away, it becomes a persistent sporophorous vesicle (Fig. 15).

The body within the sporophorous vesicle is the sporont which, when multinucleate, is referred to as the sporogonial plasmodium. The sporont acquires an electron-dense surface coat which later becomes the exospore layer of the spore wall (Fig. 15). This surface coat is thus an indicator of the commitment to sporogony. The sporont divides into sporoblasts. The division may be direct by binary fission

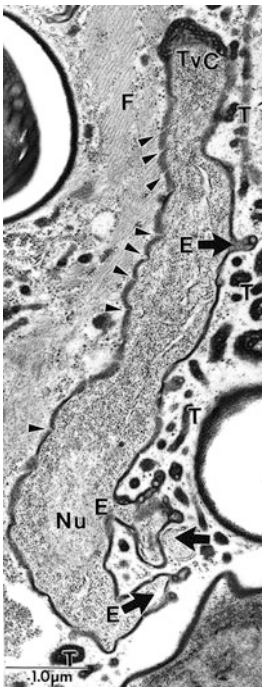

Fig. 17 *Brachiola vesicularum* produces protoplasmic extensions, unique to this parasite. They branch and terminate in extensive vesiculotubular structures, believed to function in providing for the parasite's nutritional needs (Reprinted from Cali et al. 1998)

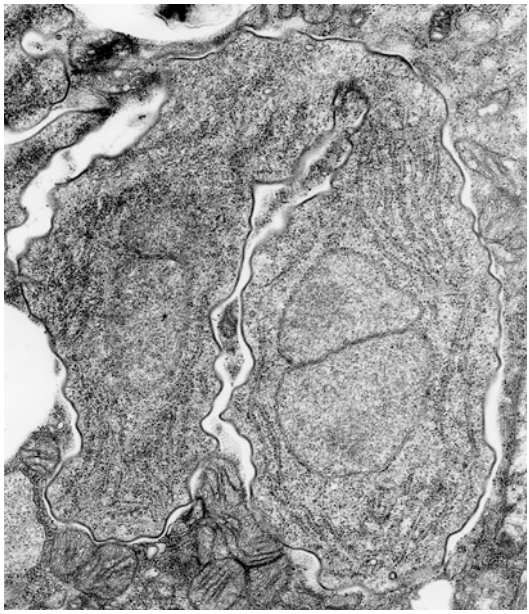

Fig. 18. *Nosema bombycis* sporont cell possessing a thickened membrane. The diplokaryon has undergone karyokinesis, and cytokinesis has commenced, but a connection between the two diplokaryotic parts of the cell is still present (Reprinted from Cali 1970)

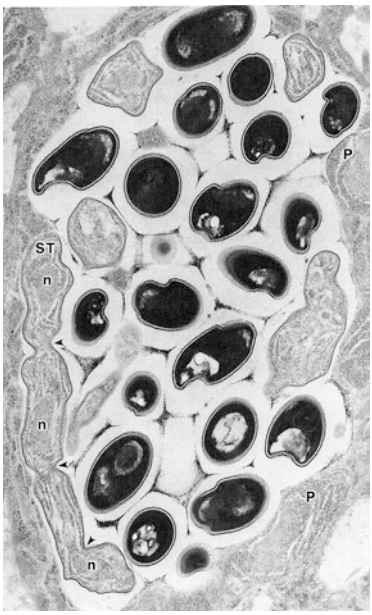

Fig. 19 *Encephalitozoon* (*Septata*) *intestinalis* in a parasitophorous vacuole with a fibrillar lamina separating the individual parasite cells. An elongated multinucleate (n) sporont (ST) cell is in the process of cytokinesis (*arrow head*). This cluster of parasite cells also contains many mature electron-dense spores as well as proliferative cells (P) (Reprinted from Cali et al. 1993)

(*Telomyxa*, *Berwaldia*) or multiple fission (*Gurleya*, *Amblyospora*, *Toxoglugea*). It may be a two-phase division whereby a multiple fission gives rise to uninucleate products (sporoblast mother cells), which undergo binary fission into sporoblasts (*Glugea* and possibly *Vavraia*). In *Pleistophora*, there is a series of divisions whereby the plasmodium separates into smaller and smaller segments, ending in uninucleate sporoblasts, plasmotomy.

Little is known of the ploidy of the nuclei in genera such as *Pleistophora*, *Vavraia*, and *Glugea* where the nuclei remain isolated throughout the life cycle or in genera such as *Nosema* or *Anncaliia* where the nuclei remain as diplokarya throughout their life cycle. However, in the genera *Thelohania*, *Amblyospora*, *Parathelohania*, and *Polydispyrenia*, which have nuclei in diplokaryon arrangement at the onset of sporogony, and in *Gurleya*, which has unikaryotic sporonts, structures interpreted as synaptonemal complexes have been observed in the young sporont nuclei. These have been taken to indicate meiosis (Loubès 1979).

The original demonstration of karyogamy is that of Hazard and Brookbank (1984) in *Amblyospora* sp. in *Culex salinarius*. They found that fusion of the two haploid nuclei of the diplokaryon occurred in presporonts only when they had entered cells of the fat body after a phase in hemocytes. They further reported that synapsis of homologous chromosomes occurred not after this fusion but later, after chromosome replication and restoration of the diplokaryon. These new diplokaryotic nuclei were diploid. There was some uncertainty about the events of meiosis, which according to Hazard and Brookbank (1984) are "dramatically unlike classical meiosis." Subsequently, Flegel and Pasharawipas (1995) clarified and corrected the conclusions of Hazard and Brookbank (1984) by reanalyzing their data into " two developmental

sequences, one abortive and the other for typical meiosis, a better fit was obtained between cytological stages and micro photometric measurement of DNA content," thus demonstrating that microsporidial meiosis is in fact typical for eukaryotes.

The number of diplokarya in the early sporont of the genera that undergo meiosis determines the number of haploid nuclei and, therefore, the number of sporoblasts arising from sporont division: eight sporoblasts are derived from sporonts with one diplokaryon in *Amblyospora*; 32 and 64 from sporonts with four and eight diplokarya, respectively, in *Polydispyrenia*. In *Gurleya*, where the sporont has a single nucleus, four haploid sporoblasts are produced in the sporophorous vesicle. In *Janacekia* the diplokaryotic nuclei characteristic of the meronts, separate in preparation for sporogony, and cytoplasmic division between them gives uninucleate sporonts as in *Gurleya. Janacekia* differs from *Gurleya* in that meiosis is followed by several mitoses, giving rise to 16 to 32 haploid nuclei and a corresponding number of sporoblasts. In this genus (as in other genera of the family Tuzetiidae), as the sporoblasts separate, the sporophorous vesicle accompanies the division, and each sporoblast becomes individually enclosed in a vesicle. According to genus, sporophorous vesicles can thus contain 1, 2, 4, 8, 16, or a variable number of sporoblasts, depending on the number of nuclei in the sporogonial plasmodium.

(b) Development Without Sporophorous Vesicles (formerly apansporoblastic)

In the remaining genera no envelope of parasitic origin is formed to isolate the stages of sporogony from the host cell cytoplasm, and the laying down of the electron-dense surface coat is the only sign of the onset of sporogony (Figs. 18 and 20). An exception is the genus *Enterocytozoon* (see below).

Sporogony of this type is often referred to as apansporoblastic. A diversity of division processes also distinguishes genera in this group. Sporonts may be diplokaryotic with disporoblastic development (Fig.18), *Nosema*, *Ichthyosporidium*, and *Mrazekia*, or with polysporoblastic development, *Golbergia*. Alternatively, sporonts may have isolated nuclei and disporoblastic development, *Encephalitozoon* (in a host-derived parasitophorous vacuole) (Figs.13, 19) and *Unikaryon*; tetrasporoblastic development, *Tetramicra*; or polysporoblastic development, *Perezia*,

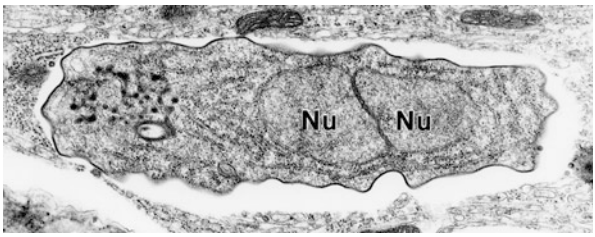

Fig. 20 *Nosema bombycis* late sporoblast, undergoing the morphogenic process for spore formation. This is indicated by the presence of the vesicular Golgi and associated tubular cross sections of polar filament. Additionally, the "thick" cell limiting membrane will become the exospore coat (Reprinted from Cali 1970)

Ameson, and *Nosemoides*. In some genera sporonts produce variable numbers of sporoblasts, *Culicospora* and *Orthosomella*.

Polymorphism Polymorphism, whereby a single species is able to express sporogonic and even proliferative development of entirely different types, each type formerly considered to be characteristic at the generic and even subordinal level, is being more and more commonly demonstrated among Microsporidia. Sometimes one sporogonic sequence takes place in a sporophorous vesicle giving uninucleate spores, while another gives rise to binucleate spores free in the cytoplasm, *Parathelohania*, *Amblyospora*, *Vairimorpha*, and *Burenella*. There are probably others of this type, in which the sequence producing spores in sporophorous vesicles closely resembles that of the foregoing genera, *Polydispyrenia*. In *Amblyospora* spp., the free spores are produced in adult females and are responsible for transovarial transmission to the next generation. This has been shown for a number of *Amblyospora* species, e.g., in the mosquito *Aedes cantator* (Andreadis 1983). The uninucleate spores in sporophorous vesicles produced in larvae are not infective to mosquitoes; Hazard and Brookbank (1984) found that these spores are haploid. In a species of *Amblyospora* in *Culex annulirostris*, Sweeney *et al*. (1985) demonstrated that the uninucleate spores are infective to the copepod *Mesocyclops albicans*, in which a further cycle of development takes place, producing a third type of spore infective to mosquitoes. Similar results were obtained by Andreadis (1985) who transmitted a species of *Amblyospora* from the mosquito, *Aedes cantator*, to the copepod, *Acanthocyclops vernalis*. These findings – that meiosis, polymorphism, and an alternation of hosts can occur in some microsporidial life cycles – are important discoveries in microsporidial biology.

In other types of dimorphism, both spore types are free. In *Hazardia*, binucleate and uninucleate spores are formed: one sequence is *Nosema*-like; the other produces sporonts with 1, 2, 4, 8, or 16 isolated nuclei and gives rise to corresponding numbers of uninucleate sporoblasts. In the genus *Spraguea* one sequence is *Nosema*-like while the other is *Nosemoides*-like, i.e., multinucleate with isolated nuclei (Loubes et al. 1979b). Therefore, there are features common to *Hazardia* and *Spraguea*, but by reason of other aspects of their development they are considered distinct genera. In *Nosema helminthorum*, a hyperparasite of cestode worms, unikaryotic and diplokaryotic stages have been observed (Canning and Gunn 1984). These engage in disporoblastic sporogony, which results in two types of free spores. This may be yet another type of dimorphism with stages resembling *Unikaryon* and *Nosema*.

The Sporoblast After the last cell division of sporont cells, the resulting cells will undergo a metamorphosis into spores. These morphogenic cells are the sporoblasts (Fig. 20). Young sporoblasts usually have an increased complement of endoplasmic reticulum compared with earlier developmental stages. Their surface characteristics, including the electron-dense coat deposited previously at the surface of the sporont, often leaves them with crenated outlines when observed by electron microscopy. As the sporoblasts mature, the organelles characteristic of the spore can be seen at various

stages of development. Sometimes the differentiation begins even before the division of the sporont is complete. The polar filament develops, at least in part, from a vesicular mass, described as Golgi-like and demonstrated to be a true Golgi apparatus histochemically in *Glugea stephani* (Takvorian and Cali 1994, 1996). Polar filament morphogenesis has been most completely described by Vinckier (1975) for *Nosemoides vivieri*. In this species, an anterior anchoring disc (polar sac) develops from a vesicle that lies between the nucleus and the Golgi vesicles. The Golgi vesicles coalesce to form the core and sleeve of the polar filament. The polar sac then migrates to the anterior end of the spore, while the nucleus and Golgi vesicles move to the posterior end. In the final stages, after the entire polar filament has been elaborated the Golgi vesicles may coalesce to form the posterior vacuole (posterosome). This structure is not, however, present in the spores of all species. In *Anncaliia algerae*, the Golgi has been observed as a vesicular mass that remains as such in the mature spore and becomes apparent in the activated spores (Cali et al. 2002).

The polaroplast, an organelle associated with the extrusion of the polar filament, develops as a series of flattened sacs and vesicles around the manubroid part of the polar filament (Takvorian and Cali 1986; Takvorian et al. 2006). Spore morphogenesis is completed by the deposition of the electron lucent chitinous endospore, which appears as "intermingled fibrils" when prepared by freeze-fracture (Bigliardi et al. 1996) between the plasma membrane and the electron dense exospore. Some studies also indicate that the endospore wall contains several novel glycosylated proteins that may have a role in host invasion (Hayman et al. 2005; Li et al. 2009; Southern et al. 2007).

Enterocytozoon bieneusi, the most common human-infecting microsporidium, is an exception to this developmental process. The multinucleate sporogonial plasmodium forms many polar filament structures prior to the last cell division process. Each developing polar filament forms in association with and surrounding a nucleus (Fig. 21). Subsequently, cell division occurs, isolating each nucleus/polar filament complex into individual late sporoblasts cells which then secrete the electron lucent endospore wall thus becoming mature spores (Cali and Owen 1990).

The Spore. Microsporidial spores range in size and shape from the 1 μm-diameter spherical spores of *Chytridiopsis aquaticus* and *Enterocytozoon bieneusi* to cylindrical spores, more than 20 μm long, of *Mrazekia argoisi*. Most Microsporidia have ovoid or ellipsoid spores measuring about 4 μm in length. A variety of more complex shapes is exhibited and has been used to distinguish between genera which otherwise follow similar patterns of development. Spores, such as those of *Caudospora*, *Jirovecia*, and *Inodosporus*, may be adorned with appendages, and there are abundant fine filaments like a covering of hairs on spores of *Ameson* and *Hirsutusporos* (Batson 1983). These appendages appear on developmental stages and persist, during spore morphogenesis, to become extensions of the exospore layer (Vavra and Larsson 2014).

In general, the microsporidial spore contents are encased in a resistant structure consisting of the exospore (electron dense secretions that first appear at the onset of sporogony, in most species) and the endospore (the electron lucent region forming last in spore maturation). Internally, it is lined by a membrane (formerly the cell limiting membrane, now the sporoplasm isolation membrane) which forms

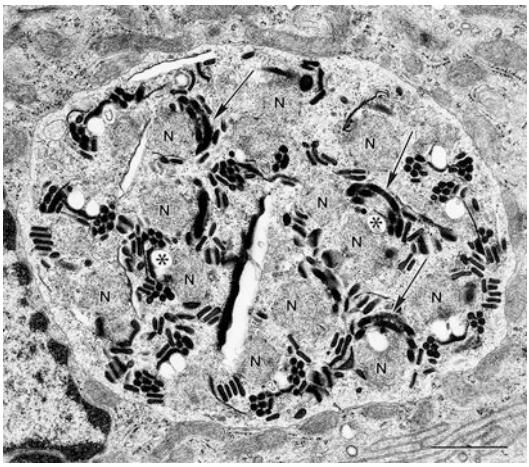

Fig. 21 *Enterocytozoon bieneusi* plasmodium with multiple developing polar filaments and many nuclei. The sporogonial plasmodium contains at least 12 nuclei (N) in a single plane of section. The round nuclei are each associated with electron dense disc complexes and electron lucent inclusions (*). Electron dense discs fuse into arcs forming polar filament coils (*arrows*). Despite the advanced maturation and organelle separation associated with each nucleus, there is no evidence of cytokinesis or plasmalemmal thickening which will occur after polar filament formation is complete. This developmental sequence is unique to the *Enterocytozoonidae* (Reprinted from Cali and Owen 1990)

invaginations around the developed polar filament. The plasmalemma, formerly thought to be just an envelope lining the endospore, has recently been demonstrated to be much more elaborate with infoldings surrounding the polar filament and thus isolating the sporoplasm from the extrusion apparatus (Cali et al. 2002).

The spore houses the infective agent (sporoplasm) and an array of structures comprising the extrusion apparatus (Vavra and Larsson 2014; Cali and Takvorian 2014). At the anterior end is an anchoring disc shaped rather like the cap of a mushroom, with the base of the polar filament inserted like its stalk (the anterior attachment complex). The polar filament runs a straight course (manubroid portion) diagonally posteriad and is posteriorly coiled in the peripheral layers of cytoplasm, later becoming isolated by the membrane infoldings (described above). The coils may be of uniform diameter (isofilar) or show a sudden change of diameter along its length (anisofilar). Surrounding the manubroid part of the filament is the polaroplast, usually a system of flattened membranes but sometimes described as vesicular, granular, or septate (Takvorian and Cali 1986; Takvorian et al. 2006). The posterior end of the spore may contain a vacuole or posterosome. Whether or not the posterior vacuole is membrane bound has not been definitively resolved (Figs. 4, 12).

In *Anncaliia algerae*, an additional organelle, the MIN (multilayered interlaced network) has been observed (Cali et al. 2002). It has been demonstrated to be associated with the end of the polar filament and surrounds the sporoplasm during the extrusion process and Golgi-like in activity (Takvorian et al. 2013). The

remaining spore contents (the sporoplasm) is the cytoplasm containing rough endoplasmic reticulum and free ribosomes surrounding one or two nuclei which is located centrally within the coiled region of the polar tube (Figs. 4 and 12a).

During spore activation, pressure attributed to swelling of the polaroplast membranes and posterosome builds up inside the spore and causes the polar filament to evert at the anterior end, breaking through the anchoring disc and the spore wall at its thinnest point (Vavra and Larsson 2014; Cali et al. 2002). This process proceeds in a fraction of a second and results in the polar filament becoming a tube as it everts with great speed and force, enabling it to inject the sporoplasm into a host cell (Figs. 5 and 6).

There have been several theories as to the mechanism of this germination process. In general, the germination requirements of Microsporidia are consistent for each species but vary among the different species. Jaronski concluded that "the spores responded to one or more stimuli: pH, ion concentration, osmolarity, digestive enzymes, redox potential and digestive products. Several lines of evidence suggest that sodium and potassium ions, within a limited pH range, act as primary germination stimuli for *Anncaliia* (*Nosema*) *algerae*." (Jaronski 1979). Weidner and Byrd (1982) found that the swelling of the polaroplast was accompanied by the displacement of internal calcium from the polaroplast membranes, possibly into the matrix between the membranes. They also found, as had Ishihara (1967), that external calcium blocked the polar tube discharge. During studies on germination in *Encephalitozoon hellem*, removal of calcium ions from the germination solution resulted in a decrease in polar filament extrusion (Leitch et al. 1995).

The pH effect on spore extrusion has been related to "priming" the spores. With *Ameson* (*Nosema*) *michaelis* a pH 10 has been reported (Weidner 1972). While *Glugea hertwigi* (Scarborough-Bull and Weidner 1985) and *E. hellem* respond to a pH 9.0 (Leitch et al. 1995), some organisms, e.g., *Vavraia culicis*, require a neutral or acidic pH to activate germination (Undeen 1983).

Undeen and Vander Meer (1994), using *Anncaliia algerae*, were able to link the role of the ions to activation or release of an enzyme trehalase which cleaves the disaccharide trehalose into smaller molecules. The rapid increase in solute concentration that results from this enzymatic action is believed to increase the intrasporal hydrostatic pressure providing the force for germination.

More recently, the infectious process of these organisms has been linked to the rapid influx of water into spores, presumably via aquaporins (AQPs), transmembrane channels that facilitate osmosis (Frixione et al. 1997). An AQP-like sequence of the microsporidium *Encephalitozoon cuniculi* (EcAQP) was cloned and expressed in oocytes of *Xenopus laevis*, which rendered these oocytes highly permeable to water (Fadiel et al. 2009; Ghosh et al. 2006).

Several small groups of Microsporidia are recognized which do not have the typical spore organelles described above. These belong to the class Rudimicrosporea, order Metchnikovellida, exclusively hyperparasitic in gregarines (Apicomplexa, Gregarinida), in which the polaroplast is absent and the polar tube consists only of a short thick tube, usually described as manubroid, terminating in a funnel. In four families, Chytridiopsidae, Hesseidae, Burkeidae, and Buxtehudeidae of the class Microsporea, the coiled polar tube is present but the polaroplast is absent (Larsson 2014).

Classification

Phylum Microsporidia Balbiani 1882, *stat. nov.*, Weiser 1977.

According to Levine et al. 1980 (in "The newly revised classification of the Protozoa") "the responsibility for the name of the high-level taxon is that of the person who established its actual level and its concept." Although Balbiani 1882 is credited with the name Microsporidies, he did not specify a taxonomic level of phylum. It was not established as a phylum until 1977, when two separate publications elevated the group (Sprague 1977; Weiser 1977) with different names. Technically, the publication of Sprague preceded that of Weiser by a few months and has priority; however, since Sprague and Becnel (1998) elected to accept Microsporidia as the correct phylum name and its usage has prevailed, the accepted form is Phylum Microsporidia.

History: A Linnaean classification of the microsporidia was first developed by Stempell in 1909, establishing three families in the Order Microsporidia. Subsequently, Leger and Hesse (1922) produced a system based only on spore morphology which was adopted by Kudo in the first major monograph on the microsporidia (Kudo 1924). Two attempts to produce a more encompassing classification to replace the previously used system were published independently in the same year by Sprague (1977) and Weiser (1977). While their classifications varied, they both elevated the microsporidia to phylum status where it has remained.

Two discoveries in microsporidial biology have had a profound effect on our concept of generic relationships. These discoveries, which apply to some genera, are the occurrence of meiosis at the onset of sporogony and the expression of dimorphic sequences of sporogony to which reference has been made above. The full significance of dimorphism was appreciated when it was shown that the two sequences could occur alongside one another; in the genus *Vairimorpha* the two sequences occur together at temperatures of 20°C and below. Sprague's system of separating the classical forms (order Microsporida) into two suborders, Pansporoblastina and Apansporoblastina, based on the presence or absence of sporophorous vesicles (pansporoblast membranes) in sporogony, is hardly tenable when both types of sporogony can occur in the life cycle of one species.

Weiser (1977) chose to separate the classical forms into two orders, Pleistophoridida and Nosematidida, based on the nuclear arrangement (whether isolated or abutting on one another as diplokarya) during sporogony and in the spores. This system does not distinguish between microsporidia that have isolated nuclei throughout development and may never undergo karyogamy and meiosis, and those that exhibit diplokarya at some stage in their life cycle – these nuclei separating and undergoing meiosis to produce the isolated haploid nuclei of the sporoblasts. The genus *Nosema* and some other genera are diplokaryotic in merogony and sporogony and, no synaptonemal complexes or karyogamy having been seen, it is presumed that meiosis is not a regular part of their development.

The importance of nuclear phenomena as a basis for indicating relationships in a classification system has been demonstrated by the splitting of the genus *Polydispyrenia* from the genus *Pleistophora* (Canning and Hazard 1982), and in the

splitting of the genus *Tuzetia* into four with the creation of the genera *Nelliemelba*, *Alfvenia*, and *Janacekia* (Larsson 1983).

Subsequent major classifications have been published including Sprague 1982; Issi 1986; Sprague et al. 1992; Voronin 1999; and Vossbrinck and Debrunner-Vossbrinck 2005 (with a rebuttal by Larsson 2005). Many molecular biologists have regrouped clusters of microsporidial genera with no indication as to how they fit into a higher scheme of the classification, and several new genera have been published without higher taxonomic placement. Sprague 1977, seems to have been the most widely used classification scheme and it can accommodate most current descriptions. We have chosen to use much of his basic scheme, omitting the suborders "Pansporoblastina" and "Apansporoblastina" which are based on the presence or absence of sporophorous vesicles. Additionally, new family names have been added to accommodate the subsequently described microsporidia as perceived by Voronin (1999) and those published since 1999. It should be noted that researchers disagree with the lines of division between the groupings and or their validity. Currently, the classification of the Phylum Microsporidia is still in major flux as demonstrated by the following published comments:

"None of the five different classification systems for microsporidia (Issi 1986; Sprague 1977; Sprague et al.1992; Vossbrinck and Debrunner-Vossbrinck 2005; Weiser 1977) satisfies the requirement of harmonizing structural data conventionally used in microsporidia classification with molecular phylogeny relationships. This is the general situation in microsporidia, where synapomorphic structural data are not well defined. The best example is *Senoma globulifera*, a mosquito parasite, which, although phylogenetically the closest relative of *Binucleata daphniae*, is structurally so dissimilar to *Binucleata*, that any conventional taxonomist would assign them at least into different families." (Refardt et al. 2008)

Currently, microsporidian sequence data can be accessed at MicrosporidiaDB (http://microsporidiadb.org). It is an NIH funded eukaryotic pathogen database resource that is continuously updated.

The following is in no way a validation or commitment to a classification but rather a work in progress. Further, as a reflection of the variations in the classification schemes, a checklist of available generic names for the Microsporidia including their type species and type hosts is presented here as has become custom (Canning and Lom 1986; Larsson 1999; Sprague and Becnel 1999; Becnel et al. 2014).

In the absence of a comprehensive revision, the higher classification proposed by Sprague and Vavra (1977) and Sprague (1982) is outlined below with the addition of new families.

•MICROSPORIDIA Balbiani 1882, *stat. nov.*, Weiser 1977
  ••Rudimicrosporea Sprague 1977
    •••Metchnikovellida Vivier, 1975
      ••••Metchnikovellidae Caullery and Mesnil, 1914
  ••Microsporea Corliss and Levine, 1963
    •••Chytridiopsida Weiser, 1974
      ••••Chytridiopsidae Sprague, Ormières and Manier, 1972
      ••••Hesseidae Ormières and Sprague, 1973

The following is a checklist of available generic names for Microsporidia with type species and type hosts. This list includes the generic names that are deemed to have met the criteria of availability as defined by the Code of Zoological Nomenclature.

1. *Abelspora* Azevedo, 1987. Type species *Abelspora portucalensis* Azevedo, 1987. Type host *Carcinus maenas* (L.) Leach, 1814 (Decapoda, Portunidae).
2. *Acarispora* Redek, Kariton, Dabert and Alberti, 2015. Type species: *Acarispora falculifera* Redek, Kariton, Dabert and Alberti, 2015. Type host: *Falculifer rostratus* (Astigmata: Pterolichoidea).
3. *Aedispora* Kilochitskii, 1997. Type species *Aedispora dorsalis* Kilochitskii, 1997. Type host *Aedes* (*Ochlerotatus*) *caspius dorsalis* (Meigen) (Diptera, Culicidae).
4. *Agglomerata* Larsson and Yan, 1988. Type species *Agglomerata sidae* (Jírovec, 1942) Larsson and Yan, 1988. Type host *Sida crystallina* (O. F. Mueller, 1785) (Cladocera, Sididae).
5. *Agmasoma* Hazard and Oldacre, 1975. Type species *Agmasoma penaei* (Sprague, 1950) Hazard and Oldacre, 1975. Type host *Penaeus setiferus* (L.) (Decapoda, Penaeidae).
6. *Alfvenia* Larsson 1983. Type species *Alfvenia nuda* Larsson 1983. Type host *Acanthocyclops vernalis* Fisher (Copepoda, Cyclopidae).
7. *Alloglugea* Paperna and Lainson, 1995. Type species *Alloglugea bufonis* Paperna and Lainson, 1995. Type host *Bufo marinus* L. (Anura, Bufonidae).
8. *Amazonspora* Azevedo and Matos 2003. Type species *Amazonspora hassar* Azevedo and Matos 2003. Type host *Hassar orestis* (Steindachner, 1875) (Teleostei, Doradidae).
9. *Amblyospora* Hazard and Oldacre, 1975. Type species *Amblyospora californica* (Kellen & Lipa, 1960) Hazard and Oldacre, 1975. Type definitive host *Culex tarsalis* Coquillett (Diptera, Culicidae). Type intermediate host *Mesocyclops leukarti* (Claus, 1875) (Copepoda, Cyclopidae).
10. *Ameson* Sprague 1977. Type species *Ameson michaelis* (Sprague, 1970) Sprague 1977. Type host *Callinectes sapidus* (Rathbun, 1896) (Decapoda, Portunidae).
11. *Amphiacantha* Caullery and Mesnil, 1914. Type species *Amphiacantha longa* Caullery and Mesnil, 1914. Type host *Ophioidina elongata* Ming. "or related species" (Gregarinida) parasite of *Lumbriconereis tingens* (Polychaeta, Eunicidae).
12. *Amphiamblys* Caullery and Mesnil, 1914. Type species *Amphiamblys capitellides* (Caullery & Mesnil, 1897) Caullery and Mesnil, 1914. Type host *Ancora* sp. (Gregarinida) parasite of *Capitellides giardi* (Polychaeta).
13. *Andreanna* Simakova, Vossbrinck, and Andreadis, 2008. Type species *Andreanna caspii* Simakova, Vossbrinck, and Andreadis, 2008. Type host *Aedes* (*Ochlerotatus) caspius* (Pallas) (Diptera, Culicidae).
14. *Anisofilariata* Tokarev, Voronin, Seliverstova, Dolgikh, Pavlova, Ignatieva, and Issi, 2010. Type species *Anisofilariata chironomi* Tokarev, Voronin, Seliverstova, Dolgikh, Pavlova, Ignatieva, and Issi, 2010. Type host *Chironomus plumosus* L. (Diptera, Chironomidae).
15. *Anncaliia* Issi, Krylova, and Nicolaeva, 1993. Type species *Anncaliia meligethi* (Issi & Radishcheva, 1979) Issi, Krylova, and Nicolaeva, 1993. Type host *Meligethes aeneus* (Coleoptera, Nitidulidae).

16. *Anostracospora* Rode, Landes, Lievens, Flaven, Segard, Jabbour-Zahab, Michalakis, Agnew, Vivarès, and Lenormand, 2013. Type species *Anostracospora rigaudi* Rode, Landes, Lievens, Flaven, Segard, Jabbour-Zahab, Michalakis, Agnew, Vivares, and Lenormand, 2013. Type hosts *Artemia franciscana* Kellogg, 1906, and *A. parthenoge- netica* Bowen and Sterling, 1978 (Anostraca, Artemiidae).
17. *Antonospora* Fries, Paxton, Tengo, Slemenda, da Silva, and Pieniazek, 1999. Type species *Antonospora scoticae* Fries, Paxton, Tengo, Slemenda, da Silva, and Pieniazek, 1999. Type host *Andrena scotica* Perkins, 1916 (Hymenoptera, Andrenidae).
18. *Areospora* Stentiford, Bateman, Feist, Oyarzún, Uribe, Palacios, and Stone, 2014. Type species *Areospora rohanae* Stentiford, Bateman, Feist, Oyarzún, Uribe, Palacios, and Stone, 2014. Type host *Lithodes santolla* Molina, 1782 (Arthropoda, Lithodidae).
19. *Auraspora* Weiser and Purrini, 1980. Type species *Auraspora canningae* Weiser and Purrini, 1980. Type host *Lepidocyrtus lignorum* Fabricius, 1781 (Collembola, Entomobryidae).
20. *Bacillidium* Janda, 1928. Type species *Bacillidium criodrili* Janda, 1928. Type host *Criodrilus lacuum* Hoffm. (Haplotaxida, Criodrilidae).
21. *Baculea* Loubes and Akbarieh, 1978. Type species *Baculea daphniae* Loubes and Akbarieh, 1978. Type host *Daphnia pulex* (de Geer, 1778) (Cladocera, Daphniidae).
22. *Becnelia* Tonka and Weiser, 2000. Type species *Becnelia sigarae* Tonka and Weiser, 2000. Type host water boatmen, *Sigara lateralis* Leach, 1817 (Heteroptera, Corixidae).
23. *Berwaldia* Larsson, 1981. Type species *Berwaldia singularis* Larsson, 1981. Type host *Daphnia pulex* (de Geer, 1778) (Cladocera, Daphniidae).
24. *Binucleata* Refardt, Decaestecker, Johnson, and Vávra, 2008. Type species *Binucleata daphniae* Refardt, Decaestecker, Johnson, and Vávra, 2008. Type host *Daphnia magna* Straus (Cladocera, Daphniidae).
25. *Binucleospora* Bronnvall and Larsson, 1995. Type species *Binucleospora elongata* Bronnvall and Larsson, 1985. Type host *Candona* sp. (Ostracoda, Cyprididae).
26. *Bohuslavia* Larsson, 1985. Type species *Bohuslavia asterias* (Weiser, 1963) Larsson, 1985. Type host *Endochironomus* sp. (Diptera, Chironomidae).
27. *Brachiola* Cali, Takvorian, and Weiss, 1998. Type species *Brachiola vesicularum* Cali, Takvorian, and Weiss, 1998. Type host *Homo sapiens* L. (Primates, Hominidae).
28. *Bryonosema* Canning, Refardt, Vossbrinck, Okamura, and Curry, 2002. Type species *Bryonosema plumatellae* Canning, Refardt, Vossbrinck, Okamura, and Curry, 2002. Type host *Plumatella nitens* Wood, 1996 (Plumatellida, Plumatellidae).
29. *Burenella* Jouvenaz and Hazard, 1978. Type species *Burenella dimorpha* Jouvenaz and Hazard, 1978. Type host *Solenopsis geminata* (Fabricius) (Hymenoptera, Formicidae).

30. *Burkea* Sprague 1977. Type species *Burkea gatesi* (Puytorac and Tourret, 1963) Sprague 1977. Type host *Pheretima hawayana* (Oligochaeta, Megascolecidae) selected here from two hosts mentioned.
31. *Buxtehudea* Larsson, 1980. Type species *Buxtehudea scaniae* Larsson, 1980. Type host *Petrobius brevistylis* Carpenter, 1913 (Thysanura, Machilidae).
32. *Campanulospora* Issi, Radischcheva, and Dolzhenko, 1983. Type species *Campanulospora denticulata* Issi, Radischcheva, and Dolzhenko, 1983. Type host *Delia floralis* Fall. (Diptera, Muscidae).
33. *Canningia* Weiser, Wegensteiner, and Zizka, 1995. Type species *Canningia spinidentis* Weiser, Wegensteiner, and Zizka, 1995. Type host *Pityokteines spinidens* Rtt. (Coleoptera, Scolytidae).
34. *Caudospora* Weiser, 1946. Type species *Caudospora simulii* Weiser, 1946. Type host *Simulium hirtipes* (Fries, 1824) (Diptera, Simuliidae).
35. *Caulleryetta* Dogiel, 1922. Type species *Caulleryetta mesnili* Dogiel, 1922. Type host *Selenidium* sp. (Gregarinida, Schizocystidae) parasite of *Travisia forbesii* (Polychaeta).
36. *Chapmanium* Hazard and Oldacre, 1975. Type species *Chapmanium cirritus* Hazard and Oldacre, 1975. Type host *Corethrella brakeleyi* (Coquillett) (Diptera, Chaoboridae).
37. *Chytridioides* Tregouboff, 1913. Type species *Chytridioides schizophylli* Tregouboff, 1913. Type host *Schizophyllum mediterraneum* Latzel = *Ommatoiulus rutilans* (Koch, 1847) (Julida, Julidae).
38. *Chytridiopsis* Schneider, 1884. Type species *Chytridiopsis socius* Schneider, 1884. Type host *Blaps mortisaga* L. (Coleoptera, Tenebrionidae).
39. *Ciliatosporidium* Foissner and Foissner, 1995. Type species *Ciliatosporidium platyophryae* Foissner and Foissner, 1995. Type host *Platyophrya terricola* (Foissner, 1987) Foissner and Foissner, 1995 (Ciliophora, Colpodea).
40. *Coccospora* Kudo, 1925. Replacement name for *Cocconema* Léger and Hesse, 1921, preoccupied. Type species *Coccospora micrococcus* (Léger & Hesse, 1921) Kudo, 1925. Type host *Tanypus setiger* Kieffer (Diptera, Chironomidae).
41. *Cougourdella* Hesse, 1935. Type species *Cougourdella magna* Hesse, 1935. Type host *Megacyclops viridis* Jurine (Copepoda, Cyclopidae).
42. *Crepidulospora* Simakova, Pankova, and Issi, 2004. Type species *Crepidulospora beklemishevi* (Simakova et al. 2003) Simakova, Pankova, and Issi, 2004. Type host *Anopheles beklemishevi* (Diptera, Culicidae).
43. *Crispospora* Tokarev, Voronin, Seliverstova, Pavlova, and Issi, 2010. Type species *Crispospora chironomi* Tokarev, Voronin, Seliverstova, Pavlova, and Issi, 2010. Type host *Chironomus plumosus* L. (Diptera, Chironomidae).
44. *Cristulospora* Khodzhaeva and Issi, 1989. Type species *Cristulospora sherbani* Khodzhaeva and Issi, 1989. Type host *Culex modestus* (Diptera, Culicidae).
45. *Cryptosporina* Hazard and Oldacre, 1975. Type species *Cryptosporina brachyfila* Hazard and Oldacre, 1975. Type host *Piona* sp. (Arachnida, Hygrobatinae).
46. *Cucumispora* Ovcharenko, Bacela, Wilkinson, Ironside, Rigaud, and Wattier, 2010. Type species *Cucumispora dikerogammari* (Ovcharenko and Kurandina,

1987) Ovcharenko, Bacela, Wilkinson, Ironside, Rigaud, and Wattier, 2010. Type host *Dikerogammarus villosus* (Sowinsky, 1894) (Amphipoda, Gammaridae).

47. *Culicospora* Weiser 1977. Type species *Culicospora magna* (Kudo, 1920) Weiser 1977. Type host *Culex pipiens* L. (Diptera, Culicidae).
48. *Culicosporella* Weiser 1977. Type species *Culicosporella lunata* (Hazard & Savage, 1970) Weiser 1977. Type host *Culex pilosus* (Dyar & Knab, 1906) (Diptera, Culicidae).
49. *Cylindrospora* Issi and Voronin, 1986. Type species *Cylindrospora chironomi* Issi and Voronin, 1986, in Issi 1986. Type host *Chironomus plumosus* L. (Diptera, Chironomidae).
50. *Cystosporogenes* Canning, Barker, Nicholas, and Page, 1985. Type species *Cystosporogenes operophterae* (Canning, 1960) Canning, Barker, Nicholas, and Page, 1985. Type host *Operophtera brumata* (L.) (Lepidoptera, Geometridae).
51. *Dasyatispora* Diamant, Goren, Yokeş, Galil, Klopman, Huchon, Szitenberg, and Karhan, 2010. Type species *Dasyatispora levantinae* Diamant, Goren, Yokes, Galil, Klopman, Huchon, Szitenberg, and Karhan, 2010. Type host *Dasyatis pastinaca* (L.) (Myliobatiformes, Dasyatidae).
52. *Desmozoon* Freeman and Sommerville 2009. Type species *Desmozoon lepeophtherii* Freeman and Sommerville 2009. Type host *Lepeophtheirus salmonis* (Krøyer) (Copepoda, Caligidae).
53. *Desportesia* Issi and Voronin, 1986. Type species *Desportesia laubieri* (Desportes & Theodorides, 1979) Issi and Voronin, 1986, in Issi 1986. Type host *Lecudina* sp. (Gregarinida, Lecudinidae) parasite of unidentified marine annelid (Echiurida). (Considered by Larsson 2014, to be a junior synonym of *Amphiamblys*)
54. *Dimeiospora* Simakova, Pankova, and Issi, 2003. Type species *Dimeiospora palustris* Simakova, Pankova, and Issi, 2003. Type host *Aedes (Ochlerotatus) punctor* Kirby (Diptera, Culicidae).
55. *Duboscqia* Pérez, 1908. Type species *Duboscqia legeri* Pérez, 1908. Type host *Termes lucifugus* = *Reticulitermes lucifugus* (Rossi) (Isoptera, Rhinotermitidae).
56. *Edhazardia* Becnel, Sprague, and Fukuda, 1989. Type species *Edhazardia aedis* (Kudo, 1930) Becnel, Sprague, and Fukuda, 1989, in Becnel, Sprague, Fukuda, and Hazard, 1989. Type host *Aedes aegypti* (L.) (Diptera, Culicidae).
57. *Encephalitozoon* Levaditi, Nicolau, and Schoen, 1923. Type species *Encephalitozoon cuniculi* Levaditi, Nicolau, and Schoen, 1923. Type host "Rabbit" (Lagomorpha, Leporidae).
58. *Endoreticulatus* Brooks, Becnel, and Kennedy, 1988. Type species *Endoreticulatus fidelis* (Hostounsky & Weiser, 1975) Brooks, Becnel, and Kennedy, 1988. Type host *Leptinotarsa undecimlineata* Stal (Coleoptera, Chrysomelidae).
59. *Enterocytospora* Rode, Landes, Lievens, Flaven, Segard, Jabbour-Zahab, Michalakis, Agnew, Vivarès, and Lenormand, 2013. Type species *Enterocytospora artemiae* Rode, Landes, Lievens, Flaven, Segard, Jabbour-Zahab, Michalakis, Agnew, Vivares, and Lenormand, 2013. Type hosts *Artemia*

franciscana Kellogg, 1906; A. *franciscana monica* Verrill, 1869; and *A. parthenogenetica* Bowen and Sterling, 1978 (Anostraca, Artemiidae).

60. *Enterocytozoon* Desportes, Le Charpentier, Galian, Bernard, Cochand-Priollet, Lavergne, Ravisse, and Modigliani, 1985. Type species *Enterocytozoon bieneusi* Desportes, Le Charpentier, Galian, Bernard, Cochand-Priollet, Lavergne, Ravisse, and Modigliani, 1985. Type host *Homo sapiens* L. (Primates, Hominidae).
61. *Enterospora* Stentiford, Bateman, Longshaw, and Feist, 2007. Type species *Enterospora canceri* Stentiford, Bateman, Longshaw, and Feist, 2007. Type host *Cancer pagurus* L. (Decapoda, Cancridae).
62. *Episeptum* Larsson 1986. Type species *Episeptum inversum* Larsson 1986. Type host *Holocentropus picicornis* (Stevens, 1836) (Trichoptera, Polycentropidae).
63. *Euplotespora* Fokin et al. Fokin et al. 2008. Type species *Euplotespora binucleata* Fokin et al. 2008. Type host *Euplotes woodruffi* (Hypotrichida, Euplotidae).
64. *Evlachovaia* Voronin and Issi 1986. Type species *Evlachovaia chironomi* Voronin and Issi 1986, in Issi 1986. Type host *Chironomus plumosus* (Diptera, Chironomidae).
65. *Facilispora* Jones, Prosperi-Porta, and Kim, 2012. Type species *Facilispora margolisi* Jones, Prosperi-Porta, and Kim, 2012. Type host *Lepeophtheirus salmonis* Krøyer (Siphonostomatoida, Caligidae).
66. *Fibrillanosema* Galbreath, Smith, Terry, Becnel, and Dunn, 2004. Type species *Fibrillanosema crangonycis* Galbreath, Smith, Terry, Becnel, and Dunn, 2004. Type host *Crangonyx pseudogracilis* (Amphipoda, Crangonyctidae).
67. *Flabelliforma* Canning, Killick-Kendrick, and Killick-Kendrick, 1991. Type species *Flabelliforma montana* Canning, Killick-Kendrick, and Killick-Kendrick, 1991. Type host *Phlebotomus ariasi* Tonnoir, 1921 (Diptera, Psychodidae).
68. *Geusia* Rühl and Korn, 1979. Type species *Geusia gamocysti* Rühl and Korn, 1979. Type host *Gamocystis ephemerae* Frantzius, 1848 (Gregarinida, Gregarinidae), parasite of *Ephemera danica* (Ephemeroptera, Ephemeridae).
69. *Globulispora* Vávra et al. Vavra et al. 2016. Type species: *Globulispora mitoportans* Vávra et al. Vavra et al. 2016. Type host: *Daphnia pulex* (Leydig, 1860).
70. *Glugea* Thélohan, 1891. Type species *Glugea anomala* (Moniez, 1887) Gurley, 1893. Type host *Gasterosteus aculea- tus* L. (Gasterosteiformes, Gasterosteidae).
71. *Glugoides* Larsson, Ebert, Vávra, and Voronin, 1996. Type species *Glugoides intestinalis* (Chatton, 1907) Larsson, Ebert, Vávra, and Voronin, 1996. Type host *Daphnia magna* Straus, 1820 (Cladocera, Daphniidae), selected here from two hosts mentioned.
72. *Golbergia* Weiser 1977. Type species *Golbergia spinosa* (Golberg, 1971) Weiser 1977. Type host *Culex pipiens* L. (Diptera, Culicidae).
73. *Gurleya* Doflein, 1898. Type species *Gurleya tetraspora* Doflein, 1898. Type host *Daphnia maxima* (Cladocera, Daphniidae).

74. G*urleyides* Voronin, 1986. Type species *Gurleyides biformis* Voronin, 1986. Type host *Ceriodaphnia reticulata* Jurine (Cladocera, Daphniidae).
75. *Hamiltosporidium* Haag, Larsson, Refardt, and Ebert, 2010. Type species *Hamiltosporidium tvaerminnensis* Haag, Larsson, Refardt, and Ebert, 2010. Type host *Daphnia magna* Straus, 1820 (Cladocera, Daphniidae).
76. *Hazardia* Weiser 1977. Type species *Hazardia milleri* (Hazard & Fukuda, 1974) Weiser 1977. Type host *Culex pipiens quinquefasciatus* Say, 1823 (Diptera, Culicidae).
77. *Helmichia* Larsson, 1982. Type species *Helmichia aggregata* Larsson, 1982. Type host *Endochironomus* sp. (Diptera, Chironomidae).
78. *Hepatospora* Stentiford, Bateman, Dubuffet, Chambers, and Stone, 2011. Type species *Hepatospora eriocheir* (Wang & Chen, 2007) Stentiford, Bateman, Dubuffet, Chambers, and Stone, 2011. Type host *Eriocheir sinensis* H. Milne Edwards, 1853 (Decapoda, Varunidae).
79. *Hessea* Ormières and Sprague, 1973. Type species *Hessea squamosa* Ormières and Sprague, 1973. Type host *Sciara* sp. (Diptera, Lycoriidae).
80. *Heterosporis* Schubert 1969. Type species *Heterosporis finki* Schubert 1969. Type host *Pterophyllum scalare* (Curs & Valens, 1831) (Perciformes, Cichlidae).
81. *Heterovesicula* Lange, Macvean, Henry, and Streett, 1995. Type species *Heterovesicula cowani* Lange, Macvean, Henry, and Streett, 1995. Type host *Anabrus simplex* Haldeman, 1852 (Orthoptera, Tettigoniidae).
82. *Hirsutusporos* Batson 1983. Type species *Hirsutusporos austrosimulii* Batson 1983. Type host *Austrosimulium* sp. (Diptera, Simuliidae).
83. *Holobispora* Voronin, 1986. Type species *Holobispora thermocyclopis* Voronin, 1986. Type host *Thermocyclops ortho- noides* (Sars) (Copepoda, Cyclopidae).
84. *Hrabyeia* Lom and Dykova, 1990. Type species *Hrabyeia xerkophora* Lom and Dykova, 1990. Type host *Nais christi- nae* Kasparzak, 1973 (Oligochaeta, Naididae).
85. *Hyalinocysta* Hazard and Oldacre, 1975. Type species *Hyalinocysta chapmani* Hazard and Oldacre, 1975. Type host *Culiseta melanura* Coquillett, 1902 (Diptera, Culicidae).
86. *Ichthyosporidium* Caullery and Mesnil, 1905. Type species *Ichthyosporidium giganteum* (Thélohan, 1895) Swarczewsky, 1914. Type host *Crenilabrus melops* L. (Perciformes, Labridae).
87. *Inodosporus* Overstreet and Weidner, 1974. Type species *Inodosporus spraguei* Overstreet and Weidner, 1974. Type host *Palaemonetes pugio* Holthius, 1949 (Decapoda, Palaemonidae).
88. *Intexta* Larsson, Steiner, and Bjørnson, 1997. Type species *Intexta acarivora* Larsson, Steiner, and Bjørnson, 1997. Type host *Tyrophagus putrescentiae* (Acari, Acaridae).
89. *Intrapredatorus* Chen, Kuo, and Wu, 1998. Type species *Intrapredatorus trinus* (Becnel & Sweeney, 1990) Chen, Kuo, and Wu, 1998. Type host *Culex fuscanus* Wiedemann (Diptera, Culicidae).
90. *Issia* Weiser 1977. Type species *Issia trichopterae* (Weiser, 1946) Weiser 1977. Type host *Plectrocnemia geniculata* (Trichoptera, Polycentropodidae).

91. *Janacekia* Larsson 1983. Type species *Janacekia debaisieuxi* (Jírovec, 1943) Larsson 1983. Type host *Simulium maculatum* Meig. (Diptera, Simuliidae).
92. *Jirovecia* Weiser 1977. Type species *Jirovecia caudata* (Léger & Hesse, 1916) Weiser 1977. Type host *Tubifex tubifex* Mueller (Oligochaeta, Tubificidae).
93. *Jiroveciana* Larsson, 1980. Type species *Jiroveciana limnodrili* (Jírovec, 1940) Larsson, 1980. Type host *Limnodrilus missionicus* (Oligochaeta, Tubificidae).
94. *Johenrea* Lange, Becnel, Razafindratiana, Przybyszewski, and Razafindrafara, 1996. Type species *Johenrea locustae* Lange, Becnel, Razafindratiana, Przybyszewski, and Razafindrafara, 1996. Type host *Locusta migratoria capito* (Saussure, 1884) (Orthoptera, Acrididae).
95. *Kabatana* Lom, Dyková, and Tonguthai, 2000. Type species *Kabatana arthuri* (Lom et al. 1999) Lom et al. 2000. Type host *Pangasius sutchi* (Siluriformes, Pangasiidae).
96. *Kinorhynchospora* Adrianov and Rybakov, 1991. Type species *Kinorhynchospora japonica* Adrianov and Rybakov, 1991. Type host *Kinorhynchus yushini* (Echinodera, Pycnophyidae).
97. *Kneallhazia* Sokolova and Fuxa 2008. Type species *Kneallhazia solenopsae* (Knell, Allen, & Hazard, 1977) Sokolova and Fuxa 2008. Type host *Solenopsis invicta* Buren (Hymenoptera, Formicidae).
98. *Krishtalia* Kilochitskii, 1997. Type species *Krishtalia pipiens* Kilochitskii, 1997. Type host *Culex pipiens pipiens* L. (Diptera, Culicidae).
99. *Lanatospora* Voronin, 1986. Type species *Lanatospora macrocyclopis* (Voronin, 1977) Voronin, 1986. Type host *Macrocyclops albidus* Jurine (Copepoda, Cyclopidae).
100. *Larssonia* Vidtmann and Sokolova, 1994. Type species *Larssonia obtusa* (Moniez, 1887) Vidtmann and Sokolova, 1994. Type host *Daphnia pulex* De Geer (Cladocera, Daphniidae).
101. *Larssoniella* Weiser and David, 1997. Type species *Larssoniella resinellae* Weiser and David, 1997. Type host *Petrova resinella* (L.) (Lepidoptera, Tortricidae).
102. *Liebermannia* Sokolova, Lange, and Fuxa, 2006. Type species *Liebermannia patagonica* Sokolova, Lange, and Fuxa, 2006. Type host *Tristira magellanica* Bruner, 1900 (Orthoptera, Tristiridae).
103. *Loma* Morrison and Sprague 1981. Type species *Loma morhua* Morrison and Sprague 1981. Type host *Gadus morhua* L. (Gadiformes, Gadidae).
104. *Mariona* Stempell 1909. Type species *Mariona marionis* (Thélohan, 1895) Stempell 1909. Type host *Ceratomyxa coris* Georgevitch, 1916 (Bivalvulida, Ceratomyxidae), parasite of *Coris julis* L. (Pisces).
105. *Marssoniella* Lemmermann, 1900. Type species *Marssoniella elegans* Lemmermann, 1900. Type host *Cyclops stren- uus* Fischer, 1851 (Copepoda, Cyclopidae).
106. *Merocinta* Pell and Canning, 1993. Type species *Merocinta davidii* Pell and Canning, 1993. Type host *Mansonia africana* (Theobald) (Diptera, Culicidae).

107. *Metchnikovella* Caullery and Mesnil, 1897. Type species *Metchnikovella spionis* Caullery and Mesnil, 1897. Type host *Polyrhabdina brasili* Caullery and Mesnil (Gregarinida, Lecudinidae) parasite of *Spio martinensis* Mesnil (Polychaeta, Spionidae).
108. *Microfilum* Faye, Toguebaye, and Bouix, 1991. Type species *Microfilum lutjani* Faye, Toguebaye, and Bouix, 1991. Type host *Lutjanus fulgens* (Valenciennes, 1830) (Perciformes, Lutjanidae).
109. *Microgemma* Ralphs and Matthews, 1986. Type species *Microgemma hepaticus* Ralphs and Matthews, 1986. Type host *Chelon labrosus* (Risso) (Mugiliformes, Mugilidae).
110. *Microsporidium* Balbiani 1884. Not an available name *sensu stricto* but used under the provisions of the code (see Glossary, p. 257) as the legitimate name of a collective group. Useful as a provisional generic name if an author desires to record an unidentified species or to form a binomen and establish a new species while there is indecision about the genus.
111. *Microsporidyopsis* Chereschewsky, 1925. Type species *Microsporidyopsis nereidis* Schereschewsky, 1925. Type host *Doliocystis* sp. (Gregarinida) parasite of *Nereis parallelogramma* Claparede (Polychaeta, Nereidae).
112. *Mitoplistophora* Codreanu, 1966. Type species *Mitoplistophora angularis* Codreanu, 1966. Type host *Ephemera danica* (Ephemeroptera, Ephemeridae).
113. *Mitosporidium* Haag, Karen L., Timothy Y. James, Jean-François Pombert, Ronny Larsson, Tobias M. M. Schaer, Dominik Refardt, and Dieter Ebert. 2014. Type species: *Mitosporidium daphnia* Haag, Karen L., Timothy Y. James, Jean-François Pombert, Ronny Larsson, Tobias M. M. Schaer, Dominik Refardt, and Dieter Ebert. 2014. Type host: *Daphnia magna* (Crustacea: Cladocera).
114. *Mockfordia* Sokolova, Sokolov, and Carlton, 2010. Type species *Mockfordia xanthocaeciliae* Sokolova, Sokolov, and Carlton, 2010. Type host *Xanthocaecilius sommermanae* Mockford, 1955 (Psocoptera, Caeciliusidae).
115. *Mrazekia* Léger and Hesse, 1916. Type species *Mrazekia argoisi* Léger and Hesse, 1916. Type host *Asellus aquaticus* L. (Isopoda, Asellidae).
116. *Multilamina* Becnel, Scheffrahn, Vossbrinck, and Bahder, 2013. Type species *Multilamina teevani* Becnel, Scheffrahn, Vossbrinck, and Bahder, 2013. Type host *Uncitermes teevani* (Isoptera, Termitidae, Syntermitinae).
117. *Myospora* Stentiford, Bateman, Small, Moss, Shields, Reece, and Tuck, 2010. Type species *Myospora metane- phrops* Stentiford, Bateman, Small, Moss, Shields, Reece, and Tuck, 2010. Type host *Metanephrops challengeri* Balss, 1914 (Decapoda, Nephropidae).
118. *Myosporidium* Baquero, Rubio, Moura, Pieniazek, and Jordana, 2005. Type species *Myosporidium merluccius* Baquero, Rubio, Moura, Pieniazek, and Jordana, 2005. Type host *Merluccius capensis*/*paradoxus* complex (Gadiformes, Merlucciidae).
119. *Myrmecomorba* Plowes et al. 2015. Type species *Myrmecomorba nylanderiae* Plowes et al. 2015. Type host *Nylanderia fulva* (Formicidae, Hymenoptera).

120. *Myxocystis* Mrazek, 1897. Type species *Myxocystis ciliata* Mrazek, 1897. Type host *Limnodrilus claparedianus* Ratzel (Oligochaeta, Tubificidae).
121. *Nadelspora* Olson, Tiekotter, and Reno, 1994. Type species *Nadelspora canceri* Olson, Tiekotter, and Reno, 1994. Type host *Cancer magister* Dana, 1852 (Decapoda, Cancridae).
122. *Napamichum* Larsson, 1990. Type species *Napamichum dispersus* (Larsson, 1984) Larsson, 1990. Type host *Endochironomus* sp. (Diptera, Chironomidae).
123. *Nelliemelba* Larsson 1983. Type species *Nelliemelba boeckella* (Milner & Mayer, 1982) Larsson 1983. Type host *Boeckella triarticulata* (Thomson) (Copepoda, Calanoidea).
124. *Nematocenator* Sapir et al. 2014. Type species: *Nematocenator marisprofundi* Sapir et al. 2014.Type host: *Desmodora marci* (Superfamily Desmodoroidea, Desmodoridae).
125. *Nematocida* Troemel, Félix, Whiteman, Barrière, and Ausubel, 2008. Type species *Nematocida parisii* Troemel, Félix, Whiteman, Barrière, and Ausubel, 2008. Type host *Caenorhabditis elegans* (Rhabditida, habditidae).
126. *Neoflabelliforma* Morris and Freeman, 2010. Type species *Neoflabelliforma aurantiae* Morris and Freeman, 2010. Type host *Tubifex tubifex* (Oligochaeta, Tubificidae).
127. *Neoperezia* Issi and Voronin, 1979. Type species *Neoperezia chironomi* Issi and Voronin, 1979. Type host *Chironomus plumosus* L. (Diptera, Chironomidae).
128. *Neonosemoides* Faye, Toguebaye, and Bouix, 1996. Type species *Neonosemoides tilapiae* Faye, Toguebaye, and Bouix, 1996. Type host *Tilapia guineensis* (Perciformes, Cichlidae).
129. *Nolleria* Beard et al. 1990. Type species *Nolleria pulicis* Beard et al. 1990. Type host *Ctenocephalides felis* (Boche, 1833) (Siphonaptera, Pulicidae).
130. *Norlevinea* Vávra, 1984. Type species *Norlevinea daphniae* Vávra, 1984. Type host *Daphnia longispina* O. F. Mueller (Cladocera, Daphniidae).
131. *Nosema* Naegeli 1857. Type species *Nosema bombycis* Naegeli 1857. Type host *Bombyx mori* L. (Lepidoptera, Bombycidae).
132. *Nosemoides* Vinckier 1975. Type species *Nosemoides vivieri* (Vinckier, Devauchelle, and Prensier, 1970) Vinckier 1975. Type host *Lecudina linei* Vinckier 1975 (Gregarinida, Monocystidae), parasite of *Lineus viridis* (Fabricius) (Heteronemertea, Lineidae).
133. *Novothelohania* Andreadis, Simakova, Vossbrinck, Shepard, and Yurchenko, 2012. Type species *Novothelohania ovalae* Andreadis, Simakova, Vossbrinck, Shepard, and Yurchenko, 2012. Type host *Aedes* (*Ochlerotatus*) *caspius* (Pallas) (Diptera, Culicidae).
134. *Nucleospora* Docker, Kent, Hervio, Khattra, Weiss, Cali, and Devlin, 1997. Type species *Nucleospora salmonis* (Chilmonczyk, Cox, & Hedrick, 1991) Docker, Kent, Hervio, Khattra, Weiss, Cali, and Devlin, 1997. Type host *Oncorhynchus tshawytscha* (Walbaum) (Salmoniformes, Salmonidae).

135. *Nudispora* Larsson, 1990. Type species *Nudispora biformis* Larsson, 1990. Type host *Coenagrion hastulatum* Charpentier, 1925 (Odonata, Coenagrionidae).
136. *Obruspora* Diamant, Rothman, Goren, Galil, Yokes, Szitenberg and Huchon 2014. Type species *Obruspora papernae* Diamant, Rothman, Goren, Galil, Yokes, Szitenberg and Huchon 2014. Type host *Callionymus filamentosus*(Teleostei: Callionymidae).
137. *Octosporea* Flu, 1911. Type species *Octosporea muscaedomesticae* Flu, 1911. Type host *Musca domestica* L. (Diptera, Muscidae).
138. *Octotetraspora* Issi, Kadyrova, Pushkar, Khodzhaeva, and Krylova, 1990. Type species *Octotetraspora* paradoxa. Type host *Wilhelmia mediterranea* (Diptera, Simuliidae).
139. *Oligosporidium* Codreanu-Bălcescu, Codreanu, and Traciuc, 1981. Type species *Oligosporidium arachnicolum* (Codreanu-Bălcescu, Codreanu, & Traciuc, 1978) Codreanu-Bălcescu, Codreanu, and Traciuc, 1981. Type host *Xysticus cambridgei* (Araneae, Thomisidae).
140. *Ordospora* Larsson, Ebert, and Vávra, 1997. Type species *Ordospora colligate* Larsson, Ebert, and Vávra, 1997. Type species *Daphnia magna* (Cladocera, Daphniidae).
141. *Ormieresia* Vivares, Bouix, and Manier, 1977. Type species *Ormieresia carcini* Vivares, Bouix, and Manier, 1977. Type host *Carcinus mediterraneus* Czerniavsky, 1884 (Decapoda, Portunidae).
142. *Orthosomella* Canning, Wigley, and Barker, 1991. Type species *Orthosomella operophterae* (Canning, 1960) Canning, Wigley, and Barker, 1991. Type host *Operophtera brumata* (L.) (Lepidoptera, Geometridae).
143. *Orthothelohania* Codreanu and Balcescu-Codreanu, 1974. Type species *Orthothelohania octospora* (Henneguy, 1892, *sensu* Pixel-Goodrich, 1920) Codreanu and Balcescu-Codreanu, 1974. Type host *Palaemon serratus* (Pennant, 1777) (Decapoda, Palaemonidae).
144. *Ovavesicula* Andreadis and Hanula, 1987. Type species *Ovavesicula popilliae* Andreadis and Hanula, 1987. Type host *Popillia japonica* Newman (Coleoptera, Scarabaeidae).
145. *Ovipleistophora* Pekkarinen et al. 2002. Type species *Ovipleistophora mirandellae* (Vaney & Conte, 1901) Pekkarinen et al. 2002. Type hosts *Gymnocephalus cernuus* (L.) (Perciformes, Percidae) and *Rutilus rutilus* (L.) (Cypriniformes, Cyprinidae), single type host not identified.
146. *Pankovaia* Simakova, Tokarev, and Issi, 2009. Type species *Pankovaia semitubulata* Simakova, Tokarev, and Issi, 2009. Type host *Cloeon dipterum* (L.) (Ephemeroptera, Baetidae).
147. *Paradoxium* Stentiford et al. 2015. Type species *Paradoxium irvingi* Stentiford et al. 2015. Type host *Pandalus montagui* (Decapoda, Pandalidae).
148. *Paraepiseptum* Hyliš, Oborník, Nebesářová, and Vávra, 2007. Type species *Paraepiseptum polycentropi* (Weiser, 1965) Hyliš, Oborník, Nebesářová, and Vávra, 2007. Type host *Polycentropus flavomaculatus* (Polycentropodidae).

149. *Paranosema* Sokolova, Dolgikh, Morzhina, Nassonova, Issi, Terry, Ironside, Smith, and Vossbrinck, 2003. Type species *Paranosema grylli* (Sokolova, Seleznev, Dolgikh, & Issi, 1994) Sokolova, Dolgikh, Morzhina, Nassonova, Issi, Terry, Ironside, Smith, and Vossbrinck, 2003. Type host *Gryllus bimaculatus* Deg. (Orthoptera, Gryllidae).
150. *Paramicrosporidium* Corsaro, D., J. Walochnik, D. Venditti, KD. Muller, B. Hauroder, and R. Michel. 2014. Type species: *Paramicrosporidium saccamoebae* Corsaro, D., J. Walochnik, D. Venditti, KD. Muller, B. Hauroder, and R. Michel. 2014. Type host: *Saccamoeba.* sp (Amoebozoa, Tubulinea, Euamoebida). (Authors of the genus considered it to be a member of the Rozellomycota related to microsporidia but not a genus of it - a sister group.)
151. *arapleistophora* Issi, Kadyrova, Pushkar, Khodzhaeva, and Krylova, 1990. Type species *Parapleistophora ectos- pora* Issi, Kadyrova, Pushkar, Khodzhaeva, and Krylova, 1990. Type host *Tetisimulium desertorum* (Diptera, Simuliidae).
152. *Parastempellia* Issi, Kadyrova, Pushkar, Khodzhaeva and Krylova, 1990. Type species *Parastempellia odagmiae* Issi, Kadyrova, Pushkar, Khodzhaeva and Krylova, 1990. Type host *Odagmia ferganica* (Diptera, Simuliidae).
153. *Parathelohania* Codreanu, 1966. Type species *Parathelohania legeri* (Hesse, 1904) Codreanu, 1966. Type host *Anopheles maculipennis* Meigen, 1818 (Diptera, Culicidae).
154. *Paratuzetia* Poddubnaya, Tokarev, and Issi, 2006. Type species *Paratuzetia kupermani* Poddubnaya, Tokarev, and Issi, 2006. Type host *Khawia armeniaca* Cholodkovsky, 1915 (Cestoda, Lytocestidae) from oligochaete *Potamothrix paravanicus.*
155. *Pegmatheca* Hazard and Oldacre, 1975. Type species *Pegmatheca simulii* Hazard and Oldacre, 1975. Type host *Simulium tuberosum* (Lindstrom, 1911) (Diptera, Simuliidae).
156. *Perezia* Léger and Duboscq, 1909. Type species *Perezia lankesteriae* Léger and Duboscq, 1909. Type host *Lankesteria ascidiae* (Lankester, 1872) (Gregarinida, Diplocystidae) parasite of *Ciona intestinalis* (L.) (Dictyobranchia, Ascidiidae).
157. *Pernicivesicula* Bylen and Larsson, 1994. Type species *Pernicivesicula gracilis* Bylen and Larsson, 1994. Type host *Pentaneurella* sp. Fittkau and Murray, 1983 (Diptera, Chironomidae).
158. *Pilosporella* Hazard and Oldacre, 1975. Type species *Pilosporella fishi* Hazard and Oldacre, 1975. Type host *Wyeomyia vanduzeei* Dyar and Knab, 1906 (Diptera, Culicidae).
159. *Pleistophora* Gurley, 1893.Type species *Pleistophora typicalis* Gurley, 1893. Type host *Cottus scorpius* = *Myoxocephalus scorpius* (L.) Perciformes, Cottidae).
160. *Pleistophoridium* Codreanu-Bălcescu and Codreanu, 1982. Type species *Pleistophoridium hyperparasiticum* (Codreanu-Bălcescu & Codreanu, 1976)

Codreanu-Bălcescu and Codreanu, 1982. Type host *Enterocystis rhithrogenae* M. Codreanu, 1940 (Gregarinida, Monocystidae), parasite of *Rhithrogena semicolorata* (Curt, 1834) (Ephemeroptera).

161. *Polydispyrenia* Canning and Hazard 1982. Type species *Polydispyrenia simulii* (Lutz & Splendore, 1908) Canning and Hazard 1982. Type host *Simulium venustum* Say = *Simulium pertinax* Kollar (Diptera, Simuliidae).
162. *Potaspora* Casal et al. 2008. Type species *Potaspora morhaphis* Casal et al. 2008. Type host *Potamorhaphis guianensis* (Beloniformes, Belonidae).
163. *Pseudoloma* Matthews, Brown, Larison, Bishop-Stewart, Rogers, and Kent, 2001. Type species *Pseudoloma neu- rophilia* Matthews, Brown, Larison, Bishop-Stewart, Rogers, and Kent, 2001. Type host *Danio rerio* (Hamilton & Buchanan, 1822) (Cypriniformes, Cyprinidae).
164. *Pseudonosema* Canning, Refardt, Vossbrinck, Okamura, and Curry, 2002. Type species *Pseudonosema cristatel- lae* (Canning, Okamura, & Curry, 1997) Canning, Refardt, Vossbrinck, Okamura, and Curry, 2002. Type host *Cristatella mucedo* Cuvier, 1798 (Plumatellidae, Cristatellidae).
165. *Pseudopleistophora* Sprague 1977. Type species *Pseudopleistophora szollosii* Sprague 1977. Type host *Armandia brevis* (Polychaeta, Opheliidae).
166. *Pulcispora* Vedmed, Krylova, and Issi, 1991. Type species *Pulcispora xenopsyllae* Vedmed, Krylova, and Issi, 1991. Type host *Xenopsylla hirtipes* (Siphonaptera, Pulicidae).
167. *Pyrotheca* Hesse, 1935. Type species *Pyrotheca cyclopis* (Leblanc, 1930) Poisson, 1953. Type host *Cyclops albidus* Jurine, 1820 (Copepoda, Cyclopidae).
168. *Rectispora* Larsson, 1990c. Type species *Rectispora reticulata* Larsson, 1990c. Type host *Pomatothrix hammoniensis* (Michaelson, 1901) (Oligochaeta, Tubificidae).
169. *Resiomeria* Larsson 1986b. Type species *Resiomeria odonatae* Larsson 1986b. Type host *Aeshna grandis* (Odonata, Aeshnidae).
170. *Ringueletium* Garcia, 1990. Type species *Ringueletium pillosa* Garcia, 1990. Type host *Gigantodox rufidulum* Wigodzinsky and Coscaron (Diptera, Simuliidae).
171. *Schroedera* Morris and Adams, 2002. Type species *Schroedera plumatellae* Morris & Adams, 2002. Type host *Plumatella fungosa* Pallas (Plumatellida, Plumatellidae).
172. *Scipionospora* Bylen and Larsson, 1996. Type species *Scipionospora tetraspora* (Léger & Hesse, 1922) Bylen and Larsson, 1996. Type host *Tanytarsus* sp. Léger and Hesse, 1922 (Diptera, Chironomidae).
173. *Semenovaia* Voronin and Issi 1986. Type species *Semenovaia chironomi* Voronin and Issi 1986, in Issi 1986. Type host *Chironomus plumosus* (Diptera, Chironomidae).
174. *Senoma* Simakova, Pankova, Tokarev, and Issi, 2005. Type species *Senoma globulifera* (Issi & Pankova, 1983) Simakova, Pankova, Tokarev, and Issi, 2005. Type host *Anopheles messeae* Fall. (Diptera, Culicidae).

175. *Septata* Cali, Kotler, and Orenstein, 1993. Type species *Septata intestinalis* Cali, Kotler, and Orenstein, 1993. Type host *Homo sapiens* L. (Primates, Hominidae).
176. *Sheriffia* Larsson 2014. Type species *Sheriffia brachynema* (Richards and Sheffield 1971) Larsson 2014. Type host *Biomphalaria glabrata* (Say, 1818) (Mollusca, Gastropoda).
177. *Simuliospora* Khodzhaeva, Krylova, and Issi, 1990. Type species *Simuliospora uzbekistanica* Khodzhaeva, Krylova, and Issi, 1990, in Issi et al. 1990. Type host *Tetisimulium alajense* (Diptera, Simuliidae).
178. *Spherospora* Garcia, 1991. Type species *Spherospora andinae* Garcia, 1991. Type host *Gigantodox chilense* (Philippi) (Diptera, Simuliidae).
179. *Spiroglugea* Léger and Hesse, 1924. Type species *Spiroglugea octospora* (Léger & Hesse, 1922) Léger and Hesse 1924. Type host *Ceratopogon* sp. (Diptera, Ceratopogonidae).
180. *Sporanauta* Ardila-Garcia and Fast, 2012. Type species *Sporanauta perivermis* Ardila-Garcia and Fast, 2012. Type host *Odontophora rectangula* (Axonolaimidae).
181. *Spraguea* Weissenberg, 1976. Type species *Spraguea lophii* (Doflein, 1898) Weissenberg, 1976. Type host *Lophius piscatorius* (Lophiiformes, Lophiidae).
182. *Steinhausia* Sprague, Ormieres, and Manier, 1972. Type species *Steinhausia mytilovum* (Field, 1924) Sprague, Ormieres, and Manier, 1972. Type host *Mytilus edulis* L. (Pelecypoda, Mytilidae).
183. *Stempellia* Léger and Hesse, 1910. Type species *Stempellia mutabilis* Léger and Hesse, 1910. Type host *Ephemera vulgata* L. (Ephemeroptera, Ephemeridae).
184. *Striatospora* Issi and Voronin, 1986. Type species *Striatospora chironomi* Issi and Voronin, 1986, in Issi 1986. Type host *Chironomus plumosus* (Diptera, Chironomidae).
185. *Systenostrema* Hazard and Oldacre, 1975. Type species *Systenostrema tabani* Hazard and Oldacre, 1975. Type host *Tabanus lineola* Fabricius (Diptera, Tabanidae).
186. *Takaokaspora* Andreadis, Takaoka, Otsuka, and Vossbrinck, 2013. Type species *Takaokaspora nipponicus* Andreadis, Takaoka, Otsuka, and Vossbrinck, 2013. Type host *Ochlerotatus japonicus japonicus* (Theobald) (Diptera, Culicidae).
187. *Tardivesicula* Larsson and Bylen, 1992. Type species *Tardivesicula duplicata* Larsson and Bylen, 1992. Type host *Limnephilus centralis* (Curtis, 1884) (Trichoptera, Limnephilidae).
188. *Telomyxa* Léger and Hesse, 1910. Type species *Telomyxa glugeiformis* Léger and Hesse, 1910. Type host *Ephemera vulgata* L. (Ephemeroptera, Ephemeridae).
189. *Tetramicra* Matthews and Matthews, 1980. Type species *Tetramicra brevifilum* Matthews and Matthews, 1980. Type host *Scophthalmus maximus* (L.) (Pleuronectiformes, Bothidae).

190. *Thelohania* Henneguy, 1892. Type species *Thelohania giardi* Henneguy, 1892, in Henneguy and Thélohan, 1892. Type host *Crangon vulgaris* (Decapoda, Crangonidae).
191. *Toxoglugea* Léger and Hesse, 1924. Type species *Toxoglugea vibrio* (Léger & *Hesse, 1922*) Léger and Hesse, 1924. Type host *Ceratopogon sp. (Di*ptera, Ceratopogonidae).
192. *Toxospora* Voronin, 1993. Type *species Toxospora volgae*Voronin, 1993. Type host *Corynoneura* sp. (Diptera, Chironomidae).
193. *Trachipleistophora* Hollister, Canning, Weidner, Field, Kench, and Marriott, 1996. Type species *Trachipleistophora hominis* Hollister, Canning, Weidner, Field, Kench, and Marriott, 1996. Type host *Homo sapiens* L. (Primates, Hominidae).
194. *Trichoctosporea* Larsson, 1994. Type species *Trichoctosporea pygopellita* Larsson, 1994. Type host *Aedes vexans* (Meig.) (Diptera, Culicidae).
195. *Trichoduboscqia* Léger, 1926. Type species *Trichoduboscqia epeori* Léger, 1926. Type host *Epeorus torrentium* Eat. (Ephemeroptera, Heptageniidae).
196. *Trichonosema* Canning, Refardt, Vossbrinck, Okamura, and Curry, 2002. Type species *Trichonosema pectinatel- lae* Canning, Refardt, Vossbrinck, Okamura, and Curry, 2002. Type host *Pectinatella magnifica* (Leidy, 1851) (Plumatellida, Pectinatellidae).
197. *Trichotuzetia* Vávra, Larsson, and Baker, 1997. Type species *Trichotuzetia guttata* Vávra, Larsson, and Baker, 1997. Type host *Cyclops vicinus* Uljanin, 1875 (Copepoda, Cyclopidae).
198. *Tricornia* Pell and Canning, 1992. Type species *Tricornia muhezae* Pell and Canning, 1992. Type host *Mansonia africana* (Theobald) (Diptera, Culicidae).
199. *Triwangia* Nai, Hsu, and Lo, 2013. Type species *Triwangia caridinae* Nai, Hsu, and Lo, 2013, in Wang et al., 2013.Type host *Caridina formosae* (Decapoda, Atyidae).
200. *Tubulinosema* Franzen, Fischer, Schroeder, Scholmerich, and Schneuwly, 2005. Type species *Tubulinosema ratis- bonensis* Franzen, Fischer, Schroeder, Scholmerich, and Schneuwly, 2005. Type host *Drosophila melanogaster* (Diptera, Drosophilidae).
201. *Tuzetia* Maurand, Fize, Fenwick, and Michel, 1971. Type species *Tuzetia infirma* (Kudo, 1921) Maurand, Fize, Fenwick, and Michel, 1971. Type host *Cyclops albidus* (Jurine, 1820) (Copepoda, Cyclopidae).
202. *Unikaryon* Canning, Lai, and Lie, 1974. Type species *Unikaryon piriformis* Canning, Lai, and Lie, 1974. Type host *Echinostoma audyi* Umathevy, 1975 (Digenea, Echinostomatidae).
203. *Vairimorpha* Pilley, 1976. Type species *Vairimorpha necatrix* (Kramer, 1965) Pilley, 1976. Type host *Pseudaletia unipuncta* (Haworth) (Lepidoptera, Noctuidae).
204. *Vavraia* Weiser 1977. Type species *Vavraia culicis* (Weiser, 1947) Weiser 1977. Type host *Culex pipiens* L. (Diptera, Culicidae).
205. *Vittaforma* Silveira and Canning, 1995. Type species *Vittaforma corneae* (Shadduck, Meccoli, Davis, & Font, 1990) Silveira and Canning, 1995. Type host *Homo sapiens* L. (Primates, Hominidae).

206. *Weiseria* Doby and Saguez, 1964. Type species *Weiseria laurenti* Doby and Saguez, 1964. Type host *Prosimulium inflatum* (Davies) (Diptera, Simuliidae).
207. *Wittmannia* Czaker, 1997. Type species *Wittmannia antarctica* Czaker, 1997. Type host *Kantharella antarctica* Czaker, 1997 (Mesozoa, Kantharellidae), parasite of *Pareledone turqueti* Joubin, 1905 (Cephalopoda).
208. *Zelenkaia* Hyliš, Oborník, Nebesářová, and Vávra 2013. Type species *Zelenkaia trichopterae* Hyliš, Oborník, Nebesářová, and Vávra 2013 Type host *Halesus digitatus* (Shrank, 1781) (Trichoptera, Limnephilidae).

Current notes on Classification: In a 2009 editorial from the International Society of Protistologists, it was proposed that the classification of Adl et al. 2005 be considered and the "elements of a description of a new taxon" used for the description of any new unicellular taxa (Lynn and Simpson 2009). However, the microsporidiologists, as a group, at "The first United Workshop on Microsporidia from invertebrate and vertebrate hosts" recommended that the Microsporidia be considered closest to the fungi but not in any fungal group and consequently "that the International Code of Zoological Nomenclature should continue to be applied for taxonomic descriptions of the Microsporidia" (Weiss 2005). This policy was made official in 2009 (Redhead et al. 2009).

Maintenance and Cultivation

Microsporidia are normally found by direct examination of natural populations of their hosts. Methods developed for the collection, maintenance, identification, processing, and storage of microsporidia have been covered in reviews by Maddox and Solter (1996), Undeen (1997), and Visvesvara et al. (1999), to which reference should be made for details. Extrusion of polar tubes is useful for confirmation of the microsporidian nature and for infection of cultures. Techniques employed for activation of the spores (depending on species) by various means, including the simple process of drying and rehydration, may be found in publications such as (Undeen 1990; Undeen and Epsky 1990; Leitch and Ceballos 2008).

Many species can be maintained in the laboratory in their natural hosts, other hosts, or in cell culture. Spores should be extracted from their hosts by homogenization and repeated washing. Excellent purification can be achieved on Percoll or Ludox gradients. Spores can be administered with the diet of terrestrial hosts or added to the water of aquatic hosts. Some of the dimorphic microsporidia, e.g., *Amblyospora* in mosquitoes, can only be transmitted horizontally in the mosquito population via a copepod intermediate host (Fig. 9).

It is often convenient to propagate a parasite of a small, natural host in a larger, more conveniently reared, laboratory host. This can sometimes be achieved in animals which are not normally susceptible by bypassing the gut and inoculating the spores into the body cavity. Large lepidopteran larvae have been used in this way to great effect for large-scale production of Microsporidia.

Several techniques have been used to infect cells. The first cultures were established by adding hemolymph, removed from silkworms previously infected with *Nosema bombycis*, to cultured silkworm ovarian cells. Infections have arisen in primary cultures of cells derived from infected animals and the most widely used technique is to harvest the spores in a sterile condition from an infected host and to add them to primary cultures or established cell lines (Visvesvara et al. 1999).

A prerequisite for successful infection of cultured cells is that the spores should germinate in contact with the cells and inoculate the sporoplasms through the membrane. Cells can be in suspension or in attached monolayers. Some microsporidia germinate easily and spontaneously when added to the cell culture medium. Cultures of *E. cuniculi* have repeatedly and independently been set up by adding spore-contaminated rabbit urine, mouse peritoneal exudate, or spores harvested and resuspended in balanced saline to cell cultures.

The cultured cells need not be derived from the natural host animals. Microsporidia of invertebrate origin have been grown in cells from other invertebrates and from vertebrates. *Anncaliia algerae*, derived from mosquitoes, has been grown in lepidopteran cell lines, in numerous types of mammalian cells, and in amphibian cells (Undeen and Maddox 1973; Undeen 1975). The upper temperature limit for survival of the invertebrate microsporidium was thought to be 35°C for many years; however, it has subsequently been shown that *A. algerae* will grow at 37°C but at a much slower rate (Lowman et al. 2000). *Encephalitozoon cuniculi* has almost always been grown in mammalian cells at 37°C, but success has also been achieved in chick fibroblasts. Surprisingly, its development has also been completed, including spore production, in fat head minnow cells, even at 18°C, but there are no records of development in invertebrate cells.

Cell types vary considerably in their ability to support growth of Microsporidia. RK13 and MDCK cell lines from the American Type Culture Collection support prolific growth of *E. cuniculi*. Spores harvested from cultures, either from the medium or by disruption of the cells, show no loss of viability. Cell culture of microsporidia provides a convenient means of studying most aspects of development.

The most convenient method of storage of microsporidial spores is in aqueous suspension with added antibiotics to inhibit bacterial growth. Stored in this way at 4°C, many species will survive for months or years. A few species can be stored dry, e.g., *Nosema whitei*. Considerable success has been achieved with storage in liquid nitrogen; several species derived from terrestrial insects have proved viable after removal from liquid nitrogen, but *Anncaliia algerae* derived from mosquito larvae did not survive. However, *Nosema eurytremae* in trematodes in aquatic snails survives well, so no general conclusion can be drawn about species from aquatic hosts. A few microsporidia, e.g., *Nosema apis*, *Nosema pyrausta*, and *Vairimorpha necatrix*, have also been lyophilized with little loss of viability (Maddox and Solter 1996).

Evolutionary History

Since their discovery, classification of the microsporidia and establishing their relationship to other eukaryotic organisms can perhaps best be characterized as one of tentative assignments. This has been primarily due to a number of unique characteristics making it difficult to unite the microsporidia into a specific phylogenetic position. The first described species of Microsporidia, *Nosema bombycis* Naegeli 1857, was considered to be related to the yeast and placed with the Schizomycetes but moved by Balbiani (1882) to the Sporozoa. For much of their history, the microsporidia have been considered to be within the phylum Protozoa, but in 1977 they were elevated to phylum status in two new classifications (Weiser 1977; Sprague 1977). Levine et al. 1980 elevated the Protozoa to subkingdom status containing seven phyla, one of which was the Microsporidia. Questions lingered about whether microsporidia should be considered protozoa which resulted in a new assignment into the group Archezoa containing ancient eukaryotes primarily based on the absence of mitochondria (Cavalier-Smith 1987), a placement soon supported by the first rRNA phylogenetic reconstruction placing them as a deep branch of eukaryotes (Vossbrinck and Woese 1986). By the mid-1990s evidence was accumulating that microsporidia were not primitively amitochondriate as they possessed mitochondrial derived genes as well as vestigial mitochondria (reviewed by Keeling et al. 2014). At about the same time, new gene trees were consistently indicating that Microsporidia were related to fungi (reviewed in Vávra and Lukeš 2013; Keeling et al. 2014 and Corradi 2015). Various studies placed them with different groups within the fungi, but other studies placed them at the base of the fungal trees raising the question as to whether the microsporidia are fungi or a sister group to the fungi, protista (James et al. 2006). The link with the newly created phylum Cryptomycota was established with the publication of the genome of *Rozella allomycis* (James et al. 2013) with this group containing the aphelids, rozellids, and the microsporidia. Relationships between members of the Cryptomyocota continue to evolve with the newly described species of *Paramicrosporidium*, parasites of amobozoans (Corsaro et al. 2014a,b) and *Mitosporidium daphnia* that emerge at the root of the microsporidian tree with spores that contain a polar filament but retains a mitochondrial genome (Haag et al. 2014). Descriptions of new species of rozellids and aphelids are adding additional information to help clarify relationships within this group and provide new insights on the origins of the microsporidia (Corsaro et al. 2016; Karpov et al. 2016). Genetic information on the primitive microsporidian groups Metchnikovellidea and Chytridopsida (Larsson 2014) have yet to be obtained but should make a significant contribution to clarifying the relationships of microsporidia to other groups within the Cryptomycota.

The use of genomics and molecular information has clearly elucidated the fact that the microsporidia are not primitive. We look forward to this technology continuing to provide information to aid in the understanding of the microsporidia and their place in the biological hierarchy in the coming years. The information gleaned since 1960, when electron microscopy was first applied to microsporidia, is akin to

our expectations of the future with the application of genomics and proteomics to the understanding of this enigmatic group of organisms.

Acknowledgments We are grateful to Dr. R. Larsson for discussion and comments regarding classification.

Apusomonadida

44

Aaron A. Heiss, Matthew W. Brown, and Alastair G. B. Simpson

Abstract

Apusomonadida is a small group of free-living heterotrophic flagellates. Apusomonads are small (~5–20 μm long) gliding aerobes with two flagella. The dorsal cell membrane is underlain by a pellicle, which also supports a "skirt" of folded membrane that extends laterally/ventrally. The anterior flagellum is enclosed by a sleeve-like extension of the skirt system, forming a flexible proboscis. *Apusomonas* itself is a rounded cell with an anterior extension, the mastigophore, that contains the flagellar apparatus. All other apusomonads (usually now assigned to the genera *Amastigomonas, Chelonemonas*, *Manchomonas, Multimonas*, *Podomonas*, and *Thecamonas*) are elongated and plastic and may form ventral pseudopodia. *Apusomonas* is a soil flagellate. Most other apusomonads that have been cultured to date are marine. Apusomonads are closely related to opisthokonts (e.g., animals and fungi), making them an important group for examining, for example, the origins of multicellularity. The genome of *Thecamonas trahens* encodes several proteins and pathways previously considered specific to animals, including much of the integrin system, which functions in cell-cell communication and adhesion in metazoa. This chapter also briefly reviews breviates and ancyromonads, two groups of surface-associating flagellates that are (or may be) closely related to apusomonads and are of similar evolutionary significance. Breviates comprise

Introduction

General Characteristics

Apusomonadida is a group of small free-living heterotrophic flagellates that glide on surfaces. All known apusomonads have two flagella, with the anterior flagellum surrounded by a membranous "sleeve" that extends from the main cell body. The combined flagellum-sleeve apparatus forms a highly mobile proboscis, which is a primary characteristic of the group (Karpov and Myl'nikov 1989). The posterior flagellum runs underneath the cell venter (ventral face), on the left side of the cell. Pseudopodia, which are used for feeding, are produced from the ventral region of the cell in some members of the group. The dorsal cell membrane is underlain by a pellicle, which continues into a ventrally projecting "skirt" on the sides of the cell, and which is continuous with the proboscis sleeve (Fig. 1).

Apusomonads are currently divided into at least five main phylogenetic groups, based on molecular and morphological data of cultured strains (Cavalier-Smith and Chao 2010; Heiss et al. 2015): (i) Apusomonadinae, containing the genera *Apusomonas* and *Manchomonas*; (ii) the genus *Podomonas*; (iii) the genus *Multimonas*; (iv) Thecamonadinae, including the genus *Chelonemonas* and the

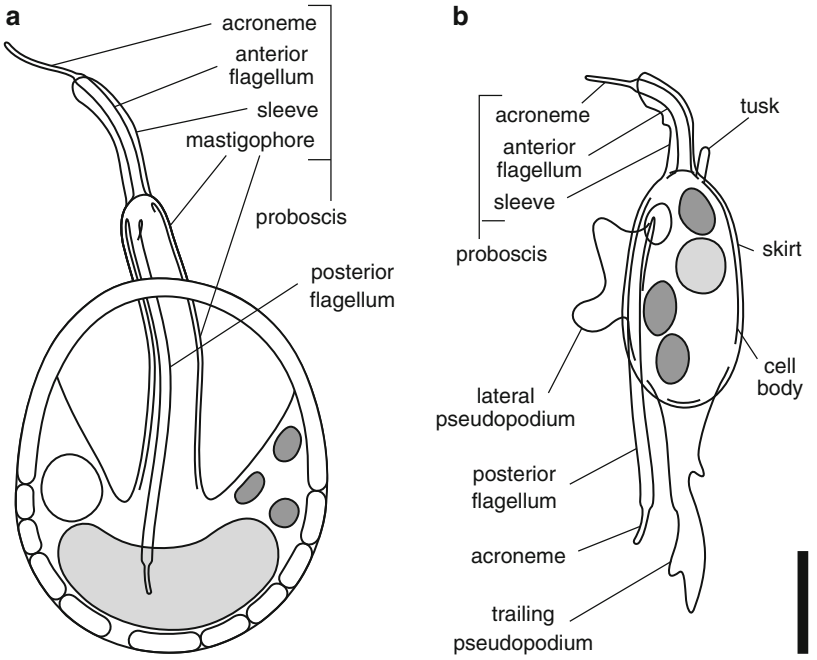

Fig. 1 Appearance by light microscopy of living apusomonads. (**a**) *Apusomonas proboscidea*; (**b**) *Thecamonas trahens*. Nuclei are *light grey*; mitochondria are *dark grey*. Scale bar in (**b**) = 2 μm for both drawings

majority of members of the genus *Thecamonas*; and (v) the single freshwater species "*Thecamonas*" *oxoniensis* (Figs. 1 and 2; Table 1). Another genus, *Amastigomonas* sensu stricto (see below), is of uncertain position relative to other apusomonads. The most distinctive genus is *Apusomonas*, which has an inflexible, rounded body and an extended "mastigophore" that contains both the proboscis and the flagellar apparatus (Karpov and Myl'nikov 1989; Vickerman et al. 1974; Figs. 1a and 2d). The other genera contain more elongate, flexible cells, with the flagellar apparatus positioned within the anterior end of the main cell body. The morphological differences between them are often subtle, and until recently all apusomonads other than *Apusomonas* were assigned to the genus *Amastigomonas* (a practice continued by some authors: Karpov 2011; Myl'nikov and Myl'nikova 2012).

Apusomonads have an important phylogenetic position within the eukaryote tree of life. They are amongst the closest relatives of Opisthokonta, the "supergroup" that includes both animals and fungi (Brown et al. 2013; Burki et al. 2016; Cavalier-Smith and Chao 1995; Cavalier-Smith et al. 2014; Derelle and Lang 2012; He et al. 2014; Kim et al. 2006; Paps et al. 2013; Torruella et al. 2012, 2015). This suggests that apusomonads are important for understanding the origins of multicellularity in animals and fungi. In particular, the genome of the apusomonad *Thecamonas trahens* encodes most components of the integrin machinery critical to cell adhesion in animals (Sebé-Pedrós et al. 2010). *Thecamonas* also has a more complex flagellar apparatus cytoskeleton than that seen in opisthokonts, and this sheds light on the deep-level evolution of the cytoskeletal architecture in extant eukaryotes (Heiss et al. 2013b).

Occurrence

The majority of known apusomonads are marine; however, *Apusomonas* occurs in soil and "*Thecamonas*" *oxoniensis* was isolated from the surface of a terrestrial plant, both being essentially freshwater organisms (Cavalier-Smith and Chao 2010). The original account of *Amastigomonas* (see below) was also of a freshwater organism (de Saedeleer 1931). Apusomonads are one of the most frequently encountered groups of heterotrophic flagellates in microscopy studies of marine sediments (Patterson and Lee 2000), though almost always at low cell numbers.

Literature and History of Knowledge

The scientific history of apusomonads extends back a century, although the group was united less than three decades ago. The first described apusomonad was originally called *Rhynchomonas mutabilis* (Griessmann 1913), although it was not recognized as an apusomonad until almost 80 years later (Larsen and Patterson 1990; true *Rhynchomonas* organisms are kinetoplastids – see ▶ Kinetoplastea). *Apusomonas* itself was known from an unpublished account in 1917 (Vickerman et al. 1974) and was formally described a few years later (Aléxéieff 1924). Shortly after

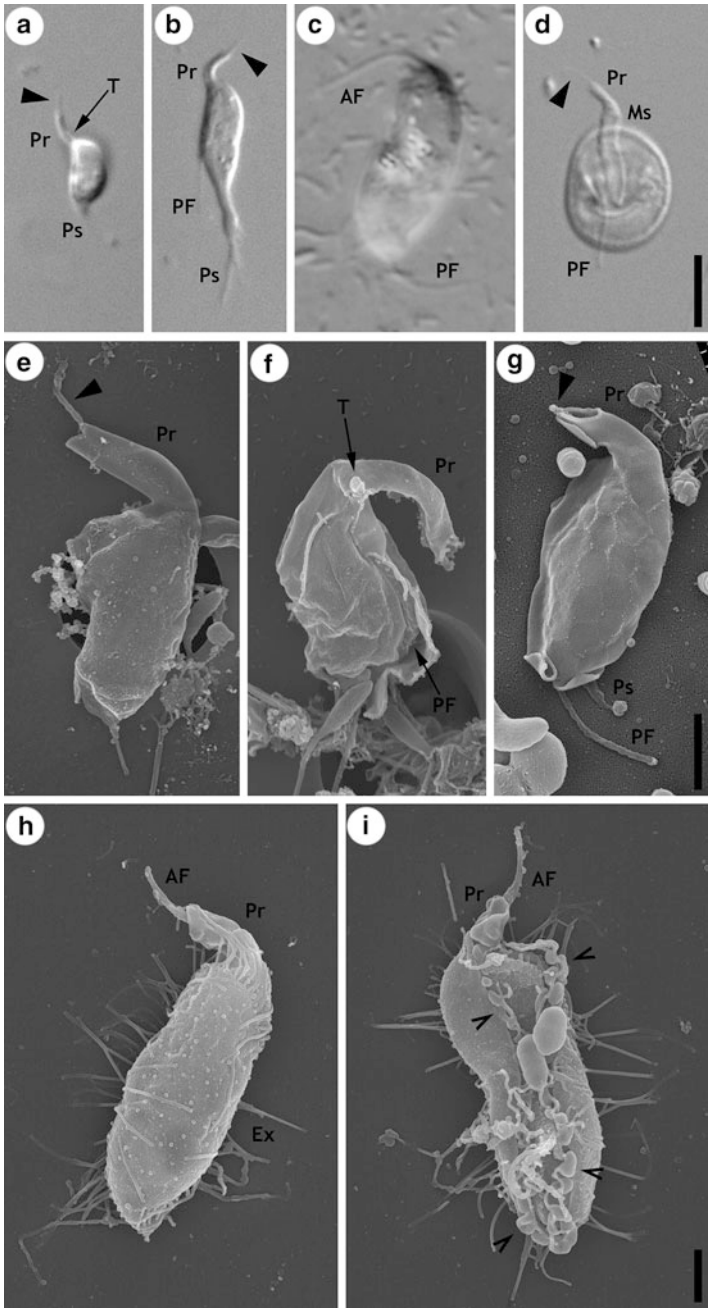

Fig. 2 Light (**a**–**d**) and scanning electron (**e**–**i**) micrographs of apusomonads. Panels (**a**–**d**) are differential interference contrast images of living cells: (**a**) *Thecamonas trahens* without prominent pseudopodia but with visible "tusk" (T); (**b**) *Thecamonas trahens* with prominent trailing

this, the genus *Amastigomonas* was established (de Saedeleer 1931) for *Amastigomonas debrunyei*, a gliding organism with a prominent proboscis but no visible flagella (hence the name), although the cells were probably biflagellated in reality (see below). Apusomonads remained little studied for the next 40 years, until the redescription of *Apusomonas proboscidea* by Vickerman et al. (1974). Additional new species were assigned to *Amastigomonas* from the 1970s onwards (Ekelund and Patterson 1997; Hamar 1979; Larsen and Patterson 1990; Myl'nikov 1999; Myl'nikov and Myl'nikova 2012; Zhukov 1975). Ultrastructural studies in the 1980s led to the recognition that *Apusomonas* was related to the various organisms described as *Amastigomonas* species, and to the proposal of the taxon Apusomonadida, containing both types of organisms (Karpov and Myl'nikov 1989). The monophyly of Apusomonadida has since been confirmed by SSU rRNA gene phylogenies (e.g., Cavalier-Smith and Chao 2003, 2010; Cavalier-Smith et al. 2004, 2008; Heiss et al. 2015; Nikolaev et al. 2006; Walker et al. 2006).

Recently there has been a considerable expansion in the number of described genera and species of apusomonads. Larsen and Patterson (1990) introduced the new genus *Thecamonas* for certain small apusomonads. It was soon recognized, however, that these organisms were very similar to those previously known as *Amastigomonas*, and *Thecamonas* was temporarily considered a junior synonym (Molina and Nerad 1991). Until 2010, additional information on *Amastigomonas*-like apusomonads continued to be referred to the genus *Amastigomonas* (Cavalier-Smith 2002; Ekelund and Patterson 1997; Lee 2002; Lee et al. 2005; Molina and Nerad 1991; Patterson and Simpson 1996; Tikhonenkov et al. 2006; Vørs 1993). In 2010, however, the first broad molecular phylogenetic study of apusomonads demonstrated that the "amastigomonad"-type apusomonads were genetically diverse and represented a paraphyletic group within apusomonads (Cavalier-Smith and Chao 2010). As a consequence, these were divided into several genera, including the reestablished genus *Thecamonas* and the new genera *Manchomonas*, *Multimonas*, and *Podomonas* (Cavalier-Smith and Chao 2010), with an additional

[z]: Including 3D reconstuction of the entire cell

"amastigomonad"-like genus, *Chelonemonas*, being described recently (Heiss et al. 2015). Under this scheme, the genus *Amastigomonas* has been retained to encompass only freshwater organisms closely resembling the original account of *Amastigomonas debruynei* (de Saedeleer 1931). As mentioned above, however, this scheme has not been universally accepted, with some authorities continuing to use *Amastigomonas* for all non-*Apusomonas*-type apusomonads (Karpov 2011; Myl'nikov and Myl'nikova 2012). Regardless, there are neither molecular nor ultrastructural data for *Amastigomonas* sensu stricto at present, and consequently its identity as a relative of other apusomonads is in some doubt (Cavalier-Smith and Chao 2010).

There are several cursory accounts of the ultrastructure of apusomonads (Cavalier-Smith and Chao 2010; Karpov and Myl'nikov 1989; Karpov and Zhukov 1984, 1986; Molina and Nerad 1991; Myl'nikov 1989b), with detailed reconstructions of the flagellar apparatus completed for *Apusomonas proboscidea* (Karpov 2007) and *Thecamonas trahens* (Heiss et al. 2013b). At the time of writing, most sequence data is from *Thecamonas trahens*, for which there is a genome project (Ruiz-Trillo et al. 2007).

Practical Importance

All known apusomonads are free-living. One species, "*Thecamonas" oxoniensis*, was isolated from the surface of a leaf of English ivy, but it has not been established whether this species is a true epibiont (Cavalier-Smith and Chao 2010). The ecological importance of apusomonads is essentially unknown (see below). They have not been exploited commercially. Their primary scientific relevance at present is their importance for understanding the deep evolutionary history of eukaryotes and the evolution of multicellularity (see below).

Habitats and Ecology

All known apusomonads are gliding organisms, and thus primarily surface-associated. All are heterotrophic, and primarily or exclusively bacterivorous (Karpov and Zhukov 1984; Cavalier-Smith and Chao 2010). Apusomonads appear to be ubiquitous: apusomonad cells or SSU rRNA sequences have been detected in samples from fresh water (Lee et al. 2005; Scheckenbach et al. 2006), marine material (Larsen and Patterson 1990; Lee and Patterson 2000; Massana et al. 2011; Myl'nikov and Myl'nikova 2012; al-Qassab et al. 2002; Tong 1997; Tong et al. 1998; Vørs 1993), soil samples (Ekelund and Patterson 1997; Vickerman et al. 1974), and from at least moderately hypersaline environments (Patterson and Simpson 1996). They have been recovered from surface waters (Massana and Pedrós-Alió 2008; Scheckenbach et al. 2005), littoral sediments (al-Qassab et al. 2002; Massana et al. 2015; Tikhonenkov et al. 2006), and the deep sea (López-García et al. 2003; Scheckenbach et al. 2005; Takishita et al. 2007, 2010). The marine apusomonads

(currently understood as the genera *Thecamonas* sensu stricto, *Chelonemonas*, *Multimonas*, *Podomonas*, and *Manchomonas*) are collectively among the 20 most-encountered varieties of heterotrophic flagellates in microscopy studies of marine sediment samples (Patterson and Lee 2000), although always in low densities (Arndt et al. 2000). Freshwater apusomonads ("*Thecamonas*" *oxoniensis* and *Amastigomonas* sensu stricto) have only rarely been encountered (Cavalier-Smith and Chao 2010). Soil-dwelling apusomonads are widely distributed and can be abundant (Ekelund and Patterson 1997; Foissner 1991).

It is important to note that all apusomonads other than *Apusomonas* appear rather similar and that their recognition as different genera was a recent proposal, which has not been adopted universally (see above and below). Consequently, these apusomonads have been recorded as one member or another of the genus *Amastigomonas* in almost every ecological survey published to date. Because of this, the true distribution across habitats is unknown for all genus-level taxa of apusomonads other than *Apusomonas*.

Characterization and Recognition

General Appearance

Apusomonads are all small, usually 5–10 μm in length, though some species may approach 20 μm. Most have an ovoid main cell body (though the main cell body of *Apusomonas* has a subcircular profile), with a characteristic highly mobile anterior proboscis that includes the anterior flagellum (reported cell lengths generally refer to the main cell body, without the proboscis). The proboscis has a smooth anterosinistral motion and often curves along its length as it moves (Cavalier-Smith and Chao 2010; Heiss et al. 2013b; Karpov and Myl'nikov 1989; Vickerman et al. 1974). An acroneme (from the anterior flagellum) may emerge from the tip of the proboscis, and may be distinguishable by light microscopy. The posterior flagellum runs under the cell body, along its left side, and (depending on the taxon) may extend beyond the cell outline to trail behind the cell (Figs. 1 and 2). The cell is generally two to three times as long as it is wide, though most taxa are relatively flexible. Most genera produce pseudopodia, which emerge from the cell venter and may extend in any direction, though rarely more than half the cell length (Figs. 1b, 2a, b, e, f, and 3b; Cavalier-Smith and Chao 2010; Heiss et al. 2013b; Karpov and Myl'nikov 1989), except in the case of the trailing pseudopodium (see below).

All genera except for *Apusomonas* (see below) appear quite similar under the light microscope. *Podomonas* is larger than other apusomonads (12–20 μm) and has lines of refractile granules running in parallel to the posterior flagellum, a reduced proboscis sleeve, and more-prominent pseudopodia (Fig. 2c). *Multimonas* occasionally forms syncytia. *Multimonas*, *Thecamonas*, and *Chelonemonas* will often have a prominent trailing pseudopodium that may be up to twice the length of the cell body (Fig. 2b). "*Thecamonas*" *oxoniensis* is somewhat leaf-shaped, though the cell body

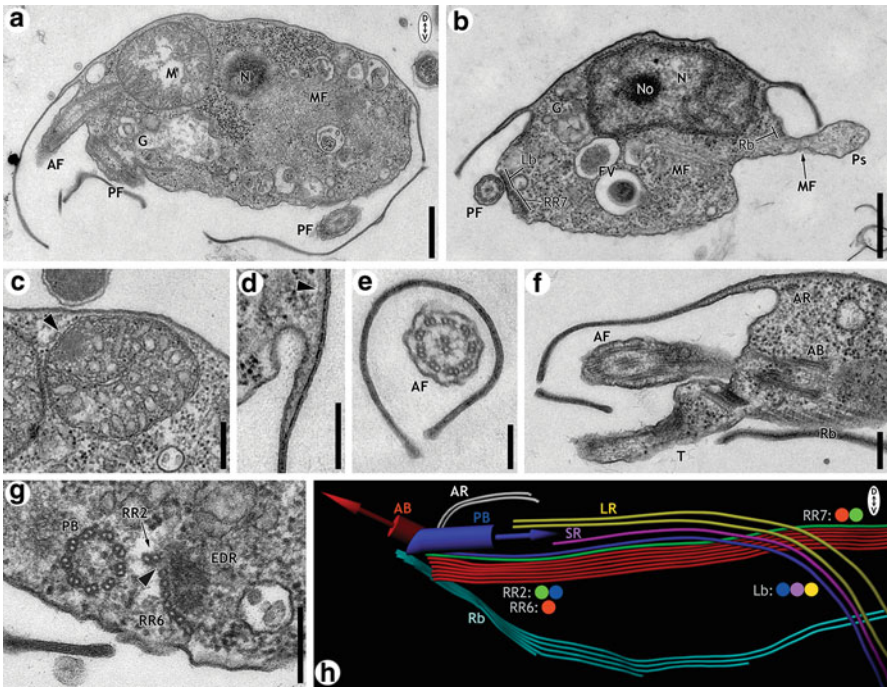

Fig. 3 Intracellular features of the apusomonad *Thecamonas trahens*. Panels (**a**–**h**) are transmission electron micrographs: (**a**) longitudinal section of whole cell, showing general cell features; (**b**) cross section roughly one third through whole cell, showing principal organelles as well as pseudopodium (*Ps*) and components of posterior flagellar apparatus; (**c**) mitochondrion, showing tubular cristae and nucleoid (*arrowhead*); (**d**) cross section of cell showing pellicle (dark layer under plasma membrane) and subpellicular layer (*arrowhead*); (**e**) cross section of proboscis, showing anterior flagellum (*AR*) surrounded by double layer of cell membrane; (**f**) internal structure of 'tusk' (*T*); (**g**) arrangement of posterior roots near distal end of posterior basal body (*PB*), with split (*arrowhead*) in right root between 2-membered (*RR2*) and 6-membered (*RR6*) subparts, and associated electron-dense rod (*EDR*). (**h**) Three-dimensional reconstruction of anterior (proximal) flagellar apparatus, with basal bodies represented as large cylinders (*arrows* begin at transition zone and indicate direction of flagellum) and individual microtubules as small cylinders. *AB* anterior basal body; *AF* anterior flagellum; *AR* anterior root; *FV* food vacuoles; *G* Golgi apparatus; *LR* left posterior root; *M* mitochondrion; *MF* bundles of microfibrils; *N* nucleus; *No* nucleolus; *PB* posterior basal body; *PF* posterior flagellum; *Ps* pseudopodium; *Rb* right band of microtubules; *RR* right posterior root; *RR2* 2-membered part of right root; *RR6* 6-membered part of right root; *SR* singlet root; *T* 'tusk'. Scale bars in (**a**) & (**b**) = 500 nm; scale bars in (**c**–**g**) = 200 nm (All micrographs and reconstruction reproduced from originals used for Heiss at al. (2013b))

can "fold" longitudinally and has tiny refractile granules and a contractile vacuole (consistent with its being a freshwater organism). *Manchomonas* has neither acronemes nor conspicuous pseudopodia and a more leftward than anteriorly oriented proboscis (Cavalier-Smith and Chao 2010; Heiss et al. 2015; Molina and Nerad 1991). *Amastigomonas* itself has a contractile vacuole and supposedly lacks a visible posterior flagellum (Cavalier-Smith and Chao 2010).

Apusomonas differs in having a relatively inflexible main cell body, from which emerges an anterior extension called the mastigophore. The mastigophore forms the proximal part of the proboscis (Figs. 1a and 2d). It contains the basal bodies of both flagella as well as the proximal portions of the posterior flagellum and of the flagellar roots (see below). It is therefore significantly thicker than the distal flagellum-and-sleeve portion of the proboscis. The proboscis of *Apusomonas* thus has a tripartite appearance (from proximal to distal): mastigophore, anterior flagellum and sleeve, and acroneme (Karpov 2007; Karpov and Myl'nikov 1989; Karpov and Zhukov 1984, 1986).

Ultrastructure

Apusomonads have characteristic folds that emerge from the lateral edges of the cell body and extend ventrally, forming a "skirt" about the cell body that is most easily resolved using scanning or transmission electron microscopy (SEM; TEM). The "skirt" is continuous with the sleeve that extends around the anterior flagellum to form the proboscis (Figs. 1 and 2; Heiss et al. 2013b; Vickerman et al. 1974). The posterior flagellum runs between the left lip of the skirt and the main cell body for at least half of the cell length (Figs. 1, 2, and 3a, b). The dorsal cell membrane is underlain by a thin pellicle (sometimes called a "theca," a term that usually denotes an extracellular covering) that extends into and supports the skirt. As a consequence, the dorsal cell membrane is smoother than the unsupported ventral cell membrane when viewed by SEM or TEM (Figs. 2e–i and 3a, b). The pellicle has a polygonal substructure in *Chelonemonas* that is visible on the dorsal surface of the cell in SEM preparations (Heiss et al. 2015; Fig. 2g). Scanning electron microscopy images of the dorsal surface of *Multimonas* strains have shown small knobs and elongate strands that may represent undischarged and discharged extrusomes, respectively (Heiss et al. 2015; Fig. 2h). Some apusomonads have an anterior projection of the cell body, the "tusk," which is rigid, and contains complex supporting material (Figs. 1b, 2a, f, and 3f; Heiss et al. 2013b). It is known to be present in at least some strains of *Thecamonas*, *Chelonemonas*, and *Podomonas* and to be absent in *Manchomonas* and *Apusomonas*. The tusk is under 1 μm long in *Thecamonas* and is just barely visible using light microscopy under optimal conditions (Fig. 2a; Heiss et al. 2013b, 2015).

Internally, apusomonads have a dorsally positioned nucleus with a distinct central nucleolus. The nucleus is usually but not always circular; in *Apusomonas*, it is strongly reniform (Figs. 1a and 2d). The single Golgi body is found near the anterior of the cell. The multiple mitochondria have tubular cristae (Fig. 2c). At least some taxa have conspicuous, densely-staining microbodies; in *Thecamonas trahens*, there is usually one per cell (Heiss et al. 2013b). Food vacuoles are most often found in the ventral half to two-thirds of the cell (Fig. 3a, b; Cavalier-Smith and Chao 2010; Heiss et al. 2013b; Karpov 2007).

The flagellar apparatus has been reconstructed in detail for *Apusomonas* (Karpov 2007) and *Thecamonas trahens* (Fig. 3h; Heiss et al. 2013b). The flagellar apparatus

comprises the two basal bodies, which are joined by at least two (probably three) fibrous connectives, plus three posterior microtubular roots, one anterior microtubular root, a "ribbon" of microtubules associated with the anterior basal body, and a number of nonmicrotubular accessory structures (Fig. 3b, f–h). Apusomonads appear to show the typical eukaryotic pattern of flagellar transformation during the cell cycle, with the anterior basal body younger and the posterior elder (Cavalier-Smith and Chao 2010). The posterior right root ("RR"; equivalent to R2 in the universal terminology of Moestrup 2000) comprises several microtubules (eight to sixteen have been reported: Heiss et al. 2013b; Karpov 2007; Karpov and Myl'nikov 1989; Molina and Nerad 1991); the leftmost two of which split off from the remainder (Fig. 3g, h). The posterior left root ("LR," equivalent to R1) generally contains two microtubules, and a singlet root arises between the other posterior roots. The anterior microtubular root ("AR," equivalent to R3) is a doublet that runs across the dorsal cell surface posteriorly and to the left (Fig. 3f, h). The "ribbon" has sometimes been identified as a flagellar microtubular root (Cavalier-Smith and Chao 2010; Karpov 2007; Molina and Nerad 1991) but may instead be homologous to the systems of secondary peripheral microutubules in other eukaryotes (Heiss et al. 2013b). It originates alongside the anterior basal body in association with a non-microtubular sheet. In the posterior half of *T. trahens* at least, the posterior roots reorganize into two structures, both on the left side of the cell; (i) a dorsally displaced root comprising most of the right root microtubules ("RR7") and (ii) a ventral "left band" made of the left root, the singlet root, and one microtubule from the right root (Fig. 3b, h; Heiss et al. 2013b). The left band extends to the posterior end of the cell, likely into the base of the trailing pseudopodium. The right root runs opposite the left lip of the skirt, and in a similar fashion, the ribbon runs opposite the right lip of the skirt, likely reinforcing the cell outline.

Life Cycle

Only a single cell type has been observed in the majority of apusomonads, that of gliding flagellates. Cells divide by mitotic binary fission; sex has not been observed (Karpov and Myl'nikov 1989). Cysts are known for "*Thecamonas*" *oxoniensis* (Cavalier-Smith and Chao 2010). *Apusomonas* can recover following seasonal desiccation, but a true cyst form appears to be absent (Cavalier-Smith and Chao 2010; Karpov and Myl'nikov 1989). Vickerman et al. (1974) reported a wall-less cryptobiotic stage in *Apusomonas* but also indicated that this form does not survive total desiccation.

Systematics

The formal taxon for apusomonads is the family Apusomonadidae Karpov and Myl'nikov 1989, the sole member of order Apusomonadida Karpov and Myl'nikov 1989. The clade comprising *Apusomonas* and *Manchomonas* has been recognized as

the subfamily Apusomonadinae Karpov and Myl'nikov 1989) (sensu Cavalier-Smith and Chao 2010) and that comprising *Chelonemonas* and marine *Thecamonas* as Thecamonadinae Larsen and Patterson 1990 (sensu Heiss et al. 2015).

Maintenance and Cultivation

Members of five apusomonad lineages have been maintained in monoprotistan but not axenic laboratory culture (see Table 1). Such cultures were generally established through serial dilution (e.g., Cavalier-Smith and Chao 2010), although cell migration has also been used (Heiss et al. 2015; Molina and Nerad 1991). They have been grown in standard laboratory media, generally water of appropriate salinity (distilled water, sterilized bottled mineral water, or artificial or natural seawater, often diluted) with a plant-based carbon source (either a sterile cereal grain or an infusion of such material, e.g., Cerophyl). Live prey bacteria (e.g., *Pseudomonas*) can be added instead of the carbon source. When grown in standard culture tubes or tissue culture flasks, cultures of most strains can last for >2 months but are always sparse; cultures generally last longer and grow to higher density in tissue culture flasks than in tubes (AAH, pers. obs.). When grown in Petri plates, the same strains can form visible plaques of very high density within days of inoculation, but die within ~2 weeks (AAH, pers. obs.). Cultures can be maintained at 14 °C (e.g., Cavalier-Smith and Chao 2010) but often are more robust at 16–21 °C or room temperature (AAH, pers. obs.).

Evolutionary History

Internal Relationships

As discussed above, five clades of apusomonads with cultured representatives have been delimited using phylogenies of SSU rRNA genes (Cavalier-Smith and Chao 2010; Heiss et al. 2015). Two of these are Apusomonadinae (comprising the genera *Apusomonas* and *Manchomonas*) and Thecamonadinae (comprising the genus *Chelonemonas* and the marine members of the genus *Thecamonas*). Another two lineages are represented by individual genera (*Podomonas* and *Multimonas*). The final lineage comprises the single freshwater species "*Thecamonas*" *oxoniensis*, a species with no specific relationship to the marine members of the genus *Thecamonas* (Cavalier-Smith et al. 2014; Heiss et al. 2015). No stable relationships between the five lineages have been established to date (Cavalier-Smith and Chao 2010; Heiss et al. 2015). At least four additional lineages are known from environmental sequences only; nothing is known about the biology of the organisms corresponding to those sequences.

Overall Phylogenetic Position

The first molecular phylogenetic study to include an apusomonad identified the group as a possible relative of opisthokonts (Cavalier-Smith and Chao 1995). Some of the first multigene phylogenies also weakly supported this relationship (Kim et al. 2006). Recent multigene analyses (Katz et al. 2011; Paps et al. 2013) and phylogenomic studies (Brown et al. 2013; Burki et al. 2016; Cavalier-Smith et al. 2014; Derelle and Lang 2012; Torruella et al. 2012, 2015; Zhao et al. 2013) have lent increasing support to the placement of apusomonads as a sister group to opisthokonts.

Some studies have also demonstrated that another enigmatic group of organisms, the breviates, (see Coda and Fig. 4a) is most closely related to apusomonads and opisthokonts, and this relationship has been formalized by the erection of the taxon Obazoa, which encompasses all three groups (Brown et al. 2013). However, it is not clearly resolved whether apusomonads alone represent the closest relatives to opisthokonts or whether it is an apusomonad-breviate clade that represents the sister group to opisthokonts. The most detailed phylogenomic analysis to date, with relatively limited taxon sampling, found that the preferred phylogeny depended on the evolutionary model used for phylogenetic inference (Brown et al. 2013): more complex evolutionary models incorporating among-site model heterogeneity, such as CAT-GTR (Le et al. 2008), favor an apusomonad-opisthokont clade, to which breviates are the sister group (Brown et al. 2013). Recent phylogenomic studies with expanded taxon sampling have not clearly resolved between these hypotheses (Cavalier-Smith et al. 2014); it is hoped that additional taxon and gene sampling data will more precisely resolve the position of the apusomonads in the near future.

Meanwhile, Cavalier-Smith (2002) proposed that the pellicle of apusomonads was homologus to that of another "non-supergroup" lineage, the ancyromonads (see Coda and Fig. 4b), and suggested a common evolutionary history for the two groups. Interestingly, some early SSU rRNA phylogenies including ancyromonads suggested a close relationship with opisthokonts (Atkins et al. 2000b; Cavalier-Smith and Chao 2003), similarly to the early SSU rRNA phylogenies of apusomonads (see above). This arrangement has been loosely supported by recent multigene phylogenetic and phlyogenomic analyses, although it is unclear at present whether ancyromonads fall within Obazoa like apusomonads, or are a sister to Obazoa, or are more distantly related (Cavalier-Smith et al. 2014; Katz et al. 2011; Paps et al. 2013).

Implications for Eukaryote Evolution

Apusomonads are important for our understanding of eukaryote evolution for at least two reasons. One of these concerns the evolution of the flagellar apparatus

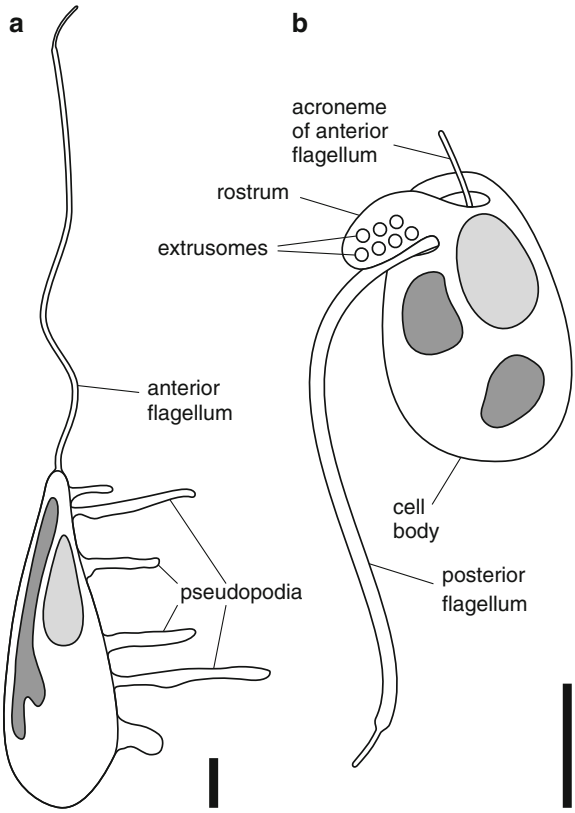

Fig. 4 Appearance by light microscopy of living breviates and ancyromonads. (**a**) *Breviata anathema*; (**b**) *Ancyromonas sigmoides*. Nuclei are *light grey*; mitochondria (*Ancyromonas*) or mitochondrion-related organelles (*Breviata*) are *dark grey*. Scale bars = 2 μm for each drawing

cytoskeleton at the "supergroup" level. Apusomonads possess a complex flagellar apparatus with multiple posterior microtubular roots, including an R2 root that splits into two parts and a "supernumerary" singlet microtubular root, as well as a posteriorly directed array of secondary microtubules (the ribbon). These structures are also found together in ancyromonads and breviates (Heiss et al. 2011, 2013a), in "typical excavates" (Simpson 2003), and in other taxa such as some stramenopiles (Moestrup and Thomsen 1976; Yubuki et al. 2010), suggesting that these specific features may have been ancestral to the majority of major eukaryote lineages (Cavalier-Smith 2013; Heiss et al. 2013b; Leander and Yubuki 2013). Since apusomonads are most closely related to opisthokonts and (less so) to amoebozoans, this suggests that the simple flagellar apparatus cytoskeletons seen in opisthokonts and many flagellated amoebozoans (e.g., pelobionts) are not primitive ancestral systems but in fact could represent independent secondary simplifications from a complex ancestral form.

The other area of importance concerns the evolution of multicellularity. The supergroup Opisthokonta includes two substantial lineages that have evolved multicellularity independently of one another: animals and fungi. Each lineage has

established key systems associated with multicellularity, including cell-cell communication and adhesion (Grosberg and Strathmann 2007). Interestingly, elements of some of these systems are encoded in the genome of *Thecamonas trahens*, indicating that such pathways were present in the common ancestor of apusomonads and opisthokonts, and substantially predate the evolution of multicellularity in both animals and fungi. For example, the *Thecamonas* genome encodes most components of the integrin system (Sebé-Pedrós et al. 2010). In animals, integrins span the cell membrane, connecting to the actin cytoskeleton on the cytoplasmic side (via a series of associated proteins, mostly present in *Thecamonas*) and binding to the laminin and collagen of the extracellular matrix. Sodium-channel (Cai 2012) and calcium-signalling (Cai and Clapham 2012) genes involved in cell communication in animals, and absent from fungi, are also present in the *Thecamonas* genome. The cyclin dependent kinase 4/6 and cyclin D subfamilies are also thought to play a part in the development of animal-type multicellularity and are also found in *Thecamonas*, as well as in amoebozoans (Cao et al. 2014).

Coda: Breviates and Ancyromonads

Apusomonads are not the only organisms to have been suggested to have a close relationship to opisthokonts. Molecular phylogenetic evidence indicates that several more obscure lineages of small protozoa, mostly heterotrophic flagellates, may also be closely related to opisthokonts and/or apusomonads. The best known of these understudied groups are breviates and ancyromonads.

Breviates (Cavalier-Smith et al. 2004) are a group of anaerobic or microaerophilic amoeboid flagellates with an apical anterior flagellum and either a posterior flagellum or a nonflagellated posterior basal body (Figs. 4a and 5). There are four described genera, each with a single species: the freshwater *Breviata anathema* and the marine *Subulatomonas tetraspora*, *Pygsuia biforma* and *Lenisia limosa*. They are surface-associated gliding organisms, although a distinct swimming stage is also known in *Pygsuia* (Figs. 5a, c; Brown et al. 2013). Breviates produce fine pseudopodia that typically form at near-regular intervals from a point at the anterior end of the cell, thus forming a series down the cell as it glides forward (Figs. 4a and 5b). The cells engulf bacteria with these pseudopodia (Heiss et al. 2013a). The cells have a moderately complex cytoskeleton including several flagellar microtubular roots, and some unusual non-microtubular elements (Figs. 5g-k; see Heiss et al. 2013a for details). At least some breviates are reported to form cysts, though this is not well documented (Katz et al. 2011; Walker et al. 2006). No sexual stages have been observed. Cultures and/or SSU rRNA sequences have been obtained from environmental samples taken from Europe, North America, and Japan (Katz et al. 2011; Brown et al. 2013).

All investigated breviates have a large mitochondrion-related organelle (MRO; Fig. 5e), which in *Breviata* has occasionally been found to contain a few tubular cristae (Fig. 5f; Heiss et al. 2013a). However, all cultured breviates are maintained exclusively under anaerobic or suboxic conditions (Brown et al. 2013; Heiss

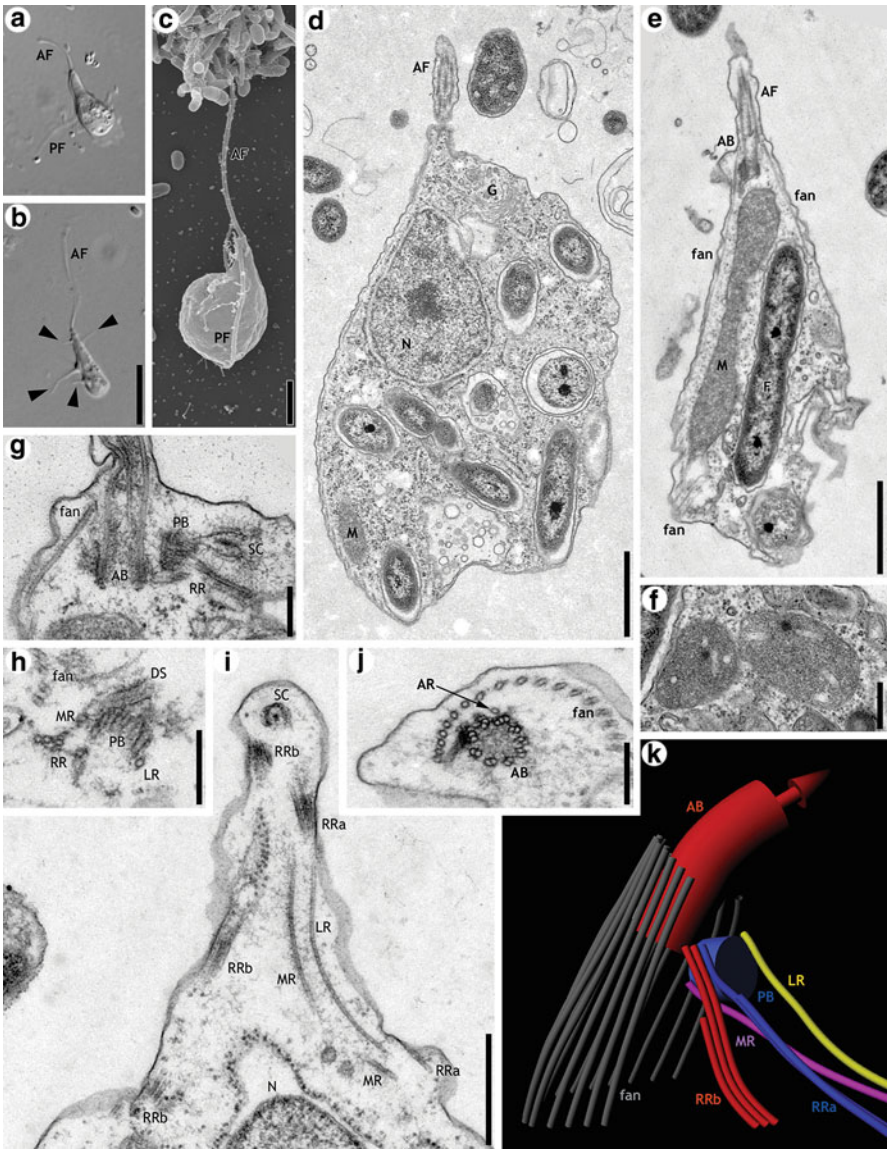

Fig. 5 Images of breviates. Panels (**a** and **b**) are differential interference contrast images of live cells: (**a**) *Pygsuia biforma*, showing both flagella; (**b**) *Breviata anathema*, showing its single flagellum. Panel (**c**) is a scanning electron micrograph of *Pygsuia biforma*. Panels (**d**–**j**) are transmission electron micrographs of *Breviata anathema*: (**d**) longitudinal section of whole cell showing general cell features; (**e**) longitudinal section of whole cell showing size of mitochondrion-related organelle (*M*) and its proximity to anterior basal body (*AB*); (**f**) mitochondrion-related organelle with tubular cristae; (**g**) longitudinal section through flagellar apparatus showing relationship between flagellated anterior (*AB*) and nonflagellated posterior (*PB*) basal bodies, as well as longitudinal section through "semicone" structure (*SC*); (**h**) section through posterior basal body

et al. 2013a; Katz et al. 2011; Walker et al. 2006). The biochemical capacity of these MROs has been inferred primarily from transcriptome data from *Pygsuia* (Stairs et al. 2014), with some additional information from *Breviata* (Minge et al. 2009). The MRO does not produce energy using classical oxidative phosphorylation (electron transport chain complexes I, III–V are absent) but instead acts as a hydrogenosome that generates ATP anaerobically via substrate-level phosphorylation (Stairs et al. 2014). The *Pygsuia* MRO has several highly unusual features, the most notable being an archaeal-related "SUF" system for Fe-S cluster assembly, which appears to have replaced the "ISC" system that is found in virtually all other mitochondria and MROs across eukaryotes (Stairs et al. 2014).

The first known breviate (*Breviata*) was originally identified as a member of the pelobiont genus *Mastigamoeba* (see ▶ Archamoebae), a situation that led to *Mastigamoeba* appearing to be polyphyletic when molecular phylogenies included multiple organisms attributed to it (Edgcomb et al. 2002; Stiller and Hall 1999). Resolution of this misidentification led to the recognition of a new lineage of eukaryotes (Cavalier-Smith et al. 2004) and the new genus *Breviata* for this single species (Walker et al. 2006). The first phylogenomic analysis including (relatively sparse) data from this strain suggested that breviates were basal to or branched within Amoebozoa (Minge et al. 2009). However, several environmental SSU rRNA sequences have been identified as belonging to breviates (summarized in Katz et al. 2011), and strains from additional lineages have now been cultivated in the laboratory, including the recently described *Subulatomonas tetraspora* (Katz et al. 2011), *Pygsuia biforma* (Brown et al. 2013) and *Lenisia limosa* (Hamann et al. 2016). Recent SSU rRNA gene trees, multigene phylogenies, and phylogenomic analyses that include more breviate species show that breviates are actually most closely related to apusomonads and/or opisthokonts (Brown et al. 2013; Burki et al. 2016; Cavalier-Smith et al. 2014; Katz et al. 2011; see above). Interestingly, as with the apusomonad *Thecamonas trahens*, a large complement of genes encoding integrin complex proteins is present in the breviate *Pygsuia* (Brown et al. 2013).

Fig. 5 (continued) (*PB*) showing roots near point of origin; (**i**) longitudinal section through anterior end of cell showing paths of posterior roots, as well as cross-section of "semicone" (*SC*); (**j**) section through anterior basal body (*AB*) showing short anterior root (*AR*) and dorsal fan. (**k**) Three-dimensional reconstruction of flagellar apparatus, with basal bodies represented by large cylinders (*arrow* begins at transition zone and points in direction of flagellum) and individual microtubules by small cylinders. *AB* anterior basal body, *AF* anterior flagellum, *AR* anterior root, *DS* "double sandwich" structure between basal bodies, *F* food (bacteria), *fan* dorsal microtubular fan, *G* Golgi apparatus, *LR* left posterior root, *M* mitochondrion-related organelle, *MR* middle posterior root, *N* nucleus, *PF* posterior flagellum, *Ps* pseudopodium, *RR* right posterior root, *RRa* left part of right root, *RRb* right part of right root, *SC* "semicone" structure. Scale bar in (**b**) = 10 μm for (**a** and **b**); scale bar in (**c**) = 2 μm; scale bars in (**d** and **e**) = 1 μm; scale bars in (**f**, **g**, **i**) = 500 nm; scale bars in (**h**, **j**) = 200 nm (Micrograph in (**a**) by MWB; micrograph in (**b**) by AAH; scanning electron micrograph in (**c**) reproduced from original used for Brown et al. (2013); transmission electron micrographs and reconstruction in (**d**–**k**) reproduced from originals used for Heiss et al. (2013a))

Ancyromonads (Atkins et al. 2000b; Cavalier-Smith 1997; also called planomonads: see Cavalier-Smith et al. 2008; Heiss et al. 2010) are a molecularly diverse but morphologically conservative group of small bacterivorous flagellates (Figs. 4b and 6). There are about 15 nominal species in four genera. Ancyromonads have a rounded cell body, typically 4–6 μm long, which is dorsoventrally compressed and essentially inflexible (Figs. 4b and 6a–c). The anterior-left portion of the cell forms a laterally/posteriorly directed rostrum that contains extrusomes (Figs. 4b and 6e, f). The anterior flagellum is generally short and often either terminates at the cell outline or is almost entirely an acroneme (Figs. 4b and 6c, d) and thus difficult to detect by light microscopy. The posterior flagellum is about two to three times the length of the cell (4B, 6A, 6C). The cell adheres to the substrate using the distal portion of the posterior flagellum and either glides or tethers to one location. The cell body nods rapidly due to flexure of the proximal part of the flagellum (Glücksman et al. 2013; Heiss et al. 2010). Like apusomonads, ancyromonads have a pellicle (Fig. 6h), in this case underlying almost all of the cell surface. Unlike apusomonads, ancyromonads have flat mitochondrial cristae (Fig. 6d, j). The microtubular cytoskeleton is complex, with five distinct flagellar microtubular roots (Figs. 6i-k; see Heiss et al. 2011 for details). Neither sexual stages nor cysts are known. Ancyromonads are as widely distributed as apusomonads, though generally more locally abundant (Atkins et al. 2000a; Chen et al. 2008; Ekelund and Patterson 1997; Hänel 1979; Larsen and Patterson 1990; Lee 2002; Lee and Patterson 2000; Lee et al. 2005; Patterson and Simpson 1996; Patterson and Zölffel 1991; al-Qassab et al. 2002; Scheckenbach et al. 2005; 2006; Stock et al. 2009; Tikhonenkov et al. 2006; Tong 1997; Tong et al. 1997, 1998; Vørs 1993), and have been cultured under the same conditions (Cavalier-Smith et al. 2008; Glücksman et al. 2013; Heiss et al. 2010; Myl'nikov 1990).

Ancyromonads were first identified over 130 years ago (Saville Kent 1882) but received little mention until phylogenetic analysis identified them as an independent lineage with opisthokont affinities (Atkins et al. 2000b; Cavalier-Smith 1997). The most recent taxonomic scheme for ancyromonads (Glücksman et al. 2013) is based on SSU rRNA gene phylogenies, which distinguish five clades. Three of these are marine and correspond to the genera *Ancyromonas*, *Planomonas*, and *Fabomonas*. The other two clades are known from fresh water and have both been placed in the genus *Nutomonas*, as they are sister taxa; they have been separated into the subgenera *Striomonas* (containing *N. longa*) and *Nutomonas* (containing all remaining species in the genus). *Ancyromonas* and *Nutomonas* are sisters in published phylogenies (Cavalier-Smith et al. 2014; Glücksman et al. 2013), comprising a clade that has been given the name Ancyromonadidae (Glücksman et al. 2013). The other genera (*Planomonas* and *Fabomonas*) may or may not be a clade; the name Planomonadidae has been proposed for such a grouping. Another fresh water genus, *Phyllomonas* (Klebs 1893), has been regarded as an ancyromonad by some researchers (Lemmermann 1914; Patterson and Simpson 1996; Tong et al. 1998) but not by others (Cavalier-Smith et al. 2008; Hänel 1979; Patterson and Zölffel 1991; Patterson et al. 2000); its actual status awaits a modern study (Cavalier-Smith et al. 2008; Heiss et al. 2010).

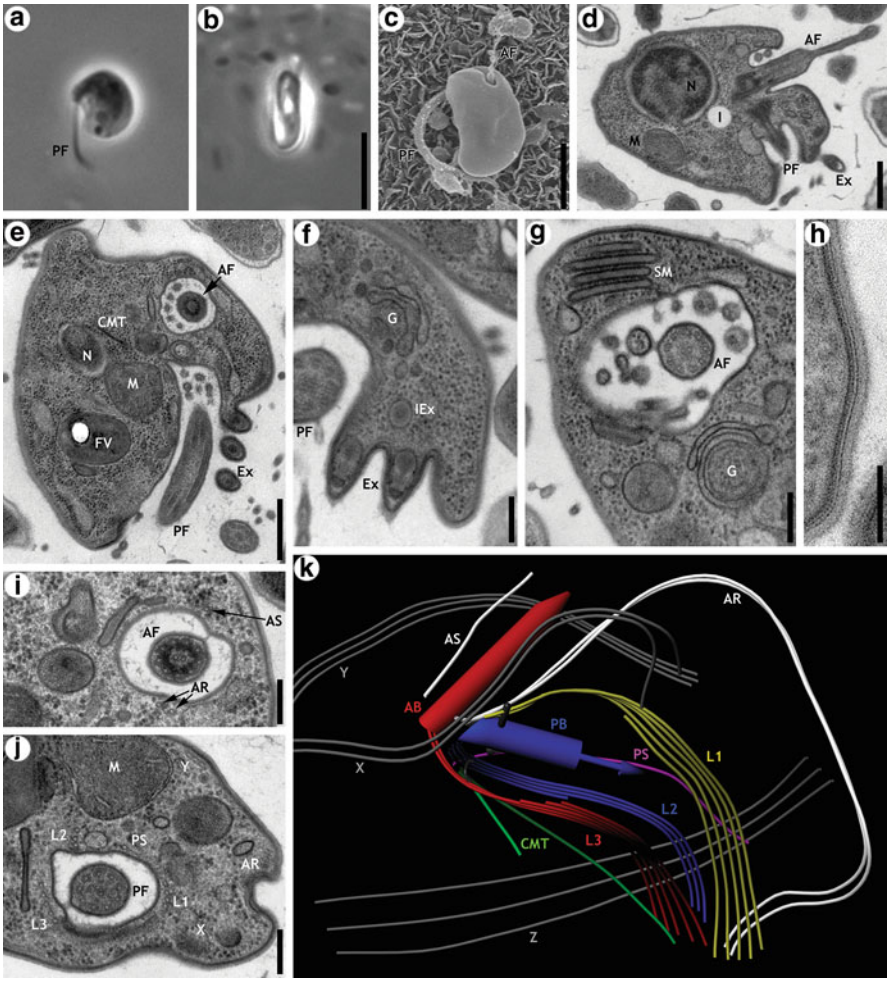

Fig. 6 Images of *Ancyromonas sigmoides*. Panels (**a** and **b**) are phase-contrast micrographs of living cells, viewed from dorsal (**a**) and lateral (**b**) aspects. Panel (**c**) is a scanning electron micrograph of a fixed cell. Panels (**d**–**j**) are transmission electron micrographs: (**d**) section through both basal bodies, showing full extent of anterior flagellum (*AF*); (**e**) longitudinal section through cell, with cross-section of extrusomes (*Ex*); (**f**) longitudinal section through both Golgi apparatus (*G*) and extrusomes (*Ex*), with immature extrusome material (*IEx*) in transition from Golgi apparatus to "firing" position; (**g**) cross section through Golgi apparatus (*G*) and section through stacked membrane structures (*SM*); (**h**) closeup of pellicle; (**i**) anterior root (*AR*) and anterior singlet (*AS*) on either side of anterior flagellum (*AF*) in flagellar pocket; (**j**) arrangement of roots around posterior flagellum (*PF*) in flagellar pocket, as well as mitochondrion (*M*) with flat cristae. (k) Three-dimensional reconstruction of flagellar apparatus, including full extent of anterior basal body (*AB*) and flagellum, as well as various peripheral microtubular structures (*X, Y, Z*; the latter two are possible homologues to the dorsal fan of breviates and the right band of apusomonads). *AB* anterior basal body, *AF* anterior flagellum, *AR* anterior root, *AS* anterior singlet, *CMT* crescent microtubules (part of posterior left root), *Ex* extrusome, *G* Golgi apparatus, *I* electron-lucent inclusion, *IEx* immature extrusome material, *L1* posterior left root, *L2*, *L3* parts of posterior

As stated above, the phylogenetic positions of breviates and ancyromonads are not fully resolved (the latter especially). However, both groups have complex flagellar apparatus cytoskeletons with most of the potentially ancestral features for eukaryotes discussed above for apusomonads (Figs. 3h, 5k, and 6k; Heiss et al. 2011, 2013a, b). Irrespective of the precise phylogenetic positions of ancyromonads and breviates, this reinforces the notion that the ancestors of the opisthokonts and Amoebozoa each had complex cytoskeletons.

Acknowledgments Thanks are due to WonJe Lee (Kyungnam University, South Korea) for discussion and scanning electron micrographs of *Ancyromonas sigmoides*, to Yana Eglit (Dalhousie University) for translations of the Russian literature and for providing light micrographs of *Apusomonas proboscidea*, to Courtney Stairs (Dalhousie University) and Giselle Walker (Charles University in Prague) for comments, and to Ping Li and Patricia Scallion (Dalhousie University) for assistance with electron microscopy.
